The regulation of human brown adipose tissue

Roland Stimson
University of Edinburgh, Edinburgh, United Kingdom

The obesity epidemic has underlined the need for new treatments to aid weight loss and prevent the associated cardiometabolic sequelae of obesity. The relatively recent discovery of brown adipose tissue (BAT) in adult humans has revived interest in activating this tissue to increase energy expenditure as a novel treatment for these conditions. BAT is a thermogenic organ that generates heat to maintain body temperature in a cold environment. While BAT mass and activity are reduced in obesity, BAT is a plastic organ and activity can be increased in response to certain stimuli such as repeated cold exposure. In addition, the presence of BAT in obese subjects is associated with improved metabolic health and reduced incidence of cardiovascular disease. Therefore, it is important to determine how to safely increase BAT mass and thermogenesis to determine its therapeutic potential. However, our understanding of the pathways regulating human BAT remains limited, in part due to its location and the difficulty in quantifying activity in vivo. To improve our understanding of human brown adipose tissue function, we have performed a series of physiological studies in healthy volunteers using techniques such as PET imaging, microdialysis and thermal imaging. We have determined key differences in the regulation of brown adipose tissue function between species, such as identifying how glucocorticoids regulate brown adipose tissue activation in humans. We have also determined how brown adipose tissue utilises energy substrates to fuel thermogenesis. Most recently, we have undertaken hypothesis-free transcriptomics in human brown adipocytes to identify novel pathways regulating BAT function and have demonstrated their relevance in vivo. Understanding the pathways regulating cold-induced thermogenesis in humans may ultimately lead to novel therapies to enhance energy expenditure and improve metabolic function.

Growth Hormone: An Adult Endocrine Misnomer

Vera Chesnokova, Svetlana Zonis & Shlomo Melmed
Pituitary Center, Department of Medicine, Cedars-Sinai Medical Center, Los Angeles, California, United States

Growth hormone (GH) secreted by the anterior pituitary gland regulates skeletal growth, metabolism and body composition. Although several of these actions are mediated by production of hepatic and local tissue IGF1, GH also acts independent of IGF1. GH is mainly produced from the pituitary as a systemic endocrine hormone, yet is also expressed in local tissues acting in an autocrine/paracrine/intracrine manner. Locally produced non-pituitary GH (npGH) signals the GHR to induce epithelial cell proliferation by suppressing p53, thereby enabling epithelial cell proliferation. Although endocrine GH levels drop markedly with aging, npGH increases with aging, blocking repair of age-associated DNA damage. Consistent with these findings, npGH is a component of the senescence-associated secretory phenotype thereby enabling a pro-proliferative epithelial milieu. As p53 is increased in vivo by blocking GHR signalling these mechanisms may explain the known cancer- protective effects of GH deficiency and GHR signaling disruption, as well as contributing to age-associated pathologies. Thus, GH is a powerful inducer of skeletal growth during childhood,and maintains body composition in the adult, after maturation and with aging, GHR actions are transformed to accumulate DNA damage. Unraveling these mechanisms supports a hypothesis whereby adverse aging-related processes are in fact accelerated by GHR signalling. This notion supports the protective function of low circulating GH during aging, and also would call for vigilance against inappropriate adult GH abuse .This premise also supports the potential for trials designed to block GH action to enable extended healthspan. These insights point to pituitary and non-pituitary adult GH as a regulator of DNA damage contributing to the cellular micro-environment in addition to functioning as a promoter of skeletal growth.

Setting the scene for (rare) endocrine diseases in Europe

Alberto M Pereira
Amsterdam UMC, Amsterdam, Netherlands

My research focuses on the long-term consequences of pituitary diseases, and on the effects of stress hormones on the central nervous system (CNS) in specific. This has elucidated long-term effects of hormone excess on the CNS, as well as on other organs that affect stress-resilience, and consequently, general well-being and quality of life. This profoundly affects our understanding of the biological effects of stress hormone excess on the CNS, and on the care for patients with specific rare endocrine conditions. Endocrine tumours are characterized by low incidence, genetic predisposition (either isolated or as manifestation of a hereditary tumour syndrome), abnormal hormone secretion and expression of hormone receptors, specific genetic patterns, and generally slow growth. The special biology provides unique opportunities for systems biology and for development of targeted therapies. The complexity precludes that the diagnosis and treatment modalities fit in standard concepts of care, and the low prevalence implicates that screening and clinical decision making is very important. The installation of the European Reference Networks formed the foundation to improve quality and safety and access to highly specialized health care across Europe for patients affected by rare, or low prevalence and complex conditions. The European Reference Network on Rare Endocrine Conditions (Endo-ERN) covers specific expertise from birth to senescence and provides equal responsibilities for patient representatives and health care providers. The scope and mission of Endo-ERN is complex but ultimately will thrive toward reducing health care inequalities across Europe.

Great impact in low quantities - thyroid hormones, trace elements and endocrine disruptors

Josef Köhrle
Institut für Experimentelle Endokrinologie, Charité Universitätsmedizin Berlin, Berlin, Germany

Thyroid hormones (TH) regulate (brain) development, growth, body temperature, most pathways involved in energy and structural metabolism as well as anabolic and catabolic reactions. Inadequate availability of essential trace elements (iodine, selenium, iron, zinc) limits TH biosynthesis, metabolism and action. Endocrine-disrupting chemicals (EDC), i.e., exogenous chemicals or their mixtures, can interfere with any aspect of TH synthesis, distribution, transport, metabolism, and action via (non-)canonical T3 receptor mediated signalling. Only a limited number of EDC exert their adverse effects by directly interfering with follicular TH production. Majority of EDC effects occurs by disruption of protein-protected TH distribution via bloodstream, specific TH transport across cellular membranes and/or intracellular (in-)activation and/or TH metabolism. This pre-receptor control of local T3 availability to intracellular T3 receptors, which act as ligand-modulated transcription factors for gene expression, represents the main operation field for EDC in the TH system (THS). Only few EDC modulate functions of T3 receptors, which contrasts adverse EDC actions on the sex steroid dependent reproductive processes, most of which are known to be associated with direct disruption of sex steroid receptor functions. Thus, individual blood TH concentrations only provide limited information about adverse action and consequences for EDC exposed individuals, e.g., mother-child pairs. TH, trace elements and EDC exert their direct and permissive effects in very low, locally regulated, physiological concentrations frequently not reflected at the systemic level as impressively illustrated during TH-regulated amphibian metamorphosis, embryonal development of fish or mammalian species, including humans. Considering that anthropogenic mass recently exceeded our blue planet's biomass, we must minimize exposure to EDC, contained in and released from anthropogenic products, as EDC interfere already at very low concentrations with the THS. Concomitantly, the THS needs to be fortified and protected by globally adequate supply with those essential trace elements (I, Se, Fe) required for its proper function.

Diabetic kidney disease: after years of darkness came light – finally new options for treatment!

Peter Rossing[1,2]
[1]Steno Diabetes Center Copenhagen, Gentofte, Denmark; [2]Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark

Unfortunately diabetes is a growing problem with now more than 537 million people worldwide having diabetes according to International Diabetes Federation. Excess morbidity and mortality in diabetes is related to the development of diabetic kidney disease seen in 30-40%, which not only causes end stage kidney disease, but also increases risk for cardiovascular events and mortality, which is the leading cause of death. Treatment of diabetic kidney disease has been control of glucose, lipids, and blood pressure including blockade of the renin angiotensin system, but the residual risk on optimal treatment was large. Multiple interventions have been tested and failed in this condition, but in the past few years, we have suddenly been able to find new treatment options. First cardiovascular outcome trials in diabetes found the SGLT2 inhibitors reduced progression of kidney disease or heart failure, and GLP1 receptor agonists reduced cardiovascular events and maybe also improved kidney parameters. Then an endothelin receptor antagonist demonstrated reduced progression of kidney disease, and most recently the nonsteroidal mineralocorticoid receptor antagonist finerenone demonstrated reduction in progression of kidney and cardiovascular disease. Now we suddenly have the opportunity to improve on the most deadly complications to diabetes with several interventions, and as they work on different disease pathways (hemodynamic, metabolic, inflammatory) data suggest they can be combined with extra benefit for the person with diabetes. Now implementation is key, and quality monitoring systems should be in place to ensure this.

Fatty bone stem cells
PL4

Fatty bone stem cells
Clifford Rosen
Center for Clinical and Translational Research, Maine Medical Center Research Institute, Scarborough, United States

Bone marrow adipose tissue represents a unique depot surrounded by hematopoietic elements and trabecular bone. It expands during aging, and is dynamic in response to hormonal, nutritional and mechanical stimuli. The skeletal response to the increase in marrow adipocyte number and/or size is a relevant consideration, particularly since bone marrow adipose tissue is enhanced in states with low bone mass or rapid bone loss. Excess or deficient nutrient intake are powerful inducers of bone marrow adiposity in both humans and mice. We previously showed that 30% calorie restriction in mice stimulated bone marrow adiposity and drove bone loss. This led us to determine if fasting in humans also caused bone loss and expansion of marrow adipocytes. Volunteers were fasted for 10 days or given a high calorie diet for 10 days; bone marrow aspirates and skeletal quantitation was determined by uCT and MRI. Fasting induced a 10% increase in marrow fat, which was rapidly reversed by a 2 week return to a normal diet. In pathway analysis from marrow adipocytes using RNAseq, recruitment of progenitors (adipogenesis) was the major network activated, followed by the complement pathway. qRT-PCR demonstrated that adipsin, complement factor D (CFD), was one of the most up-regulated genes in the marrow adipocytes. In vitro analysis of adipocytes from the marrow of 30% CR mice revealed increased CFU-F and alkaline phosphatase staining, and enhanced adipogenic markers with increased oil-red O staining but suppressed genes associated with impaired in vitro osteogenesis. CFD mRNA was markedly increased similar to the human data. Addition of adipsin suppressed bone marrow stromal cell osteogenesis, and reduced gene expression for col1a1, osteocalcin and other bone markers. Taken together, nutrient intake regulates bone marrow adiposity and influences skeletal remodeling. We are now studying if intermittent fasting, which now is an extremely popular weight loss program, can cause bone loss and increased marrow adiposity.

Old dogmas and new players in puberty and reproduction
PL5

Old dogmas and new players in puberty and reproduction
Manuel Tena-Sempere
Instituto Maimónides de Investigación Biomédica de Cordoba (IMIBIC); Department of Cell Biology, Physiology and Immunology, University of Cordoba, Cordoba, Spain; Hospital Universitario Reina Sofia, Spain; CIBER Fisiopatología de la Obesidad y Nutrición, Instituto de Salud Carlos III, Cordoba, Spain; Institute of Biomedicine, University of Turku, Turku, Finland

Reproduction, as essential function for the perpetuation of species, is controlled by precise maturational programs and sophisticated regulatory circuits, which have been the subject of active research. Seminal findings in the last decades of the 20th century set basic dogmas in reproductive endocrinology, including the identification of gonadotropin-releasing hormone (GnRH), as the master hypothalamic signal controlling reproduction, and the initial characterization of complex networks of central transmitters and peripheral hormones, from glutamate and GABA to nitric oxide and leptin, as key modulators of puberty and fertility. In fact, by the turn of the Millennium, there was the perception that the fundamentals of the neuroendocrine systems governing the reproductive axis had been already exposed, thus leaving little room for major conceptual developments in this apparently exhausted field of contemporary Endocrinology. Reality, however, turned out to be much more exiting, so that in the last twenty years, we have witnessed groundbreaking findings in this area, epitomized by the discovery of the reproductive roles of kisspeptins. These have not only revolutionized our understanding of the mechanisms controlling puberty and reproduction, but have also boosted kind of a New-Age in reproductive research, where basic, translational and clinical studies have surfaced novel players, neuroendocrine circuits and molecular regulatory mechanisms responsible for the precise control of the reproductive axis along the lifespan. Some examples of these recent developments will be summarized in this lecture, which aims also to identify new avenues for further progress of this fertile area of modern Endocrinology.

Thyroid Hormone Resistance, Diagnosis and Treatment
PL6

Thyroid hormone resistance, diagnosis and treatment
Carla Moran
Department of Endocrinology, UPMC Beacon Hospital, Dublin, Ireland

Resistance to Thyroid hormone (RTH) encompasses various disorders of Thyroid Hormone (TH) Action, including defective signalling through TH Receptors (RTH alpha, RTH Beta), abnormal TH metabolism (Selenoprotein deficiency) and altered cellular entry of TH (MCT8 defects). In this talk, I will focus on RTH alpha and beta. RTH beta is usually associated with mutations in the *THRB* gene and is often readily identified, due to the associated typical biochemical pattern of raised TH levels and non-suppressed TSH. Resistance to the action of TH occurs in tissues expressing the beta form of the TH receptor (hypothalamus, pituitary, liver), but TR alpha expressing tissues are exposed to elevated TH levels. Patients with Resistance to Thyroid Hormone alpha (RTH alpha; due to mutations in the *THRA* gene) are highly challenging to identify because many patients only have mildly abnormal (or even normal) thyroid hormone levels. Resistance to the action of TH occurs in tissues expressing the alpha form of the TH receptor (bone, skeletal muscle, brain and heart). The clinical features/phenotype of both RTHalpha and RTHbeta are highly variable; from mild developmental delay to severe learning impairment and disability in RTHalpha, and asymptomatic states to significant tissue specific thyrotoxicosis in RTHbeta. Treatment for RTHbeta is not always required, but beta-blockade and tri-iodothyroacetic acid (TRIAC) can be considered. Many patients with RTHalpha respond to thyroxine therapy, but optimal dosing schedules and treatment targets are not known.

Endocrine-disrupting chemicals: scientific, economic, regulatory, and policy implications

PL7

Endocrine-disrupting chemicals: scientific, economic, regulatory, and policy implications

Leonardo Trasande[1,2,3]

[1]NYU School of Medicine, New York, United States; [2]NYU Wagner School of Public Service, New York, United States; [3]NYU School of Global Public Health, New York, United States

Endocrine disrupting chemical (EDC) exposure contributes to disease and dysfunction, with annual costs >2% GDP in the US and >1% in Europe. Differences in policy explain differences in disease burden and cost. In Europe, general principles for EDCs call for minimization of human exposure, identification as substances of very high concern, and ban on use in pesticides. In the US, screening and testing programs are focused on estrogenic EDCs exclusively, and regulation is strictly risk-based. Since our reports describing 15 probable exposure-outcome associations due to EDCs, there has been a deepened understanding of their effects on human health. We have reviewed subsequent additions to the literature and identified new exposure-outcome associations with substantial human evidence. Although systematic evaluation is needed of their probability and strength, the growing evidence supports urgent action to reduce exposure. We suggest: expanded and comprehensive testing to conclusively identify EDCs, and a shift from a flawed, risk-based paradigm to one that proactively excludes chemicals with some evidence of hazardous properties. An international initiative on EDCs supported by the UN could address the weaknesses related to hazard identification and provide much-needed guidance for policies globally.

Genetic and epigenetic basis of PCOS heritability

S2.1

Prenatal androgen exposure causes transgenerational epigenetic transmission of PCOS

Elisabet Stener-Victorin
Department of Physiology and Pharmacology, Karolinska Institutet, Stockholm, Sweden

In a register-based and case-control studies it has been shown that daughters of women with or without PCOS have a five-fold increased risk of being diagnosed with the syndrom. Moreover, sons born to a mother with PCOS have two to three-fold increased risk of being obese. But how PCOS is inherited is unclear as PCOS loci identified by genome-wide association studies account for only 10% of the heritability. It has been suggested that epigenetic and developmental programming contributes to the inheritance of PCOS. In support for this, PCOS-like traits induced by androgen exposure during pregnancy in mice can be passed on from mothers (F_0) to daughters (F_1), granddaughters (F_2), and even great-granddaughters (F_3), and transcriptional and mitochondrial perturbations of oocytes accompany the transmission. Several of the oocyte gene signatures are detectable also in serum from daughters of women with PCOS and in adipose tissue of unrelated women with PCOS, indicating communication between germ cells, serum and somatic tissues/cells. Also, male offspring F_1 to F_3 of obese and androgen-exposed mothers develop aberrant reproductive and metabolic traits in adulthood. Small-noncoding (snc)RNA sequencing carried by the sperm contribute to a transgenerational epigenetic inheritance of phenotypic traits. As in females, several of sperm signatures are detectable in whole blood from sons of women with PCOS supporting the translational relevance of the mouse findings.

Parathyroid disorders clinical update (PARAT group)

S4.1

Management of primary hyperparathyroidism (PHPT)

Neil Gittoes
Department of Endocrinology, University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom

The European PARAT group have recently explored a number of practical management issues in parathyroid diseases. Herein, we present expert opinion on areas of controversy in the diagnosis and management of primary hyperparathyroidism (PHPT). Although PHPT is common, its differential diagnosis from familial hypocalciuric hypercalcaemia (FHH) poses practical problems. Proposed approaches to addressing this will be discussed. The definition and clinical course of normocalcemic PHPT remains controversial and there is particular emphasis

on excluding causes of secondary hyperparathyroidism that can cause elevated PTH with normal blood calcium levels. An algorithm is presented to explore the approach to diagnosing normocalcaemic PHPT. Recurrent PHPT is rare but requires clear definition and approaches to reassessment and redo surgery should be performed at centres with great expertise in repeat surgery. Per- and post-operative management of patients with PHPT differs from centre to centre. We propose a structured approach to patient preparation for parathyroidectomy and review causes and management of post-operative hypocalcaemia. Longer term follow up and assessment of PHPT patients is also discussed. The recommendations on clinical management presented herein serve as background for further educational material aimed at a broad clinical audience and were developed with the focus on endocrinologists in training.

Beta cells and inflammation in diabetes

Thomas Mandrup-Poulsen
Department of Biomedical Sciences, University of Copenhagen, Copenhagen, Denmark

Innate immunity contributes to inducing functional inhibition and apoptosis of pancreatic beta-cells in the pathogenesis of both Type 1 diabetes (T1D) and Type 2 diabetes (T2D). The past four decades has provided overwhelming circumstantial evidence from in vitro studies and animal models that innate immune cells and cytokines are key effectors in beta-cell killing. Pro-inflammatory cytokines activate signaling pathways that reprogram the beta-cell transcriptome and proteome, adversely affecting most functions of the cell and triggering death by the intrinsic (mitochondrial) death pathway. On the other hand, these signaling pathways also elicit numerous adaptive and protective responses that may guide development of preventive therapies. Researchers increasingly agree that environmental stressors that enhance insulin biosynthetic demand may lead to increased proinsulin misfolding, misprocessing and posttranslational modifications, triggering inflammation and neoepitope formation and presentation in the beta-cell. This novel concept attracts focus to beta-cell stress as an initiating event in the development of both T1D and T2D. There is clinical proof-of-concept that blocking the action of the pro-inflammatory cytokines interleukin-1 (IL-1) or tumor necrosis factor (TNF) improves glycaemia and beta-cell function in T2D and T1D, respectively, and meta-analyses on >2000 T2D patients substantiates the efficacy of IL-1 blockade. Yet, anti-cytokine biologics have not yet been adopted in clinical practice. This lecture will review key basic and clinical findings supporting the importance of inflammatory beta-cell damage in the pathogenesis of T1D and T2D, and will highlight central barriers that prevent clinical translation.

Cardiometabolic outcomes and mortality in patients with autonomous cortisol secretion

Henrik Olsen[1,2]
[1]Department of Medicine, Ängeholm Hospital, Ängelholm, Sweden; [2]Department of Clinical Scien ces, Lund University, Lund, Sweden

Mild autonomous cortisol secretion (MACS) has been associated with cardiometabolic risk factors and cardiovascular disease in the 2000s and with increased mortality in the 2010s. Since the range of cortisol after dexamethasone suppression ($cortisol_{DST}$) in MACS is wide, the associated risk may vary. To adequately decide treatment, the risk associated to the different levels of $cortisol_{DST}$ must be known. This year the ENSAT group published a study on cardiometabolic complications in MACS. Patients with $cortisol_{DST}$ 138 nmol/l or more had an increased adjusted prevalence ratio of hypertension 1.15 and more often had treatment with three or more antihypertensives. The adjusted prevalence ratios of dyslipidaemia and diabetes were similar, but insulin treatment was more common. Patients with $cortisol_{DST}$ 50 to 137 nmol/l had no increase in the prevalence of hypertension, diabetes, and dyslipidaemia. Last year our group published a study on 1048 patients with a median follow-up of 6.4 years. Patients with $cortisol_{DST}$ 83 to 137 nmol/l had a hazard ratio of 2.30 for mortality and patients with $cortisol_{DST}$ 138 nmol/l or more 3.04. Patients with $cortisol_{DST}$ 50 to 82 nmol/l had no significant increase in mortality. The increase in mortality was found to be linear up to $cortisol_{DST}$ levels of 200 nmol/l. The cardiovascular event rate was increased in patients with $cortisol_{DST}$ 138 nmol/l or more but unchanged at $cortisol_{DST}$ levels 50 to 137 nmol/l. The risk ratios for mortality seem larger than the relative prevalence of cardiometabolic complications. Therefore, improved medical treatment may not normalise the mortality risk in MACS. We suggest treatment of cardiovascular risk factors and incorporation of our results into the decision of which patients to recommend for adrenalectomy.

Iron and the thyroid

Michael Zimmermann
ETH Zurich, Switzerland

Despite significant progress, deficiencies of iron and iodine remain major public health problems affecting >30% of the global population. These deficiencies often coexist in populations. Iron deficiency has adverse effects on thyroid metabolism. Iron deficiency impairs thyroid hormone synthesis by reducing activity of heme-dependent thyroid peroxidase. Iron-deficiency anemia blunts, and iron supplementation improves the efficacy of iodine supplementation. Studies have demonstrated that a high prevalence of iron deficiency among children in areas of endemic goiter may reduce the effectiveness of iodized salt programs. These findings argue strongly for improving iron status in areas of overlapping deficiency, not only to combat anemia but also to increase the efficacy of iodine prophylaxis. Poor maternal iron status predicts both higher TSH and lower TT4 concentrations during pregnancy in an area of borderline iodine deficiency.

Genetics of adrenal endocrine tumors

S9.1

Genetic bases of pheochromocytoma and paraganglioma

Mercedes Robledo
Hereditary Endocrine Cancer Group, Spanish National Cancer Research Centre (CNIO), Madrid, Spain; [2]Rare Diseases Networking Biomedical Research Centre (CIBERER), Madrid, Spain

Pheochromocytoma and paraganglioma (PPGL) are rare tumours, whose genetic profile has gained complexity over the last two decades. The list of genes involved in the development of this disease has been steadily growing, and there are currently more than 20 driver genes capable of explaining either the hereditary or sporadic nature of the disease. Although genetic diagnosis is achieved in about 75-80% of cases, the genetic aetiology remains to be explained not only in patients with apparently sporadic PPGL, but also in patients with a family history or with multiple tumours, and who therefore meet the criteria to be considered as candidates for carrying mutations in as yet undiscovered genes. Taken together, the mutations in the known PPGL genes deregulate three distinct signalling pathways, which may be the starting point for personalised treatment of these patients. One of the most relevant features of PPGLs is that they show homogeneous genomic profiles according to the specific gene that is mutated in each case. This homegeneity is what is making it possible to identify new characteristics of PPGLs, including differential aspects of the tumour microenvironment, again dependent on the genetics of the tumour.

Fructose but not glucose drives DNL

Philipp A Gerber
Department of Endocrinology, Diabetology and Clinical Nutrition, University Hospital Zurich and University of Zurich, Switzerland

Observational studies conducted during the past two decades provide evidence of an association of dietary fructose consumption with obesity and metabolic diseases as non-alcoholic fatty liver disease or insulin resistance / type 2 diabetes mellitus. However, these associations are challenged by the fact that it is difficult to adjust the results of such studies for excessive caloric intake, which often co-exists with high fructose intake, e.g., by consumption of sugar-sweetened beverages. Thus, there is a clear need for direct interventional studies exploring a possible causal role of fructose in the development of metabolic diseases, as compared to other sugars. To this aim, different controlled trials were conducted by our group as well as other investigators to assess this question. Such studies expose their participants to various amounts of different sugars for several weeks to months, and investigate different outcomes related to metabolic diseases as those outlined above. With these trials, it was possible to gain direct insights into the mechanisms by which different sugars may negatively influence metabolic health. In particular, latest research provides evidence of very distinct effects of fructose consumption on hepatic metabolism, in particular regarding a "metabolic switch" in hepatic tissue towards de novo lipogenesis. Furthermore, and in addition to the effects of fructose, the co-ingestion of fructose and glucose (which is very common due to their co-existence in the sucrose molecule) may have similar or even more deleterious effects than consumption of fructose alone. Thus, these results emphasize the importance of an overall reduction of added sugars in our diet, as suggested by the WHO and other organizations.

Bone microstructure - What techniques are there, what do they tell us

Carmelo Messina[1,2]
[1]University of Milan, Milan, Italy; [2]IRCCS Istituto Ortopedico Galeazzi, Milan, Italy

Areal BMD from Dual energy X-Ray absorptiometry (DXA) accounts for approximately two-thirds of bone strength and is used as a surrogate for bone strength in clinical practice to predict fracture risk. Nevertheless, a more in-depth assessment of bone quality requires second level imaging techniques to assess bone quality parameters. Bone quality is a key parameter in determining bone strength. During time, several non-invasive high-resolution imaging techniques have been developed to visualise bone structure. As bony trabeculae measure 50–200 μm in thickness, the spatial resolution of imaging techniques applied to the the non-invasive evaluation of bone microstructure must be higher than 200 μm to spatially solve the single trabeculae. High-resolution peripheral quantitative computed tomography (HR-pQCT) is a low-dose technique that enable to image bone microarchitecture in vivo at peripheral skeletal sites, such as distal forearm and tibia. Differences and reference data exist for HR-pQCT by age and sex, race/ethnic origin and body composition. We will review the role of HR-pQCT in fractured patients, to highlight those parameters of bone microarchitecture and bone strength useful as predictors of incident fractures, as well as in subject with prevalent fractures. The role of HR-pQCT in monitoring response of anti-osteoporotic therapy will be addressed, as well as its role in patients with secondary osteoporosis and metabolic bone disorders. Finally, novel application of Hr-pQCT will be briefly reviewed. The presentation will then deal with the evaluation and quantification of bone structure and microstructure with current available MRI techniques, also comparing the MRI performance with DXA and CT measurements. Limitation of each technique will be reviewed, as well as their current applicability in clinical practice.

Artificial intelligence in osteoporosis management

Hans Peter Dimai
Department of Internal Medicine, Division of Endocrinology & Diabetology, Medical University of Graz, Graz, Austria

Background
Osteoporosis is a systemic skeletal disease characterized by low bone mass, microarchitectural deterioration of bone tissue, and the consequence of an increased fracture risk. The term "artificial intelligence (AI)" denotes a field in computer science which enables computers to simulate different aspects of human intelligence, such as natural language understanding, pattern recognition or data driven learning. Machine Learning is a subset of AI, and within this field, Convolutional Neural Networks (CNN) play a key role particularly in relation to medical imaging.
Methods
Various AI applications as currently available for the management of osteoporosis are presented, including their strengths and pitfalls.
Results
One of the mainstays of AI supported applications in osteoporosis is imaging based detection of fractures. Almost any medical imaging technique including – but not limited to - plain radiography, computed tomography (CT) and MRT, is represented in an increasing number of studies. There is evidence that AI based technical support can improve fracture detection rate. Furthermore, AI supported algorithms are used not only to assess quantitative aspects of the bone, such as bone mineral density (BMD) at the lumbar spine, the hip and the total body, but also to assess qualitative properties, such as microarchitecture and even fracture load. However, it is of note that many of the clinical studies involving AI in the field of osteoporosis are short of scientific diligence. For example, algorithms behind specific diagnostic approaches are not always published in detail. Also, the logic behind a chosen approach is not always comprehensible. In general, there is a clear lack in standardized procedures.
Conclusion
There are aspects in support of integrating AI based tools into osteoporosis management workflows in daily clinical practice. However, there is also a clear need for high quality clinical research in this field. In this regard, implementation of, e.g., internationally consented quality standards could help to improve the relevance of study outcomes and also their credibility.

Sepsis as a pan-endocrine illness

Weronika Wasyluk[1,2]
[1]Department of Internal Medicine in Nursing, Faculty of Health Sciences, Medical University of Lublin, Lublin, Poland; [2]Doctoral School, Medical University of Lublin, Lublin, Poland

Sepsis is defined as "life-threatening organ dysfunction caused by a dysregulated host response to infection". This response is expressed, inter alia, in the endocrine system and affects almost all endocrine axes. Endocrine dysfunction, in turn, may contribute to other aspects of dysregulated host response to infection, such as metabolism. Endocrine disorders in the course of sepsis are particularly noticeable in the area of the hypothalamic-pituitary-target tissue axis. Disorders of the hypothalamic-pituitary-adrenal axis manifest mainly by hypercortisolemia in the acute phase. In the hypothalamic-pituitary-thyroid axis the most typical manifestation is a triiodothyronine concentration decrease and reverse triiodothyronine concentration increase. In terms of the somatrotropic axis, a change in the secretion pattern of growth hormone and peripheral resistance to this hormone is characteristic. Hypothalamic-pituitary-gonadal axis disorders are expressed by the stress-induced amenorrhea in women and the reduction in testosterone level in men. Other changes include insulin resistance and catecholamine and β-adrenergic stimulation disorders. It is also worth bearing in mind that a patient's endocrine profile is not the same for the entire duration of the disease, but changes over time, which is noticeable especially between the acute and the chronic phase. It is suggested that some of these changes are adaptive, but there is no doubt that all of them may have an impact on the patient's clinical condition. Since the endocrine system is responsible for the homeostasis of the system, disturbances in its scope contribute to the dysregulation of other functions of the body, including metabolism, which, according to some authors, is one of the main pillars of the pathophysiology of sepsis. As stated by Singer et al., a more sophisticated understanding of the sequence, dynamics and interaction between the occurring metabolic, hormonal and immunological changes would provide a logical basis for patient-tailored therapeutic interventions, therefore this issue undoubtedly requires further researches.

Endocrine and metabolic aspects of COVID-19

Michal Kršek
Department of Internal Medicine 3, 1st Faculty of Medicine, Charles University, General University Hospital, Prague, Czech Republic

Coronavirus disease 19 (COVID-19) started to quickly spread worldwide in the end of 2019 and was declared by the WHO a pandemic on March 11, 2020. Prevailing signs and symptoms of COVID-19 comprise many organ systems and are very complex and variable and also even unpredictable and lead to tremendous increase in morbidity and mortality. Recently, there has been increasing evidence that COVID-19 affects in a complex way also the endocrine system. Renin-angiotensin-aldosterone system (RAAS) plays a crucial role in SARS-CoV-2 infection and pathogenesis. Angiotensin-converting enzyme 2 (ACE2) protein is crucial for the entry of the virus into the cells. However, it seems that overexpression of ACE2, which takes place also during the use of ACEs inhibitors, is not connected with higher susceptibility to SARS-CoV-2 infection. It is of note that the balance between ACE1 and ACE2 actions is disturbed during COVID-19 which favours proinflammatory pathways leading to tissue damage with that of lung tissue being critical for the course and prognosis of COVID-19. Thyroid gland disorders are frequently reported in relationship with COVID-19. During the severe course of COVID-19, the changes compatible with non-thyroidal illness syndrome are common. This, however, is a consequence of severe/critical illness rather than direct causal effect of COVID-19. Amongst thyroid disorders reported and studied in connection with either COVID-19 or vaccination, we can find autoimmune thyroid (AITD) disease manifestation and subacute thyroiditis. Several cases of adrenal insufficiency have been reported during or following COVID-19. These cases, however, are very likely a consequence of COVID-19 comorbidities such as antiphospholipide syndrome. It is necessary to point out that normal function of hypothalamic-pituitary adrenal axis is necessary for the survival of patients mainly with severe course of the disease and proper replacement regimens in patients with adrenal insufficiency have to be introduced. Other conditions also possibly related to COVID-19 will be mentioned, mainly diabetes and obesity.

Unmet needs in aggressive endocrine cancers

S18.1

Choosing the best treatment sequence for gepnet tumours

Eva Tiensuu Janson
Department of Medical Sciences, Uppsala University, Uppsala, Sweden

Background
Gastroenteropancreatic neuroendocrine tumors (GEP-NETs) are grouped according to the origin of the primary tumor and their proliferation index (Ki-67). The WHO classification divide GEP-NETs into G1 (Ki-67 $<3\%$), G2 (Ki-67 ≥ 3-20%) and G3 (Ki-67 $>20\%$). Both parameters are accounted for when treatment strategies are planned. Furthermore, the presence of hormone related symptoms warrant consideration.
Aim
To describe the treatment landscape for metastasized GEP-NETs.
Results/discussion
Surgery should always be discussed and performed if R0 is considered possible. Most GEP-NETs express somatostatin receptors (SSRs) and treatment with somatostatin analogs is the primary choice in metastatic low proliferating GEP-NETs, originating both in the small intestine and pancreas, and to reduce symptoms of carcinoid syndrome or in the rare event of a glucagonoma or VIPoma. SSR expression is also a prerequisite for peptide receptor radionuclide therapy (PRRT) which is usually recommended as second or third line treatment in both G1 and G2 tumors and for a selected population of GEP-NET G3. For patients with pancreatic tumors with Ki-67 $>10\%$, chemotherapy or the mTOR inhibitor everolimus may be used as first line treatment. Everolimus may also be

an option in progressing small intestinal NETs with a higher proliferation rate. Sunitinib is an alternative in progressing PanNETs. To reduce tumor burden in the liver, radiofrequency ablation or liver embolization may be used. In rare cases, liver transplantation may also be discussed, but a thorough preoperative work-up has to be performed before such an intervention is initiated. For those patients that does not respond to the traditional therapies, treatment in clinical studies can be an option.

Conclusion

The therapeutic landscape for metastasized GEP-NETs include several treatment options. However, the sequencing of therapy is still debated and choices should be made in order to preserve QoL and minimize the risk for severe side effects.

The aperitif: The neurobiology of appetite and hunger

Suzanne Dickson
Department of Physiology/Endocrine, Institute of Neuroscience and Physiology, The Sahlgrenska Academy at the University of Gothenburg, Sweden

Environmental cues recalling palatable foods motivate eating beyond metabolic need, yet the timing of this response and whether it can develop towards a less palatable but readily available food remain elusive. Increasing evidence indicates that external stimuli in the olfactory modality communicate with the major hub in the feeding neurocircuitry, namely the hypothalamic arcuate nucleus (Arc), but the neural substrates involved have been only partially uncovered. By means of a home-cage hidden palatable food paradigm, aiming to mimic ubiquitous exposure to olfactory food cues in Western societies, we investigated whether the latter could drive the overeating of plain chow in non-food-deprived male rats and explored the neural mechanisms involved, including the possible engagement of the orexigenic ghrelin system. The olfactory detection of a familiar, palatable food impacted upon meal patterns, by increasing meal frequency, to cause the persistent overconsumption of chow. In line with the orexigenic response observed, sensing the palatable food in the environment stimulated food-seeking and risk-taking behavior, which are intrinsic components of food acquisition, and caused active ghrelin release. Our results suggest that olfactory food cues recruited intermingled populations of cells embedded within the feeding circuitry within the Arc, including, notably, those containing the ghrelin receptor. These data demonstrate the leverage of ubiquitous food cues, not only for palatable food searching, but also to powerfully drive food consumption in ways that resonate with heightened hunger, for which the orexigenic ghrelin system is implicated.

Central impact of growth hormone GH-axis negative feedback and metabolic function

José Donato Júnior
Department of Physiology and Biophysics, Institute of Biomedical Sciences, University of São Paulo, São Paulo, Brazil

Growth hormone (GH) responsive cells are extensively distributed in the brain, including in neurons of the arcuate nucleus (ARH) and ventromedial nucleus (VMH) of the hypothalamus, areas that control food intake, energy expenditure and blood glucose levels. However, the functional role of central GH signaling for energy and glucose homeostasis has not been unveiled yet. We generated mice lacking GH receptor (GHR) in multiple neuronal populations to investigate whether central GHR signaling modulates energy and glucose homeostasis during normal conditions or during situations of metabolic stress. GHR ablation in AgRP neurons did not affect the body weight, food intake, energy expenditure, glucose tolerance and leptin sensitivity, compared to control animals. However, fasting induced a lower c-Fos expression, a marker of neuronal activation, in the ARH of AgRP GHR KO, suggesting that AgRP neurons are unable to appropriately sense food deprivation without GH signaling. Remarkably, GHR ablation in AgRP cells mitigated highly characteristic hypothalamic and neuroendocrine adaptations induced by weight loss. Thus, while control mice adapted to a 60% food deprivation by progressively saving energy, AgRP GHR KO mice exhibited a higher T4 and testosterone concentrations as well as an increased energy expenditure and UCP-1 mRNA expression in the brown adipose tissue, compared to control animals. These effects led to a higher rate of weight loss, which was predominantly due to fat. In contrast, GHR ablation in steroidogenic factor-1 (SF1) cells, which include VMH neurons, did not affect the responses to food restriction in comparison with control group. However, a blunted counter-regulatory response to hypoglycemia was observed in SF1 GHR KO mice, indicating that GH signaling in VMH neurons helps the organism to recover from hypoglycemia. These findings indicate a previously unidentified function of GH to induce appropriate metabolic responses that ensure survival via its action on specific neuronal populations.

Autoimmune polyendocrine syndromes

S21.1

Autoimmunity in families with Addison's disease

Marta Fichna
Poznan University of Medical Sciences, Poland

Since individuals with autoimmune Addison's disease (AD) present considerable co-occurrence of other autoimmune conditions, clustering of autoimmunity was also predicted among their relatives. We aimed to evaluate the burden of autoimmunity in families of patients with AD by means of a survey, serum autoantibody testing and correlating these data with the established genetic risk factors (*PTPN22* rs2476601, *CTLA4* rs231775, and *BACH2* rs3757247). 74.1% patients reported relative(s) with autoimmunity, and, inversely, 11.9% surveyed relatives, especially first-degree female family members, declared an autoimmune disease, most frequently Hashimoto's thyroiditis, followed by Graves' disease, vitiligo, and type 1 diabetes. Psoriasis, rheumatoid arthritis, pernicious anaemia, multiple sclerosis, and premature menopause were also quite common, while AD, alopecia, and celiac disease – less frequent. Significant correlation was noticed between the number of autoimmune conditions in AD proband and the number of affected relatives ($P=0.031$). Endocrine gland-specific serum autoantibodies were detectable in 39.8% first-degree relatives of patients with AD, including asymptomatic subjects. Antibodies to 21-hydroxylase were found in 6.2% relatives, thyroid peroxidase in 28.3%, thyroglobulin in 19.5%, glutamic acid decarboxylase in 8.0%, zinc transporter-8 in 7.1%, and islet antigen-2 in 2.6%. Autoantibodies were significantly more frequent in families of male patients ($P=0.008$; OR 3.31; 95% CI 1.334-8.234) and patients with polyglandular autoimmunity ($P=0.009$; OR 3.545; 95%CI 1.313-9.573). Autoimmunity-related genetic polymorphisms occurred more frequently among Addison's families vs controls (all $P<0.05$), and *PTPN22* rs2476601 was associated with all autoantibody prevalence, except for IA-2. In conclusion, there is convincing evidence of increased susceptibility for autoimmune endocrine conditions, especially thyroid disease, in the relatives of patients with AD, predominantly in females. Relatives of the male AD patients and of those with polyendocrine autoimmune AD are at particular risk and should undergo periodic screening for autoimmune endocrine disorders.

Autoimmune regulator mutations and autoimmunity

Bergithe Oftedal
Department of Clinical Science, University of Bergen, Norway

The autoimmune regulator (AIRE) gene is crucial for establishing central immunological tolerance and preventing autoimmunity. Mutations in AIRE cause a rare autosomal-recessive disease, autoimmune polyendocrine syndrome type 1 (APS-1). The clinical picture is highly variable, however, most patients present severe chronic mucocutaneous candidiasis and organ-specific autoimmunity from early childhood and have high levels of autoantibodies against interferon alpha and omega. Recently, it has become evident that AIRE variants also associate with more common organ-specific autoimmune diseases such as autoimmune adrenal insufficiency, gastritis, and type 1 diabetes. We have identified multiple patients with heterozygous variants in AIRE and investigated their dominant negative effect on AIRE's gene regulation. We find that dominant negative AIRE variants cluster within the PHD1 and PHD2 domains and have a varying effect on AIRE's transcriptional activity. As a group, these patients have fewer and milder manifestations masquerading as "common" organ-specific autoimmunity where enteropathy was the most frequent manifestation. Interestingly, a few of these patients have autoantibodies against interferon omega. By scrutiny of our national registry, we identified two female and two male APS-1 patients from three different families with late-onset APS-1 sharing a homozygous or compound heterozygous splice mutation in AIRE's exon 7. In addition to the late onset, they also presented with a milder phenotype compared to classical APS-1. Both normal AIRE mRNA splicing and an altered splicing pattern including skipping of exon 7 were found in the patients and in the corresponding mouse model, indicating leaky rather than abolished mRNA splicing. Further, a moderately inhibited. Aire-regulated transcriptome was found in the mouse thymus. Our results underline the dose-effect of AIRE. Taken together, our results highlight the importance of functional validation of AIRE variants and suggest a dose-dependent function of AIRE.

Thyroid autoimmunity, subfertility and assisted reproduction

Kris G Poppe[1,2]
[1]CHU St-Pierre, Brussels, Belgium; [2]ULB-Erasme, Brussels, Belgium

Severe thyroid dysfunction may lead to menstrual disorders and subfertility via direct and indirect interactions with the hypothalamo–pituitary–ovarian axis and the reproductive organs. However, the exact prevalence of subfertility in women with thyroid disorders remains unknown. Fertility problems may persist after restoring normal thyroid function, and then surgery and/or an assisted reproductive technology (ART) may be necessary to obtain a pregnancy. The initial step in an ART treatment is the ovarian stimulation, putting strain on the thyroid gland, potentially leading to (permanent) hypothyroidism in women with thyroid autoimmunity (TAI) or when already treated with thyroid hormones (LT4). Moreover, women with ovarian and unexplained causes of subfertility have a higher prevalence of TAI. In women with TSH levels >4.0 mIU/l, fertilisation rates, embryo quality and live birth rates may be impaired and improved with LT4 therapy. The increased use of intracytoplasmic sperm injection (ICSI) as a type of ART on pregnancy outcomes in women with TAI deserves more attention as therapeutic tool. In euthyroid women with TAI, LT4 should not be given systematically, but on a case-by-case basis if serum TSH is >2.5 mIU/l. Women already treated with LT4, should target a serum TSH level <2.5 mIU/l before ART. For all of the above reasons, women of subfertile couples should be screened systematically for the presence of thyroid disorders, and especially serum TSH and TPOAb. In this symposium, we will present the current state of art, discuss the gaps in the knowledge, and finally, make proposals for future investigations.

Diabetes remission: From dream to clinical goal

S24.1

Type 1 diabetes remission: who, how and when

Paolo Pozzilli[1,2]
[1]Unit of Endocrinology and Diabetes, Campus Bio-Medico University of Rome, Italy; [2]Centre of Immunobiology, St Bartholomew's and the London School of Medicine, Queen Mary, University of London, United Kingdom

Type 1 diabetes (T1D) is a chronic disease of childhood that also presents in adults, resulting from the destruction of insulin-producing β-cells by auto-reactive T cells that have escaped central and peripheral immune tolerance. It is now well established that T1D is characterised by a wide heterogeneity especially in terms of age at onset, representing a major barrier for both pathogenesis and translational efforts aimed to develop novel therapeutics approach. This concept represents a key factor in defining who should be treated with an intervention capable of inducing disease remission. The insulin secretory capacity assessed by the residual β-cell function (measurement of C-peptide) at the time of diagnosis and during the first few year after T1D diagnosis is a crucial factor to define when and how to intervene with the aim of modifying the natural history of the disease on the short and long term. We have to remember that in the vast majority of T1D patients at diagnosis a significant mass of functional islets has been destroyed by the autoimmune attack, thus lacking the chance to be either preserved or rescued by a therapeutic approach able to reverse the course of disease onset. However, some T1D patients show a substantial residual β-cell function at diagnosis and also in the first year after disease manifestation, thus representing an interesting population to target for an intervention able to protect endogenous insulin secretion. Furthermore, some patients may be overweight and become insulin resistant, thus implying that also this pathophysiological condition should be tackled. Patients with T1D and substantial residual β-cell function with or without signs of insulin resistance identify a specific endotypes of T1D. These novel concepts pave the way for new and diverse therapeutic options which can be applied to well characterised patients accordingly.

Is familial hypercholesterolemia an underdiagnosed and undertreated disease?

Juan Patricio Nogueira
Centro de Investigación en Endocrinología, Nutrición y Metabolismo (CIENM), Facultad de Ciencias de la Salud, Universidad Nacional de Formosa, Argentina

Familial Hypercholesterolemia (FH) is a monogenic disease, associated with variants in the LDLR, APOB, and PCSK9 genes. The initial diagnosis is based on clinical criteria like the DLCN criteria. A score $>$ 8 points qualifies the patient as "definite" for the diagnosis of FH. It is characterized by lifelong elevations in plasma low-density lipoprotein cholesterol (LDL-C) levels and premature coronary heart disease (CHD). FH is an underdiagnosed and undertreated genetic disorder, which affects 1 in 200 to 250 people worldwide of all races and ethnicities. The general lack of awareness about FH among the public and the medical community has resulted in only 10% of the FH population being diagnosed and adequately treated. It is recommended that children, adults, and families should be screened for FH if an individual or family member has FH, an adult plasma cholesterol level $\geq$8 mmol/l ($\geq$310 mg/dl) or in a child $\geq$6 mmol/l ($\geq$230 mg/dl), premature CHD, tendon xanthomas, or sudden premature cardiac death. In FH, low-density lipoprotein cholesterol goals are $<$3.5 mmol/l ($<$135 mg/dl) for children, $<$2.5 mmol/l ($<$100 mg/dl) for adults, and $<$1.8 mmol/l ($<$70 mg/dl) for adults with known CHD or diabetes. In addition to lifestyle and dietary advice, priority treatments are (i) in children, statins, ezetimibe, and bile acid-binding resins, and (ii) in adults, maximal potent statin dose, ezetimibe, bile acid-binding resins, and monoclonal antibodies directed against PCSK9. Lipoprotein apheresis can be offered in homozygotes and in heterozygotes with CHD refractory to treatment. FH is usually diagnosed late. Guidelines-recommended LDL cholesterol concentrations are rarely achieved with single-agent therapy. Cardiovascular risk factors and the presence of CHD were lower among non-index cases, who were diagnosed earlier. Earlier detection and an increase in the use of combination therapies are required to reduce the global burden of FH.

The challenges in male infertility research. Which are the future topics of research?

Lærke Priskorn[1,2]

[1]Department of Growth and Reproduction, Copenhagen University Hospital – Rigshospitalet, Copenhagen, Denmark; [2]International Center for Research Training in Endocrine Disruption of Male Reproduction and Child Health (EDMaRC), Copenhagen University Hospital – Rigshospitalet, Copenhagen, Denmark

Infertility affects 15%–25% of couples, and male reproductive issues related primarily to semen quality play a role in many cases. Furthermore, impaired semen quality has been linked to adverse long-term health outcomes. A key pillar in the evaluation of men from infertile couples is the traditional semen analysis, which by and large has remained unchanged for decades, including assessment of semen volume, sperm concentration, motility and morphology. Though, the process of fertilization (*in vivo*) is much more complex that what is covered with these parameters. At present, most treatment options bypass natural reproduction barriers by enhancing ovulation and/or increasing the chance of oocyte/sperm interaction, whereas only few treatments target the underlying cause of infertility. The causes of male infertility are multifactorial involving both genetic factors and exposures in fetal life and adulthood. However, the interplay between and relative contributions of health behavior, psychosocial, environmental, genetic, endocrine, metabolic, immunologic, and epigenetic factors as well as pathogenic processes at different stages of life are still poorly understood. Despite the availability of increasingly advanced diagnostic and therapeutic techniques, approximately 30% of infertile couples do not obtain a live birth after fertility treatment. Reaching beyond the traditional semen analysis and implementing artificial intelligence methods is essential to further improve our ability to **a)** study risk factors for male (and female) infertility, **b)** identify new biomarkers to diagnose subfertility and predict fecundity and response to treatment, and **c)** identify subgroups of infertility patients at risk of long-term health impairment. With the establishment of the ReproUnion Biobank and Infertility Cohort (RUBIC), including 5000 well-characterized infertile Danish and Swedish couples, we hope to create a framework for this approach in a multidisciplinary research environment. An unresolved issue is, however, how to apply the artificial intelligence methods and develop the new interdisciplinary collaborations needed.

Laboratory chaos diverted – the case of the in vitro diagnostics regulation

Michael Vogeser
Institute of Laboratory Medicine, University Hospital, LMU Munich, Germany

In vitro diagnostics (IVD) in the European Union is facing a fundamental change with the introduction of a new regulation, the so-called In Vitro Diagnostics Regulation (IVDR). Originally, the IVDR was scheduled to enter into force in May 2022, however, in January 2022, the EU legislator made a differentiated partial postponement of the application of important parts of the IVDR. The major innovation and achievement of the IVDR is that most commercially manufactured IVD products must now be certified by independent (albeit commercial) notified bodies - replacing the system of self-certification by manufacturers. Notified bodies are under surveillance by member states. Because key regulatory processes have not been implemented in time, the entry into force of the IVDR for commercial IVDs has been delayed to 2025 to 2027, depending on the risk class. For the IVD industry, the product certification process requires significant additional resources for compliance. This may result in niche products being phased out of the market by some manufacturers. In addition to commercial products, some elements of the IVDR are also mandatory for in-house manufactured products, particularly Annex I (general safety and performance requirements), starting as early as May 2022, particularly for calibration and control materials and reagents manufactured in-house. The definition of in-house products in Article 2 (IVDR) does not include measurement methods, and the term LDT (laboratory developed test) is not used by the IVDR. Compliance with this regulation is not assessed at EU level, but is the responsibility of the Member States.

Fighting endocrine disruption - Are we getting somewhere?

Barbara Demeneix
Unité PhyMA, Department 'Adaptation du Vivant', Muséum national d'Histoire naturelle, Centre National de la Recherche Scientifique, Sorbonne University, 7 rue Cuvier, 75005, Paris, France

The Daily Tolerable Intake (DTI) was reduced by BPA (bisphenol A) 100,000 fold. This is an unprecedented action to protect consumers and the environment from the most commonly used plasticizer. However, one problem identified was the fact that regrettable substitutes, such as BPS and BPF, were not included in the recommendation. There will be a fight to ensure that this passes into the European legislation. In the meantime, BP-B (,4'-(1-methylpropylidene) bisphenol (a substitute for BPA) and a sunscreen agent 4-MBC were proposed to be endocrine disruptors. Resorcinol was identified as a Substance of Very High Concern (SVHC). This was primarily due to its effects on the thyroid and other endocrine systems. GenX produced by Chemours lost their suit. Chemours had taken the EU Chemicals Agency (ECHA) to court over the inclusion of GenX chemicals in the SVHC list under REACH – the main EU law used to stop chemical pollution. Already, a multitude of other PFAS, per (and poly) fluoroalkyl substances are classed as SVHCs, mainly due to their mobility and persistence. Next, the question of mixtures. As we showed in our paper 'From Cohorts to Molecules' (https://www.science.org/-doi/epdf/10.1126/science.abe8244) the thyroid gland was among those endocrine systems affected. We showed the mixture of 8 chemicals affected language delay in children at 30 months and at 7 years of age. Given that in the US current figures for autism spectrum disorder have reached 1 in 44 children and the thyroid axis is needed for brain development the two could be linked.

Hormones and public awareness – the need for better estimates of hormonal exposure

Bruno Lapauw
Ghent University Hospital, Ghent, Belgium

Hormones are key regulators of numerous physiological processes. While most hormones are produced in select organs, their effects are felt throughout the body. Hormonal exposure is not only mediated by hormone production, but also by circulating binding proteins, and by local metabolism. Although we still heavily rely on total serum levels for the diagnosis of endocrine disorders and abnormalities, it is increasingly clear that total serum hormone levels do not always accurately reflect true exposure. Patients with binding protein defects presenting with low total hormone levels - but no profound clinical features - are a key example of this. Free serum hormone levels, the minor fractions of circulating non-protein bound (steroid) hormones, are recognized as superior markers of hormonal exposure and are increasingly used in the clinic. For example, using free testosterone is now recommended in the diagnosis of male hypogonadism and female hyperandrogenism. However, free serum hormone levels are mostly estimated using calculators, as access to direct measurements is limited because it is technically demanding and laborious. Also, alternative measurements in different matrices such as saliva and hair are being explored. Advantages of these measurements include more accurate reflections of hormonal exposure, over longer periods of time, minimizing patient discomfort, and the ability to collect samples ambulatory. Despite recent advances, further insight is necessary for a broader adaption of these new markers. In the BEED-ED project, we want to improve the clinical applicability of free steroid hormone concentrations in patients with specific conditions. As the number of available tests increases, so too does the need to educate both healthcare providers and patients. Increasing public awareness about the importance, implication and interpretation of these new measures of hormonal exposure is key to advancing both the immediate care for patients and the utility of these novel estimates of hormonal exposure.

Scaling down the study of pituitary tumours for better understanding their behaviour and intra-tumoral heterogeneity

Philippe Bertolino
Inserm U1052, CNRS UMR5286, University Claude Bernard Lyon 1, Cancer Research Center of Lyon, Lyon, France

Gonadotroph tumours (GoTs) are frequent intracranial neoplasms that represent 30% of all pituitary tumours (PiTs). While GoTs are responsible of an important morbidity, their tumorigenesis is not yet understood, and their treatment is limited to surgical resection and radiotherapy. The absence of identified driver-genes combined with their heterogeneity and silent behaviour (i.e. lack of hormone hypersecretion) limit the development of medical treatment. The current lack of relevant preclinical animal-models and patient-derived cell-lines has further slowed the study of the biological and molecular mechanism underlying gonadotroph tumorigenesis. Here we questioned whether we could scale down the culture and the functional analysis of tumour-cells derived from resected gonadotroph tumour to improve our knowledge of GoTs behaviour and intra-tumoral heterogeneity. We developed a series of approaches combining custom-made agarose-based micro-culture inserts and computerized-analyses of 3D-images to: i) characterize GoT intra-tumoral heterogeneity and ii) screen molecules to develop new therapeutics. The feasibility of these approaches was first addressed through the analysis of pituispheres obtained from rodent-pituitary cell-lines. Subsequently pituispheres obtained from GoT-patients were analyzed. Parameters such a size and percentage of tumor cells (CHGA+) vs non tumor-cells (i.e. Microenvironment, TME) and response to candidate therapeutic molecule were addresses in a 3D semi-high throughput manner (30-50 spheroids acquired through confocal scanning). Magnetic sort based on surface expressing-markers was also performed on surgically-resected gonadotroph tumours to compare the growing capabilities of different tumour-cell-populations isolated from single patients. In conclusion, we have built and validated custom-made micro-culture inserts for growing, imaging and analyzing pituitary rodent cell-lines and patient-derived cells. This work confirms that scaling down the analysis of patient-derived pituispheres could overcome the lack of patient-derived cell lines and could serve the screening of novel therapeutics for personalized medicine.

Debate Sessions

PRRT or targeted molecular therapies as preferred line of treatment

D1.1

For: PRRT or targeted molecular therapies as preferred line of treatment

Wouter W de Herder
Internal Medicine - Endocrinology, Erasmus Medical Center, Rotterdam, Netherlands

Purpose
Bronchopulmonary (BP) and gastroenteropancreatic (GEP) neuroendocrine neoplasms (NEN) are slow-growing tumors, which frequently express somatostatin receptors on their cell membranes. These receptors are targets for therapy with ^{177}Lutetium-labeled somatostatin analogues.
Experimental Design
Patients receive four treatments of ^{177}Lu-DOTATATE at a dose of 7.4 GBq every 8 weeks
Results
An objective response rate of 39% was found for all BP & GEP NEN. Stable disease was reached in 43% of patients. Progression-free survival (PFS) and overall survival (OS) for all NET patients were 29 months (95% confidence interval (CI), 26–33) and 63 months (95% CI, 55–72). Long-term toxicity included acute leukemia (0.7%) and myelodysplastic syndrome (1.5%). No therapy-related long-term renal or hepatic failure occurred. The NETTER-1 study was the first randomized phase III study of ^{177}Lu-DOTATATE and evaluated patients with midgut NENs who had progressed on standard doses of octreotide LAR. Patients were randomized to receive ^{177}Lu-DOTATATE in combination with standard-dose octreotide or high-dose octreotide (60 mg/4 weeks) alone. Median OS was 48 months (95% CI, 37-55) in the ^{177}Lu-DOTATATE group and 36 months (95% CI, 26-52) in the control group.
Conclusions
PRRT with ^{177}Lu-DOTATATE is a favorable therapeutic option in patients with metastatic bronchial and gastroenteropancreatic NETs that express somatostatin receptors. PRRT with ^{177}Lu-DOTATATE is safe with few side-effects and shows good response rates.

D3.2

For: Adjuvant radioactive iodine therapy for low to intermediate risk differentiated thyroid cancer patients

Juan Carlos Galofré
Department of Endocrinology and Nutrition, Clínica Universidad de Navarra, Pamplona, Spain

Current indications for adjuvant Radioactive Iodine (RAI) in low- and intermediate-risk differentiated thyroid cancer (DTC) are controversial. At the same time, there is universal consensus for personalized DTC management according to individual patient needs, as there does not appear to be a ''right'' way to treat patients with DTC. According to the *Martinique Principles* [1], adjuvant RAI treatment has many goals, including: initial staging of the disease, facilitate follow-up, improve disease-specific survival, decrease recurrence, improve progression-free survival and, in some cases, curative intent. The same principles state that the key elements in adjuvant treatment decision-making are post-op risk assessment, impact on outcomes of interest, side effect profile, patient values and preferences, improved initial staging, and facilitate sensitive follow-up. In addition, other factors must be consider such as the availability and quality of pre- and post-op ultrasound, the quality of RAI imaging, thyroglobulin assay accuracy, the access to an experienced thyroid surgeon, the presence of anti-thyroglobulin antibodies and preferences of local disease management multi-disciplinary team. All these factors (or a combination of them) could tip the balance for or against adjuvant RAI administration in DTC. There are fresh retrospective data showing that a decrease in the administration of adjuvant RAI in low- to intermediate-risk DTC individuals generates a substantial number of patients stranded in a misleading status labeled as "gray zone"[2]. These patients are those appropriately identified as *indeterminate* or *biochemical incomplete* response to treatment when ablative RAI is administered. A large number of patients in a broad "gray zone" could likely complicate their follow-up, with more diagnostic tests that will lead to increasing costs and raise the anxiety level of both patient and attending physician. A very recent European Thyroid Association Consensus Statement[3], recommends adjuvant RAI in intermediate-risk DTC patients who meet any of the following frequent conditions: advanced age (>45), aggressive histology, increase volume of nodal disease, extranodal extension, multiple lymph node or lymph node outside the central neck. In this conundrum we should bear in mind that changes that downgrade the intensity in the treatment of oncologic patients are normally based on the results emerging from large tertiary academic hospitals (those which are most often published). However, these results may not accurately reflect real-life outcomes. In other words, broad recommendations are not always applicable to individual cases. Finally, any proposal for change in the practice of medicine must be considered in light of both its ethical aspects and the precautionary principle, the latter emphasizes caution, pausing and review before embracing innovations that may in time prove disastrous.

Extracellular vesicles as theranostic tools in metabolic and cardiovascular diseases

MTEBS1

Extracellular vesicles in cardiometabolic disorders: from waste product to reliable disease biomarkers

Maria Felice Brizzi
Department of Medical Sciences, University of Torino, Torino, Italy

Circulating extracellular vesicles (EVs) are nano-sized bilayer membrane particles mainly released by platelets, inflammatory, endothelial cells and cancer cells, which play a pivotal role in inter-cellular communication. EV cargo, which consists of RNAs, proteins, DNA, and lipids, reflects the cell of origin and its activation state and the microenvironment; for this reason, it can be used as source of potential biomarkers in several conditions related to tumour development/progression, inflammation, atherosclerosis, thrombosis, and endothelial dysfunction. Therefore, cardiometabolic diseases can advantage of EVs for diagnostic/prognostic (theranostic) purposes. Recent advances in -omics technologies combined with artificial intelligence approaches allow high-throughput analysis, with the possibility to generate a biomolecular signature featuring a specific pathophysiological condition. An increase of specific EV sub-populations may even anticipate the rise of conventional biomarkers which usually require cell death or tissue necrosis (i.e., the rise of hs-troponin after cardiomyocyte death in cardiac ischemic disease). A change in EV secretome is expected in suffering, but still alive cells, thus providing great advantage for early diagnosis. Data on the impact of EV for diagnostic and therapeutic purposes in cardiometabolic settings will be discussed.

The role of macrophages in the endocrine system

MTEBS3

Purinergic targeting of macrophages in obesity and diabetes

György Haskó
Department of Anesthesiology, Columbia University, New York City, New York, United States

The purinergic signaling complex comprising extracellular nucleotides and nucleosides, and their receptors, the P2 and P1 purinergic receptors, respectively, as well as catabolic enzymes and nucleoside transporters is a major regulatory system in the body. Macrophages are cells of the innate immune system that play myriad roles in the body. Macrophages are subject to regulation by the purinergic signaling complex. Macrophages are known to reside in endocrine glands and a body of evidence now suggests that these cells interact closely with endocrine cells and play important roles in both physiological and pathophysiological states. In the realm of inflammatory and auto-immune diseases, endocrine organs are known to be a frequent target, possibly due to the expression of a high density of major histocomptability complex (MHC)-II molecules on resident macrophages. This implicates a key role of macrophages in the pathogenesis of auto-immune endocrine diseases and making them attractive targets for pharmacotherapy. Here I summarize the diverse roles played by the purinergic signaling complex in regulating macrophages in the endocrine system and identify potential targets for pharmacotherapy in endocrine diseases.

Personalized therapy in acromegaly
MTE1

Personalized therapy in acromegaly
Maria Chiara Zatelli
Section of Endocrinology and Internal Medicine, Department of Medical Sciences, University of Ferrara, Ferrara, Italy

Personalized medicine aims at providing indications concerning the management of each patient according to her/his specific needs and disease characteristics. Acromegaly, although a rare disease, has a profound impact on patients' quality and expectancy of life, due to increased morbidity and mortality as compared to the general population in correlation mainly due to cardiovascular disease and cancer. Several clinical variables have been investigated as predictors of response to treatment (either surgical or medical) and as prognostic factors. Tumor diameter, invasiveness, genetic predisposition are recognized as the main predictors for surgical success. Adenoma granulation at electron microscopy, somatostatin receptor status, T2-intensity at MRI, age, and AIP mutation status have been indicated as predictive of response to treatment with somatostatin receptor ligands (SRLs). If resistance to SRL is foreseen, treatment with the growth hormone receptor antagonist pegvisomant or second-generation SRL pasireotide can be proposed, with the possibility of a combination therapy. In addition to tumor characteristics, a very important issue is represented by assessment of symptoms and of quality of life (QoL). Several quaestionnaires have been developed to specifically evaluate QoL in patients with acromegaly. The patient-assessed acromegaly symptom questionnaire consists of 5 acromegaly-related symptoms (soft-tissue swelling, arthralgia, headache, excessive perspiration, and fatigue) has not yet been clinically validated. The acromegaly quality of life questionnaire is used to assess the disease-specific physical and psychologic aspects. The acromegaly treatment satisfaction questionnaire is clinically validated to assess patient satisfaction with monthly injectable SRLs. Therefore, several items are available to clinicians to aid the best therapeutic managements of acromegaly and its complications on the basis of patient charcteristics, but also (and mainly) on the basis of patiet's choice and specific health issues.

MicroRNA in Bone OR MicroRNA in bone diagnostics and treatment looking into the future
MTE4

MicroRNA in bone diagnostics and treatment looking into the future
Matthias Hackl
TAmiRNA GmbH, Vienna, Austria

MicroRNAs (miRNAs) are non-coding RNAs that control the expression of 70% of the protein-coding genes. Since their discovery in the late 1990s, the function of miRNAs in the context of biological pathways that are essential to bone homeostasis has been investigated. This has expanded our understanding of the mechanisms underlying bone health and disease and led to the identification of novel drug and biomarker candidates. From a diagnostic viewpoint the seminal finding that miRNAs can be actively or passively released from cells into biofluids such as serum or urine ("circulating miRNAs"), motivated researchers to investigate circulating miRNAs in several pathologic conditions, including bone diseases. Thus, several exploratory studies in cohorts representing various types of bone diseases have been performed. In this meet-the-expert session, the important molecular basics of intracellular miRNA function and extracellular release will be discussed, including recommendations for best (pre-)analytical practices and documentation standards for circulating miRNA research. In the second part evidence from pre-clinical and clinical studies that have investigated the utility of microRNAs as biomarkers and drug targets in musculoskeletal disorders will be presented, with a specific focus on type-2 diabetic osteopathy.

What an endocrinologist should know about in vitro fertilization treatment and egg storage
MTE7

What an endocrinologist should know about in vitro fertilization treatment and egg storage
Sophie Catteau-Jonard
CHU Lille, University of Lille, INSERM U 7211, Lille, France

Achieving pregnancy through in vitro fertilization requires a minimum number of oocytes recovered during egg retrieval. These oocytes come from ovarian hyperstimulation that allows the entire oocyte cohort to mature. In physiology in a natural cycle, a dozen follicles are recruited at the beginning of the menstrual cycle under the action of the elevation of the FSH (the « FSH window »). Then, follicles secrete estradiol through aromatase under the action of FSH. By negative feedback, FSH levels decrease (the FSH window closes) and only the follicle most independent of FSH will continue to grow until ovulation: the dominant follicle. The other follicles of the cohort attenuate allowing mono-ovulation. On the contrary, it is very important in the process of in vitro fertilization to have a multifollicular development, in order to increase the chances of pregnancy. Indeed, there are still many stages before pregnancy: puncture and selection of oocytes, obtaining fertilization and then a quality embryo to be transferred. The goal of the treatment is therefore to continue the administration of FSH to avoid the closing of the window and thus allow the maturation of all the follicles of the cohort. The other very important aspect of stimulation treatment during IVF is to control the exact time of ovulation. GnRH agonists or antagonists are used but the use of simple progestins is also possible! Finally, the triggering of ovulation is achieved through the administration of either hCG (with an LH like action) or a GnRH agonist in cycles slowed down by GnRH antagonists. Completely artificial cycles are also possible to transfer devitrified embryos.

Management of panNENs in MEN1 and vHL

MTE8

Management of pancreatic neuroendocrine tumors in Multiple Endocrine Neoplasia Type 1 and the von Hippel Lindau syndrome

Gerlof Valk
Department of Endocrine Oncology, University Medical Center Utrecht, Utrecht, Netherlands

Multiple Endocrine Neoplasia Type 1 (MEN1) and the von Hippel Lindau syndrome (VHL) are hereditary disease with an autosomal dominant inheritance. Among a wide variety of manifestations, both syndromes predispose patients to pancreatic neuro-endocrine neoplasms (PanNENs). Screening for presymptomatic diagnosis of PanNENs enables timely intervention with the intention to prevent metastasized disease and premature death. MEN1 and VHL lead to different manifestations and there are also distinct differences in occurrence and clinical course of PanNEN. Therefore the management of PanNEN occurring in both syndromes is different with consequences for the required multidisciplinary team. For both tumor syndromes screening for PanNEN should be based on clinical orientation, including general planning of screening and surveillance, utility of biochemical biomarkers, the optimal choice for imaging modality, and risk stratification for individual patients. Recent research gives more insight into the main aspects of MEN1 and VHL-related pancreatic manifestations and their clinical management. For care tailored to the needs of the individual patient and improving outcomes on an individual basis, studies are now needed to define predictors of tumor behavior and effects of more individualized interventions. Patients with MEN1 and VHL are therefore preferably treated in centers with specific expertise and dedication to collaborative research.

How do we have to treat patients with CAH to avoid complications for under-and over-treatment?

MTE10

How do we have to treat patients with CAH to avoid complications for under- and over-treatment?

Richard J Auchus
University of Michigan, Ann Arbor, MI, United States

The management of adults with congenital adrenal hyperplasia due to classic 21-hydroxylase deficiency (21OHD) is a challenging balance of hormone replacement, disease control, and avoidance of adverse effects. The approach should emphasize the clinical evaluation and patient goals, and laboratory tests are used secondarily as ancillary data. Upon transition from pediatric to adult care, the concerns shift from growth and pubertal development to fertility, neoplasia formation, and long-term complications. Each visit requires a thorough physical exam to assess for cushingoid features such as skin thinning, bruising, muscle weakness, fat redistribution, and purple striae – much of this exam can be done via telemedicine. The most useful biomarkers to aid in glucocorticoid titration are androstenedione, the androstenedione/testosterone ratio in men, and follicular-phase progesterone in women attempting pregnancy. The major androgens in most 21OHD patients are the 11-oxygenated androgens, and these steroids appear to be useful analytes of disease control as well. Hydrocortisone remains the most effective glucocorticoid for cortisol replacement therapy. More potent synthetic glucocorticoids have narrower therapeutic indices and greater the risk of adverse effects than hydrocortisone. Attention to mineralocorticoid replacement is also important, and under-replacement is a common cause of chronic fatigue. Standing blood pressure, serum potassium, and plasma renin are used to titrate the fludrocortisone acetate dose in that order. Conceptually, the endocrinologist should distinguish doses used to replace the cortisol deficiency (first priority) and then additional doses to achieve adequate disease control. New treatments are under study to improve disease control while avoiding excessive glucocorticoid exposure.

Endocrine treatment in transgenders - when, who and how?

MTE11

Endocrine treatment in transgenders - when, who and how?

Matthias Auer
Medizinische Klinik and Poliklinik IV, Klinikum der Universität München, LMU München, Munich, Germany

Treatment of transgender patients has gained increasing importance in outpatient endocrinological care due to a steadily rising influx of patients in recent years. Many gaps in knowledge regarding hormonal therapy have been filled in recent years thanks to a growing body of literature based on larger cohort studies. Nowadays therapy can be regarded as safe and effective. While puberty arrest and peripubertal hormone treatment in transgender youth has gained growing acceptance in recent years, some questions still remain unsolved but will hopefully be answered in years to come, following the steadily growing knowledge and experience in this area. This talk summarizes the current knowledge on risks and benefits of endocrine treatment in transgender individuals and should open discussion based on patient cases on questions such as optimal treatment monitoring, the use of progestins/progesterone, fertility preservation, relevant comorbidities and ideal hormone treatment across the lifespan.

Diagnostic approach and clinical management of hypophosphatemia: Is it really an endocrine disorder?

MTE12

Diagnostic approach and clinical management of hypophosphatemia: Is it really an endocrine disorder?

Sabrina Corbetta
Endocrinology and Diabetology Service, Department of Biomedical, Surgical and Dentistry, University of Milan, IRCCS Istituto Ortopedico Galeazzi, Milan, Italy

Phosphorus is involved in energy storage, metabolism, nucleic acids, cell membrane function, cell signaling; it is a fundamental constituent of skeleton and teeth. Pi homeostasis is regulated mainly by three hormones, namely parathyroid hormone (PTH), vitamin D and Fibroblast Growth Factor 23 (FGF23). Additionally, sex hormones are known to decrease circulating Pi levels, by reducing renal tubular reabsorption through direct and indirect effects on renal phosphate channels and likely stimulating FGF23 release. Though some patients may complain of muscle weakness, mild hypophosphatemia (HP) is usually asymptomatic, and, consequently, often overlooked, so that its prevalence in the general population is not known. Indeed, HP is not a rare feature in patients with osteoporosis. On the other hand, severe and chronic HP causes muscle weakness, bone pain and deformity, fragility fractures (osteomalacia), rhabdomyolysis, impaired mental status, heart failure. Several mechanisms can be involved, and reduced Pi intestinal absorption, internal redistribution or urinary loss must be differentiated. Once urinary loss has been established, differential diagnosis includes FGF23-dependent conditions [renal transplantation, tumor induced osteomalacia (TIO), hereditary hypophosphatemic rickets] and FGF23-independent ones (primary and secondary hyperparathyroidism, renal tubular defects, diuretics, glucocorticoid therapy, hereditary hypophosphatemic rickets with hypercalciuria). Diagnostic workup is complex and often unrewarding, and the cause of chronic HP can remain unexplained in a number of patients. Finally, in patients affected with osteoporosis, HP may occur as an adverse effect of the anti-osteoporotic drugs (bisphosphonates, denosumab, teriparatide), though most studies show that HP is rare and generally self-limiting in this context. Indeed, a subset of osteoporotic patients developing chronic HP on anti-osteoporotic treatment can be observed in clinical practice, but frequency and implications of this condition are not known. Lastly, it should be considered that recently a specific anti-FGF23 treatment is available implying the need to correctly diagnose FGF23-related HP.

Clinical characteristics and outcomes in hospitalized COVID-19 patients with and without diabetes at Vilnius University Hospital Santaros Klinikos (VUHSK)

Zydrune Visockiene[1,2], Valentinas Jakubkevicius[1,2], Modesta Alekniene[1,2], Laura Šiauliene[1,2], Gerda Mekionyte[1] & Joana Scerbinkinaite[1,2]
[1]Vilnius University Faculty of Medicine, Clinic of Internal Diseases, Family Medicine and Oncology, Vilnius, Lithuania; [2]Vilnius University Hospital Santaros Klinikos, Center of Endocrinology, Vilnius, Lithuania

Background
Studies suggest that diabetes mellitus (DM) is associated with greater risk of developing severe forms of COVID-19 and mortality.
Aims
To compare clinical characteristics and outcomes in hospitalized COVID-19 patients with and without DM.
Methods
A single-center, retrospective, observational study included adult patients with laboratory-confirmed COVID-19 treated at VUHSK between 2020-01-01 and 2021-03-31. Patients were allocated to DM and non-DM grousp. The demographic, laboratory and outcomes data were compared. Disease severity was described as requirement of either high flow oxygen, intubation or inotropic support.
Results
A total of 2559 patients (median age 60 years, 1424 (55.6%) men) were included. Compared with the non-DM group ($n=2058$, 80.4%), patients with DM ($n=501$, 19.6%) were older, had more co-morbidities: hypertension, coronary artery disease, heart failure, dyslipidaemia, obesity, chronic kidney disease ($P<0.05$). Serum glucose, CRP, procalcitonin, D-dimer, creatinine and lactate were significantly higher ($P<0.05$), eGFR and LYM count - significantly lower ($P<0.05$) in the DM group compared to non-DM. Patients with DM were more likely to develop acute respiratory failure (31.3 vs 20.9%; OR 1.728, 95% CI 1.391-2.146), sepsis or septic shock (9.2 vs 6.3%, OR 1.512, CI 1.063-2.149) acute kidney failure (18.4 vs 11.6%, OR 1.712, CI 1.316-2.228), to require high flow oxygen or non-invasive ventilation (16.4 vs 9.3%, $P=0.000$), intubation (12.2 vs 8.1%, $P=0.004$), inotropic support (4.6 vs 2.5%, $P=0.014$), stayed longer at the hospital (median 11 vs 13 days, $P=0.000$), had higher prevalence of severe disease (23.0 vs 14.7%, OR 1.732, CI 1.361-2.205) and mortality rate compared to non-DM patients (19.6 vs 12.7%, OR 1.674, CI 1.296-2.163). After matching for age and gender, DM remained significant risk factor for developing respiratory failure (OR 1.533, CI 1.157-2.031) and severe disease (OR 1.569, CI 1.142-2.154), but not death (19.4 vs 15.4%, OR 1.322, CI 0.952-1.837; $P=0.095$).
Conclusions
Diabetes was prevalent in one fifth of patients hospitalized with COVID-19. It was associated with longer hospitalization, greater risk of severe COVID-19 disease and death. Further investigation of the relationship between COVID-19 severity and diabetes is warranted.

Keywords: coronavirus disease 2019 (COVID-19); diabetes; mortality; outcome.

Glucose control and mortality in critically Ill patients, based on real world evidence

George Dafoulas[1], Ilias Kalamaras[2], Konstantinos Votis[2] & Alexandra Bargiota[1]
[1]Faculty of Medicine, University of Thessaly, Department of Endocrinology and Metabolic Diseases, Larisa, Greece; [2]Centre for Research and Technology Hellas, Informatics and Telematics Institute, Thermi Thessaloniki, Greece

Objective
Published results of reduced morbidity and mortality with tight Glycemic Control of critical patients could not be reproduced in large prospective trials. Glycemic goals according to current respective guidelines include a target blood glucose range 140-180 mg/dl, while lower blood glucose targets may be appropriate for some patients. This study aims to provide real world evidence to this field.
Methods
We performed a retrospective study using the Medical Information Mart for Intensive Care Units (ICU) IV open access, anonymized database (MIMIC-IV) based on 15619 ICU admissions between 2008 and 2019 at Beth Israel Deaconess Medical Center, USA. Logistic regression was performed, using age, sex, SOFA, OASIS and proportion of time in glucose bands per ICU stay as predictors, and death in ICU as the target. Glucose bands and time proportions were defined as in Finney et al.[1] (hypoglycemic: blood glucose level <80 mg/dl, stringent: 80-110 mg/dl, normal: 111-144 mg/dl, intermediate: 145-180 mg/dl, liberal: 181-200 mg/dl, hyperglycemic: ≥ 201 mg/dl), where proportions were time-weighted to cope with variable measurement frequency. The study protocol was approved by the respective Institutional Review Boards.
Results

Table 1 Relationship between ICU mortality and proportion of time spent in each glucose band, controlling for age (<0.001)., gender, SOFA score (<0.001). and OASIS score (<0.001). Odds Ratios correspond to 1 unit increase

ICU type	Model	ICU mortality (OR)	CI (95%)	*P*-value
Cardio ($n=7758$)	hypoglycemic	**4.583**	(1.12, 18.69)	**0.034**
	stringent	**0.111**	(0.06, 0.19)	**<0.001**
	normal	**0.096**	(0.06, 0.16)	**<0.001**
	intermediate	**5.050**	(2.69, 9.48)	**<0.001**
	liberal	**254.094**	(73.46, 878.95)	**<0.001**
	hyperglycemic	**28.657**	(17.18, 47.8)	**<0.001**
Medical ($n=3463$)	hypoglycemic	2.431	(0.95, 6.19)	0.063
	stringent	**0.508**	(0.34, 0.75)	**<0.001**
	normal	0.937	(0.62, 1.41)	0.753
	intermediate	**1.707**	(1.01, 2.9)	**0.048**
	liberal	2.596	(0.92, 7.31)	0.071
	hyperglycemic	1.230	(0.82, 1.83)	0.311
Surgical ($n=4398$)	hypoglycemic	**5.366**	(1.85, 15.54)	**0.002**
	stringent	**0.364**	(0.24, 0.56)	**<0.001**
	normal	**0.578**	(0.39, 0.87)	**0.008**
	intermediate	**2.558**	(1.59, 4.12)	**<0.001**
	liberal	**4.276**	(1.57, 11.62)	**0.004**
	hyperglycemic	**2.318**	(1.36, 3.96)	**0.002**

Conclusion
Overall, increased time in the hypoglycemic, intermediate, liberal and hyperglycemic bands is related to increased ICU mortality, while increased time in the stringent and normal bands is related to decreased mortality. However, in medical ICUs, these results are not statistically significant with the available data, e.g. the OR for the "normal" band being around 1.

Background
Patients with type 2 diabetes and overweight have a chronic activation of the innate immune system possibly explaining the increased risk of a hyperinflammatory response and severe COVID-19. We aimed to test whether blockade of interleukin-1β(IL-1β) using canakinumab improves clinical outcome.
Methods
CanCovDia was a multicenter, randomised, double-blind, placebo-controlled trial to assess the efficacy of canakinumab plus standard-of-care compared with placebo plus standard-of-care in patients with type 2 diabetes and a BMI $>$ 25 kg/m^2 hospitalised with SARS-CoV2 infection. Patients were randomly assigned 1:1 to a single dose of canakinumab (body weight-adapted dose of 450-750 mg) or placebo intravenously. Canakinumab and placebo were compared on the basis of an unmatched win-ratio approach consisting of length of survival, ventilation, ICU stay and hospitalization. This study is registered with ClinicalTrials.gov, NCT04510493.
Findings
Between October 23, 2020, and May 12, 2021, 116 patients were randomly assigned with 58 in each group. The win-ratio analysis between canakinumab vs placebo was 1·08 (95% CI 0·69-1·69; $P=0·72$). After four weeks, in the canakinumab group 4 people died (7·0%), 12 were hospitalized for more than 3 weeks (23·5%), and 11 were on ICU (20·0%), vs 7 (12·3%), 16 (28·3%) and 11 patients (21·6%) respectively. Median ventilation time at 29 days was 10 days [IQR 6.0, 16.5] in the canakinumab group and 16 days [IQR 14.0, 23.0] in the placebo group. Glycated haemoglobin A1c (HbA1c) in the canakinumab group after four weeks was 7·40 [6·65, 8·30] vs 7·50 in the placebo group ([6·68, 8·33] $P=0·955$) despite a lower number of antidiabetics administered in patients treated with canakinumab vs placebo (OR 0·47 [95% CI 0·23-0·95] $P=0·03$). Median ratio to baseline of endogenous Insulin (pmol/l) at four weeks was 0.94 [0.59, 1.66] in the canakinumab group vs placebo 0.64 [0.29, 1.44] (OR 2.21 [1.09, 4.48] ($P=0.029$). Serious adverse events were reported in 13 (11·4%) patients in each group treated with canakinumab and placebo, respectively.
Interpretation
In patients with type 2 diabetes who were hospitalised with COVID-19, treatment with canakinumab in addition to standard-of-care did not result in a significant improvement of the primary composite outcome despite a numerical benefit in survival, ICU and ventilation time. Patients treated with canakinumab required significant less antidiabetic drugs to achieve similar glycaemic control, possibly due to increased insulin production.

β-Caryophyllene, a dietary CB2 receptor selective cannabinoid mitigates myocardial fibrosis in a mice model of diabetic cardiomyopathy

Hebaallah Mamdouh Hashiesh[1], Azimullah Sheikh[1], MF Nagoor Meeran[1], Ahmed Al Kaabi[1], Bassem Sadek[1], Ernest Adeghate[2] & Shreesh Kumar Ojha[1]
[1]UAE University, Pharmacology and Therapeutics, Al Ain, United Arab Emirates; [2]UAE University, Anatomy, Al Ain, United Arab Emirates

β-Caryophyllene, a dietary CB2 receptor selective cannabinoid mitigates myocardial fibrosis in a mice model of diabetic cardiomyopathy
Background and aim
Diabetic cardiomyopathy (DCM), a cardiac complication in diabetes is characterized by abnormal cardiac function accompanied with myocardial fibrosis. In recent years, the cannabinoid type 2 receptors (CB2) emerged as a crucial therapeutic target for diabetes and its complications. The downregulation of CB2 receptors has been documented in various cardiovascular diseases and diabetes, that supports the concepts that activation of CB2 receptors may protect against diabetic cardiomyopathy. The present study was designed to investigate the effect of a selective CB2 receptor agonist β-Caryophyllene (BCP), a dietary natural cannabinoid compound and chemically a bicyclic sesquiterpene on myocardial fibrosis in DCM mice.
Methods
Experimental DCM was developed in Male C57/B6 mice by feeding a high-fat diet for 4 weeks followed by a low dose of streptozotocin (100 mg/kg) injection. Both DCM and control mice were then treated with or without BCP (50 mg/kg, orally) for 12 weeks by continuous feeding of a high fat or normal diet. At the end of this period, hemodynamic parameters (systolic blood pressure, diastolic blood pressure, mean arterial pressure, heart rate), and heart weight/body weight were evaluated, fasting blood glucose, oral glucose tolerance test, insulin level, lipid parameters (triglyceride, total cholesterol, low-density lipoprotein, very-low-density lipoprotein, high-density lipoprotein), and lactate dehydrogenase in serum were detected. Hematoxylin-eosin and picrosirius red were employed to determine heart morphological changes and cardiac fibrosis, respectively. Immunohistochemistry of collagen I and III and western blotting were taken to determine the expression levels of cardiac-fibrosis markers (TGF-β, SMAD, α-SMA).
Results
DCM mice exhibited hyperglycemia, insulin resistance, hyperlipidemia, hemodynamic abnormalities, significantly increased serum lactate dehydrogenase along with increased myocardial fibrosis, and hypertrophy. Oral administration of BCP significantly decreased the levels of blood glucose, serum lipids, while increased serum insulin level with improving the insulin resistance. Additionally, the myocardial enzyme (lactate dehydrogenase) was significantly decreased. Furthermore, BCP significantly improved hemodynamic changes and attenuated the abnormal morphologic change in DCM hearts. Moreover, BCP treatment decreased the expression of TGF-β, SMAD, α-SMA and reduced collagen deposition in the heart of DCM mice. Most importantly, pre-administration of the CB2 receptor antagonist AM630, abrogated the protective effects of BCP in DCM mice.
Conclusion
These results suggest that activation of CB2 receptors by BCP alleviated diabetic cardiomyopathy by attenuating hyperglycemia/hyperlipidemia-induced cardiac fibrosis and remodeling via TGF-β/SMAD signaling pathway.

Background
Increased alcohol intake is associated with several health disorders. However, its impact on body composition is still controversial and data regarding this subject in people with type 1 diabetes (T1D) are limited. We have shown that central obesity is associated with diabetes complications in T1D, and now, we investigated whether the alcohol consumption is associated with body fat distribution in adults with T1D from the Finnish Diabetic Nephropathy (FinnDiane) Study cohort.
Methods
We included 548 individuals that had their body composition assessed by dual-energy-X-Ray absorptiometry and had answered the questionnaires regarding alcohol consumption during the FinnDiane visits. The amount of alcohol was converted into standard doses (1 dose = 12 g of pure alcohol). Then, participants were divided into groups based on their alcohol consumption (dose/week) and the risk of health problems: abstainers, low risk (0.1-6.9 doses for women, 0.1-13.9 for men), moderate risk (7-15.9 for women, 14-23.9 for men) and high risk ($\geq$16 for women, $\geq$24 for men). Percentages of body fat refers to total body weight. Central obesity was defined as having $\geq$0.7% of visceral fat for women and $\geq$1.1% for men, while general obesity was $\geq$40.4% of total body fat for women and $\geq$31.8% for men. Logistic regression models adjusted for confounders were used to study the associations between alcohol consumption, central and general obesity. Similar analysis was done using the groups of alcohol, considering abstainers as the reference group.
Results
From 548 individuals, 30% had general obesity and 47% central obesity. Median age was 42 (IQR 34-53) years, duration of diabetes was 25.4 (19.6-37.5) years and 40% were men. The high risk group had the highest visceral fat percentage [2.19 (0.93-2.48), $P=0.002$] and the lowest arms and legs fat percentage [12.2 (10.1-15.1), $P=0.04$]. Total body fat percentage did not differ between groups. Each dose increase of alcohol consumption increased the odds of central obesity [OR 1.03, $P=0.03$]. The high risk group was associated with increased odds of central obesity [OR 6.8, $P=0.004$] and general obesity [OR 5.1, $P=0.008$]. Low and moderate risk groups were not.

Conclusion
In adults with type 1 diabetes, each dose increase of alcohol consumption increases the odds of central obesity by 3%. A high risk consumption of alcohol is associated with both central and general obesity. Our results motivate further longitudinal studies to explore the relationship between alcohol consumption and body fat distribution, as well as its impact on diabetes complications.

DLK1 expressing cells mark a population of progenitor cells in the adrenal cortex and contribute to the zonation of the adrenal gland

Katia Mariniello, Leonardo Guasti & Emanuel Rognoni
William Harvey Research Institute, Queen Mary University, Centre for Endocrinology, London, United Kingdom

The adrenal cortex is a dynamic organ that undergoes self-renewal. In the mouse it is divided into two concentric layers, the outer zona glomerulosa (ZG) and the inner zona fasciculata (ZF), that secrete aldosterone and corticosterone, respectively. Capsular and subcapsular stem/progenitor cells differentiate and migrate in a centripetal fashion to repopulate the gland until they reach the juxtamedullary region where they undergo senescence and apoptosis. Cell fate mapping studies have shown that the maintenance of the cortex relies on a pool of two interconnected cell populations, subcapsular undifferentiated cells secreting the morphogen Sonic Hedgehog (Shh) and capsular Gli1$^+$ cells, which can transduce the Shh signal. Our lab has shown that Delta like non-canonical Notch ligand 1 (Dlk1) is expressed in partially undifferentiated cells of the subcapsular region in rat and human adrenals, whilst it is mostly expressed in capsular cells in mice. Our recent lineage tracing analyses used a tamoxifen inducible Dlk1^{CreERT2} mouse model carrying the R26tdTom reporter. Injection of pregnant dames at embryonic day (e) 12.5 and analysis of tdTomato expression at postnatal day (p) 10 and p38 showed that 35% (p10) and 24% (p38) of Steroidogenic Factor 1(Sf1)+ cortical cells were tdTomato+. On the other hand, postnatal tamoxifen injections showed tdTomato+/Sf1+ cells only in 1-2% in cortical cells. This data indicates that capsular Dlk1 marks a population of adrenocortical progenitor cells, that are mostly active during embryonic development and near-dormant postnatally. However, postnatal Dlk1+ cells could be reactivated and contribute to the regeneration of the ZF after dexamethasone-induced atrophy. Mice were administered tamoxifen followed by 7 days of dexamethasone which resulted in ZF atrophy. Two weeks after removal of dexamethasone, regrowth of the ZF occurred and tdTomato+ cells were visible in the cortex suggesting that near-dormant capsular Dlk1+ cells are re-activated during ZF regeneration to become steroidogenic cells. Taken together, our results provide evidence for a role of DLK1+ cells as contributors to the development and zonation of the adrenal cortex.

Loss of SUMO-specific protease 2 leads to adrenal insufficiency limited to glucocorticoids

Damien Dufour[1], Typhanie Dumontet[2], Isabelle Sahut-Barnola[1], Meline Onzon[1], Eric Pussard[3], James Wilmouth Jr[1], Julie Olabe[1], Adrien Levasseur[1], Guillaume Bossis[4], Edward Yeh[5], Pierre Val[1], Antoine Martinez[1] & Lefrançois-Martinez Anne-Marie[1]
[1]CRBC (Centre de Recherche Bio Clinique), GReD, Clermont-Ferrand, France; [2]Rogel Cancer Center, Ann Arbor, United States; [3]Bicetre Hospital, Le Kremlin-Bicêtre, France; [4]Institute of Molecular Genetics of Montpellier, Montpellier, France; [5]University of Missouri, Columbia, United States

The adrenal gland produces corticosteroids essential for hydromineral and metabolic homeostasis. It is organised, in mice, in two concentric layers. The zona glomerulosa (zG) and fasciculate (zF), renewed from progenitors located in the capsular periphery. Centripetal renewal and maintenance of cortical zonation are dependant of a balance between WNT/β-catenin and ACTH/PKA signalling pathways. They provide recruitment and consecutive differentiation of progenitors into zG and zF. SUMOylation is a reversible post-translational modification mandatory for embryonic development. It consists of the serial reactions of activation, conjugation and ligation that will enables SUMOylation of a specific target protein. The presence of deSUMOylases mainly represented by SENPs makes SUMOylation particularly dynamic. In the adrenal cortex, it follows a centripetal decreasing gradient whose function is unknown. Moreover, chronic and acute PKA signalling stimulation leads to a decrease in SUMOyaltion in the adrenal cortex. In order to study the impact of hyperSUMOylation in the adrenal differentiation, we have chosen to delete the deSUMOylase SENP2 since it is positively regulated by ACTH/PKA signalling. Hence, we developed a model of *Senp2* deficiency targeting specifically the adrenal cortex thanks to cre/loxP technology. *Senp2* loss induces, as soon as 4 weeks of age, a glucocorticoids deficiency caused by zF hypoplasia without any defect in zG physiology. Even though, mice manage to normalise glucocorticoid levels throughout time, they still fail to respond properly to ACTH stimulation. We demonstrate, by biochemical and genetic experiments, that this lack of response was neither due to signalling upstream of PKA nor downstream, pointing toward a direct change in intrinsic PKA catalytic activity. The hypoplasia is associated with a stimulation of apoptosis at the zG/zF boundary. We show that this apoptosis was linked to a lack of PKA dependant phosphorylation of DRP1, whose phosphorylation state can induce either apoptosis or steroidogenesis. Finally, β-catenin, which is supposed to be limited to zG cell membrane, is found in the zF nuclei in *Senp2* mutant adrenals. Moreover, this is associated with an increase in SUMOylation of β-catenin and mild activation of the WNT signalling pathway. In conclusion, we show that HyperSUMOylation affects zF homeostatic renewal by altering the balance between ACTH/PKA and WNT/β-catenin signalling pathways and by stimulating early apoptosis of the zF cells. SUMOylation is a central mechanism of adaptive cellular responses to stress. Our results suggest that it is a fundamental pathway in the processes of functional maintenance of the adrenal cortex.

Context
Primary bilateral macronodular adrenal hyperplasia (PBMAH) with glucose-dependent insulinotropic polypeptide (GIP)-dependent Cushing's syndrome is caused by ectopic expression of GIP receptor in the adrenal tissue. The bilateral nature of this adrenal disease suggests germline genetic predisposition. We aimed to identify the molecular driver event responsible for ectopic GIP receptor expression in PBMAH.
Methods
We conducted an international, multicenter, retrospective, cohort study to collect blood and adrenal samples from patients who had undergone unilateral or bilateral adrenalectomy for familial or sporadic GIP-dependent PBMAH with Cushing's syndrome. We performed sequencing and copy-number analyses of blood and adrenal DNA. Adrenal samples from patients with PBMAH and Cushing's syndrome without food-dependent cortisol production were used as controls. RNA-sequencing on adrenal samples was performed to study gene expression in GIP-dependent Cushing's syndrome and in control samples. Functional *in vitro* studies were performed to study the impact of the genetic event identified in human adrenocortical H295R cells.
Results
17 patients with familial or sporadic GIP-dependent PBMAH with Cushing's syndrome were studied. We identified germline heterozygous pathogenic or likely pathogenic variants in the lysine demethylase 1A (*KDM1A*, or *LSD1*) gene in all 17 patients. We further identified a recurrent deletion of the short arm of chromosome 1 harboring the *KDM1A* locus in the adrenal lesions of affected patients. None of the 25 patients in the control group had *KDM1A* germline or somatic alterations. Concomitant genetic inactivation of both *KDM1A* alleles resulted in loss of *KDM1A* expression in the adrenal lesions. Transcriptome analysis of adrenals from affected patients revealed the global effect of KDM1A loss in adrenal tissue on gene transcription and identified differentially regulated genes, including those encoding for GIP receptor and some other G protein-coupled receptors involved in adrenal tumorigenesis and regulation of steroidogenesis. *In vitro* pharmacologic inhibition, silencing and knock-out by CRISPR-Cas9 genome editing of *KDM1A* led to an increase in GIP receptor transcripts and protein in H295R cells.
Discussion
We found that familial and sporadic GIP-dependent PBMAH is a genetic disease caused in 100% of cases studied by germline inactivating pathogenic variants of the *KDM1A* gene with a loss of heterozygosity of the second *KDM1A* locus in the adrenal lesions. This stepwise inactivation of KDM1A is suggestive of a tumor suppressor gene model of tumorigenesis. Uncovering of a common genetic mechanism of GIP-dependent PBMAH will enable genetic testing and counselling of affected patients and earlier detection of the disease in their relatives.

Context
Autonomous cortisol secretion (ACS) has been associated with a higher prevalence of osteoporosis and fragility fractures in several studies. However, the data rely on heterogeneous studies and criteria for osteoporosis screening in this population are still debated.
Objective
To assess the prevalence of fragility fractures and contributing factors in a large cohort of patients with adrenal incidentalomas.
Methods
We reviewed medical records of 1023 patients with adrenal incidentalomas from 1990 to 2019. Of these, 756 patients were selected after exclusion of confounders such as concomitant diseases or treatments, or missing data. Clinically-obtained electronic radiological images closest to the date of clinical evaluation, such as lateral views of spine X-rays or CT thoraco-abdominal scans, were reviewed by two experts blinded to clinical data to screen for asymptomatic morphometric vertebral fractures. Clinical fragility fractures were also recorded. 491 patients had non-secreting (NS) adrenal incidentalomas, 240 had ACS and 25 Cushing Syndrome (CS). Diagnosis of NS and ACS was based on cortisol after 1-mg dexamethasone suppression test (1 mgDST) (<50 and >50 nmol/l, respectively). Biochemical parameters of bone metabolism and hormonal data were recorded.
Results
ACS were older than NS patients (65.5 vs 60.5 years, $P<0.001$). Prevalence of fragility fractures was different ($P=0.021$) between groups, respectively 18.9% (NS), 27.1% (ACS) and 32% (CS), with significant difference between NS and ACS ($P=0.012$). When analyzed separately by sex and menopausal status, this difference remained significant in post-menopausal women ($P=0.003$), with a prevalence of 16.7% (NS), 28.2% (ACS) and 50% (CS). By contrast, prevalence of fractures was similar in males, even when analysis was adjusted for low testosterone levels (<3 ng/ml). Women with ACS aged ≥ 65 years reported a 40% prevalence of fragility fractures, as compared with 23.6% in NS ($P=0.016$). In younger women and in males with cut-off age set at 65 years, prevalence of fractures was similar between groups. Following logistic regression analysis including biochemistries and clinical data of the overall population, fragility fractures were predicted independently by age (OR = 1.04, $P<0.001$) and post-1 mgDST cortisol (OR = 2.07, $P=0.001$). After sex and menopausal status sub-analysis, an independent contributory effect from age (OR = 1.07, $P<0.001$) and 1 mgDST (OR = 4.49, $P=0.001$) remained significant only in post-menopausal women.
Conclusions
Post-menopausal women aged 65 or older with adrenal incidentalomas and ACS showed higher risk of fragility fractures than NS, with ACS likely playing an independent major pathogenetic role.

Elevated serum free cortisol is a strong predictor of mortality in hospitalized patients with Covid-19 irrespective of dexamethasone treatment

Karina Rozenfeld[1], Elena Izkhakov[2,3], Miguel Moshiashvili[2], Howard Oster[1], Karen Tordjman[2,3], Gabi Shefer[2] & Yona Greenman[2,3]
[1]Tel Aviv-Sourasky Medical Center, Internal Medicine Department A, Tel Aviv, Israel; [2]Tel Aviv-Sourasky Medical Center, Institute of Endocrinology and Metabolism, Tel Aviv, Israel; [3]Tel Aviv University, Sackler Faculty of Medicine, Medicine, Tel Aviv, Israel

Serum total cortisol has been linked to increased mortality in patients with Covid-19, but its reliability in critically ill patients is limited. We examined the association between serum free cortisol (SFC) levels and clinical outcomes in patients hospitalized with Covid-19 between 5/5/2020 and 1/3/2021 in our institution.
Methods
SFC was measured in blood samples collected at patient's admission, prior to any medical treatment. Patients' files were reviewed retrospectively.
Results
There were 241 patients (78% female), mean (SD) age 67.4 (18.5), of whom 47.3% received dexamethasone treatment (DT). According to the NIH severity index, 46.9% had asymptomatic or mild disease, 17.4% moderate, and 35.7% had severe or critical disease. The in-hospital mortality, 30-day mortality and the need for assisted ventilation were 8.7%, 14.9% and 18.3% respectively. SFC levels were higher in patients who died in hospital [3.74 (2.8) vs 1.4 (0.85) µg/dl, $P<0.0001$), or within 30 days [3.01 (2.3) vs 1.32 (0.77) µg/dl, $P<0.0001$] or who required assisted ventilation [2.77 (2.4) vs 1.4 (0.8) µg/dl, $P<0.0001$]. SFC levels were significantly higher in patients with diabetes, hypertension, cardiovascular disease and chronic renal failure. There was a positive correlation between SFC and IL-6, CRP, ferritin, LDH, D-dimers, neutrophil/lymphocyte ratio (NLR) and a negative correlation with GFR and oxygen saturation at admission ($P<0.0001$ for all pair comparisons). The area under the ROC curve (AUC) to discriminate 30-day mortality was significantly higher for SFC (0.837) compared with IL-6 (0.733, $P=0.012$), CRP (0.634, $P<0.0001$), ferritin (0.618, $P<0.0001$), LDH (0.667, p-0.001) and NLR (0.759, $P=0.039$). The AUC to discriminate in-hospital mortality for SFC (0.837) was similar to IL-6 (0.811), LDH (0.790) and ferritin (0.716), but higher than CRP (0.665, $P=0.004$) and NLR (0.715, $P=0.008$). The SFC AUC for the need for assisted ventilation was 0.723, not significantly different from the other parameters. Among patients who received

DT, 71.1% had severe or critical disease, 17.5% had moderate and 11.4% had mild disease. SFC levels were higher [1.88 (1.5) μg/dl] in patients who received dexamethasone compared with those that did not [1.36 (1) μg/dl, $P<0.0001$]. Within treated patients, SFC levels were higher in those who died in hospital (3.58 (2.8) vs 1.56 (0.9) μg/dl, $P< 0.0001$] or within 30 days [3.1(2.6) vs 1.56 (0.9) μg/dl, $P<0.0001$], compared with those that survived.
Conclusions
SFC levels strongly predict in hospital and 30-day mortality as well as the need for ventilation support in hospitalized patients with Covid-19, irrespective of DT.

Activity of abiraterone acetate in the management of cushing syndrome associated to advanced adrenocortical carcinoma: results of the ABACUS trial

Soraya Puglisi[1], Deborah Cosentini[2], Salvatore Grisanti[2], Vittoria Basile[1], Marta Laganà[2], VittorioDomenico Ferarri[2], Andrea Abate[3], Anna Calabrese[1], Elisa Rossini[3], Paola Perotti[1], Laura Saba[1], Anna Pia[1], Sandra Sigala[3], Alfredo Berruti[2] & Massimo Terzolo[1]
[1]Internal Medicine, Department of Clinical and Biological Sciences, San Luigi Hospital, University of Turin, Orbassano, Italy; [2]Medical Oncology, Department of Medical and Surgical Specialties, Radiological Sciences, and Public Health, Spedali Civili Hospital, University of Brescia, Brescia, Italy; [3]Section of Pharmacology, Department of Molecular and Translational Medicine, University of Brescia, Brescia, Italy

Background
More than 50% of adrenocortical carcinomas (ACC) in adults are associated with cortisol excess that makes tumor management challenging and has a negative impact on patient outcome. Abiraterone acetate (AA) is an irreversible inhibitor of the 17α-hydroxylase/C17, 20-lyase (CYP17 enzyme) that is used in patients with prostate cancer, in whom it leads to suppression of cortisol and androgens. The aim of this study was to assess the activity of AA to control cortisol excess in patients with advanced ACC and overt Cushing syndrome.
Methods
We designed the phase II trial ABACUS (NCT 03145285) whose primary endpoint was normalization of 24-h urinary free cortisol (UFC) excretion within 1 month from treatment start. Inclusion criteria were histologically proven ACC, locally advanced or metastatic disease, and Cushing syndrome confirmed by two 24-h UFC >1.5 times the upper normal limit with suppressed ACTH. No concomitant treatment with mitotane or chemotherapy was allowed for the first 4 weeks of the study. AA was given orally at the daily dose of 1000 mg. Data are expressed as median and interquartile range.
Results
From 2017 to 2019, we included 17 patients with ACC (2 stage III, 15 stage IV), 13 women (76%), aged 51 years (18-76), of whom 8 have been heavily pretreated and 9 were treatment naïve. In 8 patients, multiple steroid secretion was found. Patients were treated with AA for 17 days (7-163). Median 24-h UFC was 368 μg/24 h (121-7422) at baseline and 94 μg/24 h (20-1793) at end of treatment ($P=0.01$). Normalization of 24-h UFC was attained in 8 patients (53%) and a > 50% decrement in 11 patients (73%). The median time to effect was 21 days and median 24-h UFC reduction 81.8% (-97.7 - +25.9). Androgen and precursor steroids were also significantly reduced by AA treatment. Cushing Syndrome Score and blood pressure significantly decreased during treatment. In 2 patients, treatment was discontinued for toxicity. Seven patients died of ACC progression during follow-up with an overall survival of 5.4 months (0.5-39.3).
Conclusions
AA was able to control rapidly cortisol excess in most patients with a good safety profile. The results of this proof-of-concept study show that AA looks promising and may be viewed as an additional weapon to manage Cushing syndrome in patients with ACC. These findings pose the basis for power calculation and implementation of a prospective long-term study to establish AA efficacy in patients with a steroid-secreting ACC.

Real world prospective application of ATA guidelines in over 500 aspirated thyroid nodules: Is it time for changing the size cut-offs for FNA?

Stamatina Ioakim[1], George Zavros[2], Michalis Picolos[3], Akheel Syed[4,5] & Angelos Kyriacou[2,4,6]
[1]Medical School, University of Milan, Milan, Italy; [2]CEDM, Centre of Endocrinology, Diabetes & Metabolism, Limassol, Cyprus; [3]Alithias Endocrinology Centre, Nicosia, Cyprus; [4]Department of Diabetes, Endocrinology & Obesity Medicine, Salford Royal NHS Foundation & University Teaching Trust, Salford, United Kingdom; [5]Division of Diabetes, Endocrinology & Gastroenterology, Faculty of Biology, Medicine and Health, The University of Manchester, Manchester, United Kingdom; [6]Medical School, European University of Cyprus, Nicosia, Cyprus

Introduction
The 2015 American Thyroid Association (ATA) guidelines on the management of thyroid nodules and cancer recommend specific size cut-offs for fine needle aspiration (FNA) cytology. We assessed the correlation between sonographic and cytological stratification as per the guidelines, with emphasis on the size cut-offs.
Methods
In a 'real world' prospective study, we sonographically stratified 562 thyroid nodules prior to performing ultrasound-guided FNA as cysts (1.4%), very low (3.9%), low (54.8%), intermediate (19.9%), or high (19.9%) risk. Their Bethesda cytological classification was B1, B2, B3, B4, B5 and B6 in 3.6%, 77.9%, 3.9%, 5%, 2.8% and 6.8% of nodules, respectively. Strong sonographic-cytological correlation was observed ($P<0.0001$); for example, B2 (benign) cytology was reported in 100% of very low, 91.2% of low, 81.3% of intermediate and 32% of high risk nodules. Excluding B1 (non-diagnostic) results and nodules without size data, the diagnostic performance of ATA-proposed cut-offs for FNA based on sonographic appearance was compared to higher cut-offs. Increasing the size-threshold for sonographically low and intermediate risk thyroid nodules would spare FNAs at the expense of missing a small proportion of B3–B6 cytological nodules and differentiated thyroid carcinomas (DTCs). The size cut-offs are compared against the cytological result of B2 ('negative outcome') or B3–B6 ('positive outcome'). †Relative to number of available histopathology results. PPV, positive predictive value. NPV, negative predictive value.
Discussion
By increasing the size cut-off for low-risk nodules, the NPV value retains its excellent performance, whereas PPV remains unaffected with poor performance. By using a higher cut-off in intermediate-risk nodules, NPV and PPV performance remain unchanged. In high-risk nodules, both NPV and PPV perform poorly regardless of the size cut-off. The 20 mm and 40 mm cut-offs may have greater clinical significance in case of carcinoma, as they correspond to higher tumour grades (≥T2 and ≥T3), altering the clinical management.
Conclusion
Our results suggest that increasing the ATA size cut-off from 15 mm to 20 mm in sonographically low-risk nodules is clinically safe whilst reducing FNAs.

Sklodowska-Curie National Research Institute of Oncology, Gliwie Branch, Poland; [7]National Taiwan University Hospital, Department of Oncology, Taiwan; [8]The National Cancer Institute, Rio de Janeiro, Mexico; [9]University of São Paulo, Department of Endocrinology, Instituto do Câncer do Estado de São Paulo, , Brazil; [10]National Institute of Oncology, Department of Medical Oncology and Clinical Pharmacology "B," , Budapest, Hungary; [11]University of Colorado Anschutz Medical Campus, Division of Medical Oncology, Department of Medicine, Aurora, United States; [12]Exelixis Inc, Alameda, California, United States; [13]Seoul National University Hospital , Seoul, Rep. of South Korea; [14]VHIO Vall d'Hebron Institut d'Oncologia, Barcelona, Spain

Background
At a preplanned interim analysis (median follow-up 6.2 months) of the double-blind, phase 3 COSMIC-311 trial (NCT03690388), cabozantinib significantly improved progression-free survival (PFS) vs placebo (HR 0.22, 96% CI 0.13-0.36; $P<0.0001$) in 187 patients with previously treated radioiodine-refractory DTC (Brose, Lancet Oncol; 2021). Patients must have received lenvatinib or sorafenib and progressed during or after 1-2 prior VEGFR inhibitors. We present the final analysis with an extended datacut of all randomized patients (ITT population) and for prespecified subgroups who received prior lenvatinib, sorafenib, or both.
Methods
Patients were randomized 2:1 to cabozantinib (60 mg QD) or placebo. Placebo patients could cross over to open-label cabozantinib upon disease progression per blinded independent radiology committee (BIRC). PFS (ITT) and objective response rate (ORR, first 100 randomized patients) per RECIST v1.1 by BIRC were the primary endpoints.
Results
At final analysis 258 patients (170 cabozantinib, 88 placebo) were randomized at data cut (8 Feb 2021); 96 had received prior sorafenib/no lenvatinib, 102 prior lenvatinib/no sorafenib, and 60 prior sorafenib and lenvatinib. Median follow-up was 10.1 months. Forty patients crossed over to receive cabozantinib. Median PFS was 11 months for cabozantinib vs 1.9 months for placebo in the ITT population (HR = 0.22, 95% CI 0.15-0.31; $P<0.0001$). For subgroups, median PFS was 16.6 vs 3.2 months for prior sorafenib/no lenvatinib (HR = 0.13, 95% CI 0.06-0.26); 5.8 vs 1.9 months for prior lenvatinib/no sorafenib (HR = 0.28, 95% CI 0.17-0.48), and 7.6 vs 1.9 months for prior sorafenib and lenvatinib (HR = 0.27, 95% CI 0.13-0.54). In the ITT population, ORR was 11% for cabozantinib vs 0% for placebo & overall survival HR = 0.76 (95% CI 0.45-1.31). Grade 3/4 treatment emergent adverse events (TEAEs) were 62% in the cabozantinib arm vs 28% in placebo with no treatment-related grade 5 events; 67% vs 5% required dose reductions due to TEAEs; 8.8% vs 0% discontinued treatment due to TEAEs not causally related to disease.
Conclusion
In the final analysis of COSMIC-311 with longer follow-up, cabozantinib maintained its superior efficacy versus placebo. The PFS-HR was consistent with the interim analysis, in patients with previously treated radioiodine-refractory DTC irrespective of prior treatment, with no unexpected toxicities.

OC3.3

Adata-driven approach reveals emerging risk factors for recurrent and persistent differentiated thyroid cancer

Michele Gentili, Giorgio Grani & Federico Siciliano
on behalf of Italian Thyroid Cancer Observatory, Italy

Background
The appropriate risk stratification of patients with differentiated thyroid cancer (DTC) is crucial because most cases have an indolent behavior and need a conservative approach. One of the most widely used tools is included in the American Thyroid Association (ATA) Guidelines, based on heterogeneous literature data derived by different populations, settings, and timeframes. Recent research focused on the inclusion of other features or questioned the clinical relevance of some of the included ones. In this prospective cohort study, we analyzed data of DTCs managed in 40 Italian clinical centers. The aims were to develop comprehensive, data-driven prediction models, able to capture all available features and to determine the weight of the potential predictors.
Methods
The Italian Thyroid Cancer Observatory (ITCO) web-based database (NCT04031339) now includes prospectively collected data of 10000 patients with histologically confirmed thyroid cancer. Each record contains information on patient demographics and biometrics, circumstances of the diagnosis, tumor pathology, treatments, and periodic follow-up examinations. We selected consecutive cases with DTC ($n=4773$) and at least early follow-up data. We built a decision tree, a relatively simple prediction model, to assign a risk index to each patient. The model allows to investigate the impact of different variables in the prediction of the risk level.Results. 2492 patients (52.2%) are classified as low, 1873 (39.2%) as intermediate, and 408 as high risk, according to the ATA risk estimation. Their response to treatment during their whole follow-up is excellent response in 2188 (45.8%), indeterminate in 1957 (41%), biochemical incomplete response in 250 (5.2%), and structural incomplete response in 378 (7.9%). The decision-tree model outperformed the ATA risk stratification system: the sensitivity of high-risk classification for structural disease increased from 37% to 49%, and the negative predictive value for low-risk patients also slightly increased by 3%), even without including information derived from radioiodine treatment (performed only in a subgroup of patients). The feature importance was estimated: several variables not included in the ATA system significantly impact the prediction of disease persistence/recurrence: age at diagnosis, gender, body-mass index, cytology, family history of thyroid cancer, surgical approach, pre-surgical cytology, and circumstances of the diagnosis.
Conclusions
The current risk stratification systems may be complemented by the inclusion of other demographic, clinical and anthropometric data, to improve the prediction of response to treatment. The use of a complete set of variables allows for a more precise clustering of patients, to predict their responses to treatment.

Sklodowska-Curie National Research Institute of Oncology , Gliwie Branch, Gliwice, Poland; [5]National Taiwan University Hospital, Department of Oncology, Taiwan; [6]National Institute of Cancer, Brazil; [7]Instituto do Câncer do Estado de São Paulo, Department of Endocrinology, Brazil; [8]National Institute of Oncology, Department of Medical Oncology and Clinical Pharmacology "B," , Budapest, Hungary; [9]University of Colorado Anschutz Medical Campus, Division of Medical Oncology, Department of Medicine, Aurora, United States; [10]VHIO Vall d'Hebron Institut d'Oncologia, Barcelona, Spain; [11]Exelixis Inc, Alameda, United States; [12]Seoul National University Hospital Medical Research and Innovation Center, Rep. of South Korea; [13]University of Pennsylvania, Abramson Cancer Center, Philadelphia, United States; [14]Thomas Jefferson University Medical School, Sidney Kimmel Cancer Center, Philadelphia, Pennsylvania, United States

Background
Increasing age is associated with poorer survival in DTC [Oyer SL, 2012]. In the phase 3 COSMIC-311 trial (NCT03690388), cabozantinib, an inhibitor of VEGFR2, MET, AXL and RET, significantly improved the progression-free survival (PFS) vs placebo in previously treated patients with RAI-R DTC (HR 0.22, 96% CI 0.13-0.36; $P<0.0001$; median follow-up 6.2 months). The impact of age on efficacy and safety was included in the prespecified subgroup analysis.

Methods
258 patients were randomized 2:1 to receive cabozantinib (60 mg QD) or placebo. Patients were stratified by prior lenvatinib treatment and age (younger subgroup: ≤65 y, older subgroup: >65 y). Patients with RAI-R DTC must have progressed on or after 1-2 prior VEGFR-targeted therapy. The primary endpoint of PFS and other outcomes in the extended follow-up data (8 Feb 2021) were analyzed by subgroups based on age.
Results
In the younger subgroup, 49% patients had papillary thyroid cancer (PTC) in the cabozantinib arm vs 66% in placebo, whereas 53% vs 36% had follicular thyroid cancer (FTC). In the older subgroup, 64% had PTC in the cabozantinib arm vs 57% in placebo, whereas 38% vs 43% had FTC. In the younger subgroup, 65% received prior sorafenib and 61% prior lenvatinib whereas in the older subgroup 55% received prior sorafenib and 65% prior lenvatinib. Median PFS for the cabozantinib arm was 11.1 months (95% CI 7.2-NE) with HR 0.19 (95% CI 0.12-0.32) for the younger subgroup and 11.1 months (95% CI 5.9-13.8) with HR 0.27 (95% CI 0.16-0.45) for the older subgroup. ORR with cabozantinib was 10% (95% CI 4.9%–18.9%) for the younger and 12% (95% CI 5.9%–20.8%) for the older subgroup vs 0% (95% CI 0.0-8.0) for both placebo subgroups. The discontinuation rate of cabozantinib due to AE related to study treatment was 6% both in the younger and the older subgroup and the percentage of patients with any dose reduction was 65% vs 69%. The safety profile in both age groups was similar and consistent with that of the overall population. No treatment-related grade 5 adverse events were observed.
Conclusion
This subgroup analysis demonstrates that clinical benefit with cabozantinib is maintained irrespective of age in previously treated RAIR DTC patients.

Functional analysis of exosomal miRNAs secreted by thyroid cancer cells

Antonella Verrienti[1], Valentina Maggisano[2], Fancesca Capriglione[2], Marialuisa Sponziello[1], Valeria Pecce[1], Cosimo Durante[1], Marilena Celano[2], Stefania Bulotta[2] & Diego Russo[2]
[1]Sapienza University of Rome, Translational and Precision Medicine, Rome, Italy; [2]Università Magna Graecia di Catanzaro, Health Sciences, Italy

Background
MiRNAs transported by exosomes play a role in various processes of tumorigenesis and tumor progression. They can function as oncogenes able to structurally and biologically change the tumor microenvironment (TME) therefore playing a crucial role in cell-to-cell communication during tumor development and allowing cancer cells to become invasive and disseminate from the primary site to distant locations.We aimed to identify the exosome miRNAs that may be involved in thyroid cancer development and progression and to investigate their functional effects.
Methods
We searched for the presence of specific miRNA profiles in exosomes secreted by a non-tumorigenic thyroid cell line (Nthy-ori-3-1) and two papillary thyroid cancer cell lines (TPC1 and K1) and compared them with intracellular miRNA profile of each cell line. Exosomes isolated from the cells' conditioned medium were characterized by dynamic light scattering and the expression of exosome-specific markers. We evaluated the expression of 46 miRNAs by Real-Time PCR using custom TaqMan Array cards on RNA from exosomes of each cell line. Mienturnet web tool was used for the microRNA-target enrichment and network-based analysis.
Results
Exosomes secreted by thyroid cancer cell lines were enriched in five miRNAs (miR21-5p, miR221-3p, miR22-3p, miR31-5p, and miR-let7i-3p) compared to normal cell lines, with higher levels observed in more aggressive K1 compared to less aggressive TPC1 cell lines. The levels of exosome miRNAs reflected those of intracellular miRNAs. The microRNA-target enrichment analysis revealed that VEGFA−VEGFR2 Signaling Pathway, ATM-dependent DNA damage response, EGF/EGFR Signaling Pathway, and PI3K−AKT−mTOR signaling pathway may be the most affected cellular processes. Finally, Network-based analysis found seven genes (ICAM1, FOXO3, SELE, ETS1, RECK, PTEN and TIMP3) which are targets of at least three identified miRNAs. Notably, ICAM1, target of 4 out 5 identified exosome miRNAs, is known to be the most important adhesion molecule involved in the extravasation of leukocytes into the surrounding tissue.
Conclusion
We identified five exosomal miRNAs that may be involved in thyroid cancer development and progression by playing paracrine effects on the tumor microenvironment. The findings of "in silico" analysis suggest a potential role even in angiogenesis, promotion and immune-surveillance impairment. Further studies will be performed to define the effects of these exosomal miRNAs.

Objective
RET fusion genes are known driver mutation in thyroid cancer and have been described mainly in pediatric thyroid carcinomas, in which they represent the most common genetic alteration. In large cohorts of adult patients, *RET* fusions have not yet been well characterized. The aims of this study were to identify *RET* fusion-positive thyroid tumors in a cohort of different types of thyroid carcinomas and to correlate them with clinical and histopathological features and to determine the prognostic significance of *RET* fusion genes based on long-term follow-up of patients with thyroid cancer harboring this mutation.
Methods
The cohort consisted of 1067 different thyroid cancer samples (fresh frozen tissues). Based on the detected mutation, samples were triaged. Samples positive for the *BRAF*, *HRAS*, *KRAS*, *NRAS*, *RET* or *NTRK* fusion gene mutation were excluded from the further *RET* fusion gene analyses. Samples were analyzed using Real-Time PCR (LC480, Roche) or using the FusionPlex Comprehensive Thyroid and Lung panel (ArcherDx) by next generation sequencing on MiSeq sequencer (Illumina).
Results
RET fusion genes were detected in 103/914 (11.3%) papillary thyroid carcinomas, from which 32/118 (27.1%) were from pediatric patients (7-20 years old) and 71/796 (8.9%) were from adult patients. A total of 17 types of *RET* fusions were found, including the following partner genes: *CCDC6*, *NCOA4*, *PRKAR1A*, *SQSTM1*, *IKBKG*, *RASAL2*, *TPR*, *ACBD5*, *RUFY2*, *BBIP1*, *AFAP1L2*, *AKAP13*, *TRIM27*, *SPECC1L*, *FBXO41*, *GOLGA5*, *SSBP2*. The *RET* fusion-positive carcinomas were associated with follicular growth pattern, multifocality, extrathyroidal invasion, lymph node and distant metastases. Lymph node metastases were found in almost all (93.8%) pediatric cases. On the other hand, most patients responded well to radioiodine treatment.
Conclusion
In summary, RET fusion gene were found only in papillary thyroid carcinomas. The frequency was approximately three times higher in pediatric patients than in adult patients. *RET* fusion-positive carcinomas correlated with aggressive tumor behavior. In conclusion, the genetic molecular testing of *RET* fusions is important not only for patient's diagnosis and prognosis, but also for possible targeted therapy.

Biomedical Sciences, Copenhagen, Denmark; [5]Copenhagen University Hospital, Hvidovre, Dept of Endocrinology and Metabolism, Copenhagen, Denmark; [6]Copenhagen University , Department of Nutrition, Exercise and Sports (NEXS), Frederiksberg, Denmark; [7]Slagelse Hospital, Dept of Endocrinology and Metabolism, Slagelse, Denmark; [8]Novo Nordisk Foundation, Hellerup, Denmark

Objective
Hypothalamic obesity results in severe weight-gain and increased risk of cardiovascular and metabolic mortality. We aimed to assess the safety and efficacy of Tesomet (tesofensine plus metoprolol), and ongoing requirements in pituitary hormone replacement adjustments in adults with acquired hypothalamic obesity, a rare disease with no approved therapy
Research design, patients and methods
Twenty-one adults with hypothalamic obesity (16 females, 5 males, mean(SD) age 46(14.6) years; 90% with a BMI "≥" 30 kg/m^2) were randomized to Tesomet (0.5 mg tesofensine/50 mg metoprolol)($n=14$) or placebo ($n=8$) during a 24-week double-blind treatment period. Seventeen subjects (11 Tesomet; 6 placebo) continued in 24-week open-label extension, all treated with Tesomet. Primary endpoint was safety; secondary endpoints included body weight and waist circumference. Almost half had a craniopharyngioma, 86% had undergone pituitary/hypothalamic surgery, 52% irradiation. All received one or more anterior pituitary hormone replacements. Trial NCT03845075.
Results
Most common adverse events were sleep disorders, dizziness, dry mouth, and headache; mostly of mild to moderate severity. No clinically meaningful changes in heart rate or blood pressure were observed. On completion of the double-blind period, mean change in body weight from baseline was -7.84 kg for the Tesomet group vs -0.34 kg for placebo ($P=0.03$), and at the end of the open-label extension period it was -6.34 kg for the Tesomet-Tesomet group and -6.03 kg for the placebo-Tesomet group. Mean change in waist circumference from baseline was -7.1 cm for the Tesomet group vs -1.2 cm for the placebo group at the end of the double-blind period, and -5.7 cm for the Tesomet-Tesomet group and -3.0 cm for the placebo-Tesomet group at the end of the open-label extension period. Most subjects (65%) had Levothyroxine reduced; adjustments in pituitary replacement and diabetic medications were otherwise few and did not differ significantly from baseline. Mean (SD) change in levothyroxine daily dose from baseline was -6.6% (6.1) and -6.4% (9.1) in Tesomet and placebo, respectively. In both groups, change in Levothyroxine correlated with weight-loss at time of adjustment (r2 = 0.37, $P=0.006$). This tendency was maintained during the extension period and implementing the reduction of levothyroxine in the management stabilised thyroid function.
Conclusion
Tesomet was generally well tolerated after 48 weeks of treatment, did not affect heart rate or blood pressure, and resulted in significant reductions in body weight in this cohort of hypopituitary patients with hypothalamic obesity. Weight-loss necessitated reductions in levothyroxine dose in most subjects to maintain stable thyroid function.

Background
Severe congenital growth hormone deficiency (cGHD) is a rare but potentially life-threatening condition. Even though random growth hormone (GH) can confirm cGHD during the first week of life, the diagnosis remains extremely challenging in the absence of reliable reference values in healthy neonates and thus of a best diagnostic cut-off.
Aims
First, to provide solid reference values for GH concentrations in term newborns, by means of a non-invasive procedure (GH from screening cards), using a current ultrasensitive GH assay. Secondly, to investigate eventual maternal and neonatal predictors of GH concentrations.
Methods
Using Immulite 2000 assay, GH was measured simultaneously from 200 dried blood spots (DBS) and serum samples of controls, thus validating this method for DBS. With the same assay, GH concentrations were measured in 444 filter papers of term newborns after 48 hours of life. Maternal and neonatal anamnestic data were collected from clinical records.
Results
In our cohort (444 neonates, 212 males and 232 females), the auxological parameters were spread according with the reference neonatal anthropometric charts of Italian population (median length -0.05 SDS, median head circumference -0.07 SDS, median weight -0.12 SDS). Median GH value was 16.9 μg/l (IQR 11.2 - 23.1 μg/l), with no significant gender difference. We defined a lower limit of 6.5 μg/l as 5° centile through Harrell-Davis' method with a confidence interval at 90% between 5.9 and 7 μg/l by bootstrap BCA method. Considering our lower limit of GH < 6.5 μg/l, at logistic regression analysis, jaundice presented the greater association with GH concentrations ($P<0.001$). Indeed, neonates with jaundice had 5-fold increased risk of presenting a GH < 6.5 μg/l. No other significant correlation was found between GH and maternal or neonatal characteristics. Yet, the association between neonatal hypoglycaemia and lower GH concentrations was suggestive, though not significant ($P=0.077$).
Conclusions
We defined the lower limit of reference values for GH in term healthy new-borns independently from sex, gestational age and auxological parameters using for the first time a widely available assay. The relationship found between symptoms/-signs suggestive for cGHD and lower GH concentrations, even in healthy subjects, confirmed the crucial role of clinical presentation in the diagnosis of cGHD. Providing solid reference values in term newborns, we put the basis for further studies aiming at defining a reliable diagnostic cut-off of cGHD.

Background
Oral octreotide capsules (OOC) are a treatment option for patients with acromegaly in the United States. The MPOWERED trial (NCT02685709) showed that OOC were noninferior to injectable somatostatin receptor ligands (iSRLs; octreotide or lanreotide) in maintenance of biochemical control in patients previously responding to both treatments, as well as demonstrated improvements in patient-reported outcomes among patients receiving OOC.
Objective
Report long-term safety and efficacy outcomes with OOC from the open-label extension (OLE) of MPOWERED.
Methods
Patients were eligible for and could voluntarily enroll into the OLE if they had completed the 15-month core treatment phase of MPOWERED (6-month Run-in phase plus 9-month randomized controlled treatment [RCT] phase or, for OOC nonresponders during/at end of Run-in at participating sites, combination substudy evaluating OOC in combination with cabergoline) and were adequately biochemically controlled per investigator assessment. Maintenance of response

(definition: IGF-I $<1.3\times$ULN; single timepoint) was assessed in each year of the OLE in patients responding at the start of that year. Additional analyses were performed on patients switching to OOC in the OLE from iSRLs in the core study.
Results
Sixty patients elected to enroll in the OLE (35 who received OOC and 19 who received iSRLs in the RCT phase, 6 from the combination sub-study). Median and maximal OOC exposure durations in the OLE were 2.2 and 3.5 years, respectively. A total of 94%, 90%, and 93% of patients receiving OOC monotherapy maintained biochemical response at the end of years 1, 2, and 3 of the OLE, respectively (using last observation carried forward imputation). Of patients switching from iSRLs to OOC during the OLE, 79% reported very good (47%) or excellent (32%) symptom control at the end of the OLE, compared with 47% (42% very good, 5% excellent) at the end of the RCT phase while receiving iSRLs. Patients switching from iSRLs also experienced significant improvements in the treatment convenience and treatment satisfaction domains (both $P<0.05$) of the Acromegaly Treatment Satisfaction Questionnaire. Median OOC compliance rate during the OLE was 99%. OOC safety during the OLE was consistent with that observed during the core study, with no new safety signals observed with long-term exposure.
Conclusions
The OLE of MPOWERED demonstrated a high percentage ($\geq$90%) of patients maintaining biochemical response while receiving OOC monotherapy with a favorable long-term safety profile of OOC. Those who switched from iSRLs to OOC demonstrated improvements in symptom control, treatment convenience, and treatment satisfaction.

[1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Endocrinology Unit, Milan,; [2]Department of Clinical Sciences and Community Health University of Milan, Milan,; [3]Department of Experimental Medicine, Sapienza University of Rome, Rome,; [4]Endocrinology, Diabetology and Medical Andrology Unit, Humanitas Clinical and Research Hospital, Rozzano, Italy; [5]Department of Biomedical Sciences, Humanitas University,, Rozzano, Italy; [6]Neurosurgery Unit, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [7]Department of Pathophysiology and Transplantation, University of Milan, Milan, Italy; [8]Neurosurgery Unit, Humanitas Clinical and Research Hospital, Rozzano, Italy

The aim of this study was to evaluate in a long follow-up time patients with acromegaly successfully treated by transphenoidal surgery (TNS) in order to establish the recurrence rate and the need of subsequent follow up.
Methods
We retrospectively analyzed data of 283 acromegalic patients (168 females, mean age: 44.2 $\pm$12.9 years) who underwent TNS for a GH secreting pituitary adenoma between 1980 and 2020, on regular follow-up at two Pituitary Units in the city of Milan (Fondazione IRCCS Ospedale Maggiore Policlinico and IC Humanitas). Diagnosis of acromegaly was defined by the presence of clinical signs and symptoms, an elevated serum IGF-1 level, age and sex matched, and lack of GH suppression based on appropriated criteria for the assay used at the time of diagnosis (GH <2 µg/l using a RIA, 1 µg/l with a modern IRMA or <0.4 µg/l with chemiluminescent assays, CLIA). For recurrence the same biochemical parameters were used.
Results
All patients had preoperative confirmation of acromegaly (mean IGF1: $+13.7\pm9.2$ SDS, mean GH nadir: 15.9 ± 26 µg/l). MRI confirmed the presence of a pituitary adenoma in all patients (192 macro) and all patients underwent TNS. At the first follow-up after surgery (mean distance: 3.63 ± 5 months) we defined as not cured 143 patients (50%), as cured 132 (47%) and as "partially cured", i.e. with normalization of only one parameter between GH suppression and IGF-1 levels, 8 patients (3%). Considering the group of cured patients, at the last follow-up (mean: 109 months after surgery) 5/132 (3.7%) patients needed medical therapy for recurrence. In particular, only 1 patient (0.7%) after 15 months form surgery showed a biochemical status of active acromegaly (IGF1 $+5.61$ SDS, and GH nadir 1.27 µg/l assessed with CLIA). Four additional patients (3%), after a mean follow-up of 81 months, started therapy for an isolated increase in IGF1 levels (mean IGF1SDS $+3.65$). In the "partially cured" group, 2/8 (25%) patients showed after 12 and 37 months from surgery a biochemical status of active acromegaly (IGF1 SDS $+2.75$ and $+3.62$; GH nadir 0.6 and 0.5 µg/l respectively assessed with CLIA).
Conclusions
Recurrence of acromegaly occurred in less than 1% of patients successfully treated with surgery. More frequently (25%), recurrence occurred in patients with incomplete normalization of either IGF1 or GH after surgery. Our data suggest that most acromegalic patients with complete remission after surgery may be considered as definitely cured, while those in partial remission need a strict endocrinological follow-up.

Real-world injection experience and use of independent injection among patients using lanreotide autogel/depot (LAN) prefilled syringe or octreotide long-acting release (OCT) to treat acromegaly or neuroendocrine tumors (NETs): international PRESTO 2 survey

Susan Webb[1,2], Dermot O'Toole[3], Pamela Kunz[4], Aude Houchard[5], Sandra Boiziau[5], Antonio Ribeiro-Oliveira[6] & Ally Prebtani[7]
[1]Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER, Unidad 747), ISCIII, Endocrinology Department, Spain; [2]Universitat Autònoma de Barcelona (UAB), Research Center for Pituitary Diseases, Hospital Sant Pau, IIB-Sant Pau, and Dept Medicine, Spain; [3]St. Vincent's University Hospital, Neuro Endocrine Tumours-ENETS Centre of Excellence, Dublin, Ireland; [4]Yale School of Medicine, Medicine (Oncology), New Haven, CT, United States; [5]Ipsen, Boulogne Billancourt, France; [6]Ipsen, Boston, MA, United States; [7]McMaster University, Faculty of Health Sciences, Ontario, Canada

Introduction
Long-acting (LA) somatostatin analog (SSA) therapy is a common first-line medical treatment for acromegaly and NETs. There are limited real-world data on patients' injection experience with the latest LA SSA devices/formulations.
Aims
To compare the injection experience of patients with acromegaly or NETs who were receiving treatment with LAN prefilled syringe vs OCT syringe.
Methods
A 2021 e-survey of adults with acromegaly or NETs from Canada, USA, UK and Ireland who had received $\geq$3 months' treatment with LAN or OCT (planned sample size, 304 [min 76/cohort]; 50:50 ratio [+/- 10%]). The primary endpoint was the proportion of patients with pain at injection site lasting >2 days after last injection. Secondary endpoints included interference with daily life due to injection-site pain and occurrence of technical injection problems. Benefits of independent injection (by self or partner) were assessed among patients receiving LAN, excluding patients in the USA, where LAN independent injection is not in the approved labelling.
Results
There were 304 respondents (acromegaly, $n=85$; NETs, $n=219$; LAN, $n=168$; OCT, $n=136$; 69.2% female; mean age 59.6 years). Fewer patients had injection-site pain lasting >2 days after last dose with LAN (6.0%) vs OCT (22.8%); the odds of pain lasting >2 days were significantly lower for LAN vs OCT, adjusted for disease group and occurrence of injection-site reaction (OR 0.13 [95% CI 0.06–0.30]; $P<0.0001$). Secondary endpoints are summarized in the table. In the LAN group (excluding USA), 40.7% ($n=11$) of patients with acromegaly and 38.7% ($n=29$) with NETs received their last treatment via independent injection and indicated they chose this for flexibility (80.0%), time saved (70.0%) and it was easy to do (60.0%).
Conclusions

Endpoint	LAN	OCT
Interference with daily life due to injection-site pain, %[a]	$n=78$	$n=80$
Not at all	59.0	40.0
A little bit	37.2	52.5
Quite a bit	3.8	7.5
Very much	0	0
Frequency of technical problems with injection, %[b]	$n=155$	$n=126$
Never	76.8	42.9
Rarely	17.4	39.7
About half the time	1.9	11.1
Most of the time	1.3	5.6
Don't know/remember	2.6	0.8

[a]Patients with pain at last injection [b]Patients with >6 months' experience with current SSA

In this e-survey, LAN was associated with advantages relative to OCT beyond improvements in the occurrence of technical problems, especially regarding duration of pain at injection site and its interference with daily life. A substantial proportion of LAN patients had received independent injection, demonstrating the value of this treatment option.

ACROBAT advance: once daily, oral paltusotine treatment maintained long-term igf-1 at levels previously achieved with injectable long-acting somatostatin receptor ligands (LA-SRLs)

Mônica R Gadelha[1], Harpal Randeva[2], Murray B Gordon[3], Emese Mezosi[4], Mirjana Doknic[5], Miklós Tóth[6], Cesar L Boguszewski[7], Melissa Nichols[8], Theresa Jochelson[8], Scott Henley[8], Meenal Patel[8], Debbie Koh Mendez[8], Christine Ferrara-Cook[8], Alan Krasner[8], Alessandra Casagrande[8] & R Scott Struthers[8]

[1]Neuroendocrinology Research Center/Endocrinology Division–Medical School and Hospital Universitario Clementino Fraga Filho–Universidade Federal do Rio de Janeiro, Brazil; [2]University Hospitals Coventry and Warwickshire NHS Trust, United Kingdom; [3]Allegheny Neuroendocrinology Center, Allegheny General Hospital, United States; [4]University of Pécs Medical School, 1st Department of Internal Medicine, Hungary; [5]Clinical Centre Serbia, Clinic for Endocrinology, Diabetes and Metabolic Diseases, Serbia; [6]Semmelweis University, Department of Internal Medicine and Oncology, Hungary; [7]SEMPR, Endocrine Division, Department of Internal Medicine, Federal University of Parana, Brazil; [8]Crinetics Pharmaceuticals, United States

Paltusotine is a once-daily, oral, nonpeptide somatostatin receptor type 2 (SST2) specific agonist, in development for the treatment of acromegaly and neuroendocrine tumors. We report interim results from ACROBAT Advance (NCT04261712), an ongoing, multicenter, open-label, long-term extension study of paltusotine in subjects with acromegaly who previously completed either Phase 2 study ACROBAT Edge (NCT03789656) or Evolve (NCT03792555). ACROBAT Edge enrolled 47 subjects with elevated ($n=35$) or normal ($n=12$) IGF-1 taking LA-SRLs either as mono- or combination therapy at baseline. ACROBAT Evolve enrolled 13 subjects with a normal IGF-1 using octreotide LAR or lanreotide depot monotherapy. Both ACROBAT Edge and Evolve involved up to 13-weeks of paltusotine treatment followed by a 1-month drug washout period. In ACROBAT Advance, paltusotine was re-initiated at a dose of 10 mg/day with titration up to 40 mg/day based on IGF-1 and tolerability. For subjects not achieving a normal IGF-1 with 40 mg/day of paltusotine monotherapy, adjunctive treatment was allowed. Of 49 eligible subjects, 41 (84%) [median age 52 (IQR 46-62) years, 56.1% female] were enrolled at the time of the interim analysis, 23 had reached 51 weeks of treatment, and 4 had discontinued from the study. Paltusotine dose was titrated to 40 mg/day in most subjects (73%) by week 51. The frequency of adjunctive cabergoline use during the trial was the same as that prior to the trial (24%). Median IGF-1 was maintained for up to 51 weeks at levels achieved with previous parenteral LA-SRL therapy (Table 1). The most common treatment-emergent adverse events were headache [12 (29.3%)], arthralgia [9 (22%)], and fatigue [6 (14.6%)]. Most adverse events were transient and of mild-to-moderate intensity. There were 3 non-treatment-related SAEs in 2 subjects. There were 4 discontinuations (1 for headache and 3 for study drug unrelated reasons). Median HbA1c levels remained stable [baseline 6.0% (5.7-6.2), 5.9% (5.7-6.1) at week 23, and 5.8% (5.6-6.4) at week 51]. Oral once-daily paltusotine treatment was well tolerated and resulted in maintenance of IGF-1 at levels comparable to prior LA-SRL therapy for up to 51 weeks. This was seen in all subsets of acromegaly patients representing a variety of previous treatment regimens and a range of baseline disease control.

	Previous LA-SRL therapy*	ACROBAT Advance Week 31*	ACROBAT Advance Week 51*
ACROBAT Edge subjects	1.31×ULN (1.02,1.48) ($n=30$)	1.30×ULN (0.91,1.54) ($n=21$)	1.15×ULN (1.01,1.49) ($n=17$)
ACROBAT Evolve subjects	0.83×ULN (0.64,0.94) ($n=11$)	0.84 (0.75,0.96) ($n=10$)	0.89 (0.83,1.06) ($n=6$)

Pdgfrα-driven Alms1 deletion in mice recapitulates the obesity and insulin resistance of Alms1 global knockout

Eleanor McKay, Ineke Luijten, Dominique McCormick, Adrian Thomson, Gillian Gray & Robert Semple

University of Edinburgh, Centre for Cardiovascular Science, Edinburgh, United Kingdom

Background

Alström Syndrome (AS) is a rare autosomal recessive disease featuring highly accelerated insulin resistance, fatty liver, diabetes and heart failure among other syndromic features. Heart failure leads to significant early mortality, but is complex and likely multifactorial, with developmental defects, accelerated atherosclerosis, and fibrosis all implicated. These cardiometabolic complications occur in the face of only moderate obesity in many patients. AS is caused by biallelic loss-of-function mutations in the *ALMS1* gene, encoding a large centrosomal protein. The precise derangement of centrosomal and/or primary ciliary function caused by loss of ALMS1 is unknown. There is currently no specific treatment for AS. Further research is needed to address this unmet clinical need. Several global knockout (KO) mouse models have been described to recapitulate key metabolic components of AS, but none have characterised cardiac function in-vivo, and tissue-specific KO approaches have not yet been used to tease out contributions of different cell types to pathology.

Hypothesis

The metabolic profile of AS closely resembles that of lipodystrophy. We thus hypothesised that loss of Alms1 function in mesenchymal stem cell populations, such as adipose precursor cells, would recapitulate the metabolic derangement in AS. We secondarily hypothesised that this would mitigate some but not all cardiac complications.

Methods

A novel global KO mouse was generated by crossing the EUCOMM Tm1c Alms1 line with the global CAG-Cre driver. A Pdgfrα-Cre driver was used to abrogate Alms1 function only in mesenchymal progenitor cells and their descendants including preadipocytes and adipocytes. We undertook metabolic phenotyping and echocardiography of global and Pdgfrα+ Alms1-KO mouse models in both sexes on a 45% high-fat diet.

Results

Consistent with previous models and the human disease, global Alms1 KO mice were hyperphagic, obese, insulin resistant, and had severe hepatosteatosis. We show novel evidence of restrictive cardiomyopathy in 23-week-old female global KO mice, manifesting as increased left-atrial area and decreased intraventricular relaxation time. This was not seen in male global KO mice. Initial assessment did not reveal cardiac apical fibrosis on histological examination. KO of Alms1 only in MSCs and their descendants recapitulated key metabolic phenotypes of global KO animals including obesity and insulin resistance. Interestingly hyperphagia was also seen despite lack of neuronal Alms1 KO.

Conclusions

1. Female-specific restrictive cardiomyopathy is seen in mice deficient in Alms1.
2. MSC-derived lineages are critical in driving the severe metabolic syndrome in AS.
3. Hyperphagia in AS does not depend on neuronal Alms1 deficiency.

Once-weekly semaglutide delays a late phase gastric emptying of solid meal measured by repeated scintigraphic imaging in obese women with PCOS

Mojca Jensterle[1], Simona Ferjan[1], Luka Lezaic[2], Aljaz Socan[2], Katja Zaletel[2] & Andrej Janez[1]

[1]University Medical Centre Ljubljana, Department of Endocrinology, Diabetes and Metabolic Diseases, Ljubljana, Slovenia; [2]University Medical Centre Ljubljana, Department of Nuclear Medicine, Ljubljana, Slovenia

Background

GLP-1 agonism have the potential to affect gastric emptying (GE), yet the reports for subcutaneous semaglutide, currently the most effective GLP-1 RA approved for weight management, remain inconclusive. It has been demonstrated that semaglutide either had no effect on GE or it delayed GE only within the first hour,

without late phase retention. Notably, those conclusions were made by an indirect method of estimation of GE through ingestion, absorption and determination of plasma level of paracetamol. Furthermore, in previous studies GE has been evaluated as a part of the composite outcome. The indirect method with paracetamol was shown to be appropriate for evaluation of kinetics of liquid meals, whereas it might lead to inaccurate estimation of late phase GE. Scintigraphic evaluation is considered as a reference method for the purpose.
Aim
This is the first study that evaluates the effect of once weekly subcutaneous semaglutide on late phase GE of a solid meal by scintigraphy as a primary outcome in obese women with PCOS without other comorbidities.
Materials and Methods
A single-blind, placebo-controlled trial was conducted in 20 women with PCOS and obesity, without diabetes and other comorbidities, randomized to once weekly subcutaneous semaglutide 1 .0 mg (S) or placebo (P) for 8 weeks. Gastric emptying was assessed by scintigraphy after ingestion of 99mTC colloid in pancake labelled with radiopharmaceutical that maintained a stable binding within gastric environment by scintigraphy using sequential static imaging and dynamic acquisition. Estimation of GE was obtained by repeated imaging of remaining 99mTC activity (RA) at fixed time intervals over 4 hours and the half time (T1/2) of gastric emptying had been calculated. Additionally, we evaluated anthropometric, metabolic, hormonal and appetite parameters.
Results
At 30 min after ingestion significant difference in RA was observed between semaglutide group and placebo (92.5% in S vs 89% in P ($P=0,05$)) and persisted throughout the observation period up to 4 hour (37% in S vs 0% in P ($P=0,002$)). T1/2 was significantly longer in S as compared to P (171 min vs 118 min, respectively ($P<0.001$)). In addition, semaglutide led to significant decrease in weight, waist and neck circumference, HbA1c and androgen levels. Subjective ratings of appetite suppression correlated with T1/2.
Conclusion
Semaglutide 1.0 mg resulted in a significant late-phase retention of solid meal measured by repeated scintigraphic imaging. This effect correlated with appetite suppression and likely contributed to weight loss.

Weight loss attempts and weight perception in women with polycystic ovary syndrome (PCOS) - a 15-year follow-up in a population-based cohort study

Emilia Pesonen[1,2], Meri-Maija Ollila[1], Laure Morin-Papunen[1], Juha S Tapanainen[1,3], Timo Jämsä[4], Raija Korpelainen[2,5,6], Maisa Niemelä[4], Marjukka Nurkkala[2,5,6] & Terhi T Piltonen[1]
[1]University of Oulu and Oulu University Hospital, Department of Obstetrics and Gynaecology, PEDEGO Research Unit, Medical Research Center, Oulu, Finland; [2]Oulu Deaconess Institute Foundation sr., Department of Sports and Exercise Medicine, Oulu, Finland; [3]University of Helsinki, Department of Obstetrics and Gynaecology, Helsinki, Finland; [4]University of Oulu and Oulu University Hospital, Research Unit of Medical Imaging, Physics and Technology, Medical Research Center , Oulu, Finland; [5]University of Oulu and Oulu University Hospital, The Center for Life Course Health Research (CLCHR), Faculty of Medicine; [6]University of Oulu and Oulu University Hospital, Medical Research Center

Background
Women with polycystic ovary syndrome (PCOS) experience increased weight gain during life, thus weight management and preventing weight gain should be the first line treatment. Weight loss is usually self-initiated because practical support for weight management is often limited or even lacking. Perception of overweight is considered an important prerequisite for weight loss attempts, although there is no prior research regarding women with PCOS. The main aim of the study was to investigate whether women with PCOS are more likely to have multiple weight loss attempts compared to non-PCOS controls regardless of weight. In addition, we evaluated women's weight perception in relation to weight loss attempts.
Methods
The study is part of Northern Finland Birth Cohort 1966 including women with PCOS ($n=280$) and non-PCOS controls ($n=1573$) examined at ages 31 and 46 years. Multiple weight loss attempts, weight perception, body mass index (BMI), and psychological distress were analyzed along with sociodemographic factors at both time points. Binary logistic regression analysis was performed, and the results were reported as odds ratios (ORs) with 95% confidence intervals. A *P*-value <0.05 was considered statistically significant.
Results
Women with PCOS had higher prevalence of multiple weight loss attempts by age 31 and 46 years compared to controls ($P<0.001$). Despite this, women with PCOS had significantly higher BMI at both time points ($P<0.001$). PCOS was independently associated with multiple weight loss attempts at age 46 when adjusted for psychological distress and BMI (OR 1.44 [95% CI, 1.01–2.05]) or perception of overweight (OR 1.45 [95% CI, 1.03–2.03]). Perception of overweight was the most significant factor contributing to multiple weight loss attempts at both time points. Perception of overweight was more prevalent in PCOS compared to controls, and interestingly, perception of overweight was more common even among normal weight women with PCOS at age 31 ($P=0.004$) and age 46 ($P<0.001$) years. Indeed, PCOS was independently associated with perception of overweight at age 31 when adjusted for BMI and leisure-time physical activity (OR 1.69 [95% CI, 1.01–2.85]), and at age 46 when adjusted for BMI and psychological distress (OR 2.65 [95% CI, 1.37–5.13]).
Conclusions
Women with PCOS are more likely to experience multiple weight loss attempts as well as perception of overweight independent of BMI until late fertile age compared to non-PCOS controls. In clinical practice, adequate support and resources should be offered to reduce inefficient weight loss attempts and stress.

Body composition during childhood, adolescence and adulthood influences the odds of developing polycystic ovary syndrome: a mendelian randomisation study with a systematic review and meta-analysis

Laurence J Dobbie[1,2], Sizheng Steven Zhao[3], Bradley Pittam[4], Uazman Alam[1,2], Thomas M Barber[5] & Daniel J Cuthbertson[1,2]
[1]University Hospital Aintree, Liverpool University Hospitals NHS Foundation Trust, Liverpool, United Kingdom; [2]Department of Cardiovascular and Metabolic Medicine, Institute of Life Course and Medical Sciences, University of Liverpool, Liverpool, United Kingdom; [3]Centre for Epidemiology Versus Arthritis, Division of Musculoskeletal and Dermatological Sciences, School of Biological Sciences, Faculty of Biology Medicine and Health, University of Manchester, Manchester, United Kingdom; [4]Manchester University Hospital NHS Foundation Trust, Manchester, United Kingdom; [5]Warwick Medical School, University of Warwick, Coventry, United Kingdom

Background
Observational and genetic Mendelian randomisation (MR) data has demonstrated the association of adulthood overweight/obesity with development of polycystic ovary syndrome (PCOS). However, the contribution of early life (i.e. childhood/adolescence) body composition on incident PCOS is unclear. This study determines the influence of body composition on the likelihood of developing PCOS.
Methods
We conducted a 2-sample Mendelian randomisation study to determine the impact of body composition and metabolic parameters (fasting serum insulin or sex-hormone binding globulin) on the odds of PCOS. PCOS genome-wide association study meta-analysis data (from 10,074 people with PCOS, 103,164 controls) was interrogated using the inverse-variance weighted method. Furthermore, we conducted a systematic review (71 studies) and meta-analysis (63 studies) of the role of overweight, obesity and central obesity (defined via waist circumference / waist-hip ratio) on odds of PCOS in adults and adolescents.
Results
From Mendelian randomisation, significant associations were shown between body composition and odds of PCOS. For every standard deviation increase in BMI (a BMI increase of 4.8 kg/m^2), odds of PCOS increased significantly (OR: 2.76, 2.27 - 3.35). Similar associations were demonstrated between body fat percentage (OR: 3.05 per 8.5%, 2.24 - 4.15), whole-body fat mass (OR: 2.53 per 9.6 kg, 2.04 - 3.14), fasting insulin (OR: 6.98 per 0.79 pmol/l, 2.02 - 24.13) and sex-hormone binding globulin (OR: 0.74 per 28 nmol/l, 0.64 - 0.87). Genetically determined childhood body size increased odds of PCOS after adjusting for adult body size (OR: 2.56, 1.57 - 4.20). *From meta-analysis*, women with overweight (OR 3.80, 2.87- 5.03)), obesity (OR 4.99, 3.74 – 6.67) and central obesity (OR 2.93, 2.08 – 4.12) had increased odds of PCOS. For adolescents with overweight and/or obesity the PCOS odds were greater than for adults (adult vs adolescent: overweight: OR 3.57 and 5.32; Obese: OR 4.66 and 7.86).
Conclusions
Using two complementary epidemiological techniques we demonstrate a clear relationship between markers of body composition, indicative of excess body fat accumulation, and odds of developing PCOS, especially in childhood and adolescence. MR reports that genetically determined childhood body composition increases PCOS likelihood independent of adult body composition. From meta-analysis, women with overweight, obesity and central obesity had increased odds of PCOS, with odds even higher in adolescents with overweight and obesity.

Overall, this study has implications for the prevention and treatment of obesity and the importance of effective weight maintenance from early years and beyond.

The glucocorticoid transporter ATP-binding cassette subfamily C member 1 (ABCC1) influences adiposity, glucose homeostasis and insulin sensitivity in male mice

Elisa Villalobos[1], Allende Miguelez-Crespo[1], Ruth A Morgan[1], Ruth Andrew[1], Mark Nixon[1] & Brian R Walker[1,2]
[1]The Queen's Medical Research Institute - University of Edinburgh, British Heart Foundation Centre for Cardiovascular Science, Edinburgh, United Kingdom; [2]Translational and Clinical Research Institute - Newcastle University , Newcastle upon Tyne, United Kingdom

Background
Glucocorticoids (GCs) modulate glucose homeostasis by acting on metabolic tissues including liver, adipose and skeletal muscle. GC access to corticosteroid receptors in these tissues is regulated e.g. by pre-receptor metabolism. We recently identified a role for ABCC1, a transmembrane 'drug-resistance' transporter, as a GC exporter which limits intracellular GC concentrations and action in adipose tissue. Here, we tested the hypothesis that ABCC1, which is also highly expressed in skeletal muscle, influences glucose metabolism and insulin sensitivity, through regulation of tissue GC action.
Methods
Male global *Abcc1* knockout (*Abcc1*$^{-/-}$) and wild-type (WT) littermate mice were fed chow diet or high-fat diet (HFD - 58% fat and sucrose) for 9 weeks, starting at 8-12 weeks of age ($n=10$-13 each group). Glucose and insulin tolerance tests were performed (week 7-8), all procedures were done with ethical approval. Plasma and tissue GC concentrations were measured by Liquid Chromatography Tandem Mass Spectrometry, and tissue GC-responsive genes and metabolic markers (mRNA and protein) by RT-qPCR and Western blot.
Results
Our findings show that on chow diet, *Abcc1*$^{-/-}$ mice have similar body weight, despite reduced fat mass (subcutaneous, gonadal and brown adipose tissue), normal glucose tolerance in the presence of reduced fasting insulin levels, and increased levels of corticosterone in plasma, subcutaneous adipose tissue (sWAT) and gastrocnemius muscle compared to WT mice, By contrast, on HFD, *Abcc1*$^{-/-}$ mice had similar body weight gain and fat mass to WT mice, but impaired glucose and insulin tolerance and fasting hyperinsulinemia, without measurable alterations in plasma or tissue GC levels. Interestingly, on HFD, WT mice protein levels of ABCC1 were upregulated in sWAT but not in skeletal muscle. Further, we investigated a number of genes and pathways that might be affected by the changes in insulin e.g GSK-3β We identified upregulation on the levels of pGSK-3β in skeletal muscle, but not in adipose tissue from *Abcc1*$^{-/-}$ mice on chow diet. By contrast, on HFD, the levels of pGSK-3β were upregulated in skeletal muscle from WT mice but not in *Abcc1*$^{-/-}$. These changes were absent in adipose tissue.
Conclusions
Abcc1 influences adiposity, insulin sensitivity and glucose homeostasis differently according to diet and obesity, and by mechanisms which are likely to be only in part GC-dependent. Further dissection of the substrates for ABCC1 which mediate these effects may reveal new avenues for therapy in metabolic disease.

Fetal sex predicts perinatal outcomes in women with gestational diabetes

Catarina Cidade-Rodrigues[1], Catarina Chaves[1], Anabela Melo[2], Odete Figueiredo[2], Ana Morgado[2], M Céu Almeida[3], Mariana Martinho[1], Margarida Almeida[1] & Filipe M Cunha[1]
[1]Centro Hospitalar do Tamega e Sousa, Endocrinology, Portugal; [2]Centro Hospitalar do Tamega e Sousa, Gynaecology and Obstetrics, Portugal; [3]Maternidade Bissaya Barreto, Centro Hospitalar e Universitário de Coimbra, Obstetrics, Portugal

Introduction
Gestational diabetes (GD) is a known risk factor for delivery, fetal and perinatal complications. Fetal male sex is known to be associated with worse perinatal outcomes, such as macrosomia, neonatal hypoglycemia, low Apgar scores, birth defects and mortality. However, studies evaluating the impact of fetal sex on perinatal outcomes in women with GD are scarce.
Objectives
We aimed to study whether male newborn sex is associated with neonatal outcomes, in women with GD.
Methods and Methods
Retrospective study based on the national register of GD. Included women with live-born singleton pregnancies followed between 2012 and 2017. Excluded women without data on variables of interest. Primary endpoint: Neonatal hypoglycaemia, neonatal macrosomia, respiratory distress syndrome (RDS) and neonatal intensive care unit admission (NICUA). BMI as pregestational weight divided by squared height. Female and male newborns were compared. Multivariate logistic regression models were built and included variables with different distribution between groups and with known association with the endpoint under analysis.
Results and Conclusions
We studied a total of 10768 newborns in mothers with GD, 5635 (52.3%) male, 438 (4.1%) had neonatal hypoglycaemia, 406 (3.8%) were macrosomic, 671 (6.2%) had RDS, and 671 (6.2%) had a NICUA. Male sex newborns were heavier, more frequently small and large for gestational age. No differences were observed on maternal age, BMI, HbA1c, anti-hyperglycaemic treatment, pregnancy complications or gestational age at delivery. In the multivariate regression analysis, male sex was independently associated with neonatal hypoglycaemia [OR 1.27 (IC 95%:1.04-1.55), $P=0.02$], neonatal macrosomia [1.98 (1.58-2.48), $P<0.001$], NICUA [1.27 (1.06-1.55), $P=0.01$] and RDS [1.33 (1.03-1.71), $P=0.03$]. Male newborns from mothers with GD have a 27% higher risk of neonatal hypoglycaemia, almost 2-fold higher risk of macrosomia, 33% higher risk of RDS and 27% higher risk of NICUA.

Background
It is well established that life-long follow-up is required for patients with hereditary pheochromocytomas and paragangliomas (PPGLs), due to the potential of developing recurrent disease. However, whether follow-up of patients with sporadic PPGLs is necessary, remains unclear.
Aims
To examine the prevalence and predictors of recurrent disease in patients with sporadic PPGLs.Materials and method: This multicenter study included retrospective clinical data of 528 patients with PPGLs. Recurrent disease was defined as presence of new tumor and/or locoregional recurrence and/or metastases one year after initial tumor diagnosis. Patients with sporadic PPGLs were defined as

those without germline mutations in known genes associated with hypoxia (cluster 1) or kinase (cluster 2) signaling pathways.
Results
Fifty-three percent of the patients had sporadic PPGLs and presented with a recurrence rate of 17.3%, which mainly reflected metastatic disease (10%). This was significantly lower than those with cluster 1 (54.3%), but similar to those with cluster 2 mutations (14.1%). Among patients with sporadic PPGLs and recurrent disease, 70.7% developed recurrence within 10 years from initial tumor diagnosis. Multivariable Cox regression analysis showed that larger (>4.5 cm) size (HR 1.8, 95% CI 1.13-3.0, $P=0.015$) and extra-adrenal location (HR 2.4, 95% CI 1.4-4.11, $P=0.001$) of the primary tumor, were independent predictors of recurrence in patients with sporadic PPGLs. Indeed, patients with small (≤4.5 cm) sporadic pheochromocytomas presented with the lowest (7.8%) rate of recurrent disease ($P<0.001$).
Conclusion
Among patients with sporadic PPGLs, prevalence of recurrence was mainly due to metastases and high enough to mandate long-term follow-up. Importantly, our findings indicate that size and tumor location are important to consider for further stratification and management of patients with sporadic PPGLs.

Prostate cancer (PCa) is one the leading causes of cancer-related deaths among men in developed countries. Therefore, identification of novel molecular and therapeutic approaches to tackle this pathology are urgently needed. In this scenario, our group has recently reported that elements of the cellular machinery controlling alternative splicing processes might be used as potential novel therapeutic tools against PCa and castration-resistant PCa (CRPC). In this context, RBM22 has been identified as a key spliceosome component, playing a crucial role for normal development; however, the potential dysregulation and functional role of RBM22 in cancer still remain unknown. Here, we identify for the first time a profound downregulation of RBM22 (at mRNA/protein-levels) in two well-characterized cohorts of PCa patients, compared to non-tumor control samples. Notably, RBM22 levels were inversely associated to key clinical aggressiveness features in PCa (i.e. extraprostatic extension and perineural invasion). These results were confirmed in two additional, independent *in silico* human cohorts. Overexpression of RBM22 in PCa cells decreased aggressiveness parameters *in vitro* (e.g. proliferation, migration, tumorsphere- and colony-formation, etc.), and drastically decreased tumor development and progression *in vivo* (using a preclinical mouse model), which would underlie a relevant direct association of lower RBM22 levels with enhanced tumor progression. These results were corroborated using the TRAMP mouse model, wherein gradual reduction of RBM22 from prostatic intraepithelial neoplasia to moderately differentiated PCa and to poorly differentiated PCa was observed. These actions are likely mediated through the modulation of key signaling pathways (i.e. cycle-apoptosis, PI3K pathways, etc.) and critical molecular regulators (i.e. MYC, MCYN and E2F), and may also involve the alteration of alternative splicing events of key genes involved in these pathways. Therefore, our study demonstrates for the first time that RBM22 plays a critical functional role in the pathophysiology of PCa and suggests that targeting negative regulators of RBM22 could represent a novel therapeutic strategy to tackle this devastating pathology.

Context
Mosaicism is a feature of several inherited tumor syndromes but is rarely systematically looked for in routine. MEN1 is an autosomal dominant hereditary syndrome characterized by several endocrine tumors affecting parathyroids, pancreas, and anterior pituitary most of the time, due to inactivating mutations in the *MEN1* gene. Few cases of mosaicism in Multiple Endocrine Neoplasia type 1 (MEN1) have been described. *MEN1* mosaicism is probably under-diagnosed because it is not routinely investigated. At present, Next generation sequencing (NGS) offers new possibilities to detect mosaicism. The challenge is to distinguish true mosaicism from sequencing artifacts. We reported the first study systematically looking for *MEN1* mosaicism in MEN1 suspected patient but without MENI pathogenic variants (PV) at heterozygote state.
Methods
For that, we set up in routine a digital targeted NGS including unique molecular identifiers (UMIs). UMIs are tools for improving molecular detection of rare events in somatic DNA. We established the analytic performance of such method. Next *MEN1* mosaicism was then looked for in a cohort of unresolved MEN1 cases addressed in the molecular biology laboratory between 2017 and 2019.
Results
For *MEN1*, sensitivity was 100% for detecting the variants up to an allelic frequency (AF) of 1%. By using UMIs, false positives were reduced by 98.4% for *MEN1*. Among a cohort of 119 patients harboring from 2 to 5 MEN1 lesions, we identified 3 patients with *MEN1* mosaic PVs. The allelic frequencies ranged from 2.3 to 9.5%. The detection rate of MEN1 mosaicism in patients bearing at least 3 MEN1 lesions was 17% (3/18). No cases are detected in patients with 2 lesions.
Conclusion
we reported here 3 new cases with *MEN1* mosaicism. This study deciphered the performances of UMI in *MEN1* mosaic diagnosis in routine and underlined that the frequency of mosaicism is probably underestimated in MEN1 suspected patients.

Introduction
A syndrome of MEN2A and Hirschsprung's disease described in Israeli Jews of Moroccan descent is caused by Cys 618 Arg mutation, one of the less common causes of MEN2A. We aimed to define the clinical characteristics of a large cohort with this mutation from a multi-center Israeli registry.

Methods
The Israeli MTC registry including 8 centers was searched retrospectively for results of RET mutational analysis. Patients with a Cys 618 Arg mutation belonging to a single large extended family were included in the study, as were their first-degree family members with MTC without available genetic test results. Clinical, laboratory and pathological data, as well as long-term surveillance data were retrieved.
Results
Of the 274 patients in the Israeli registry, 53 (19.3%) had documented RET mutations, and 29/53 (54.7%) had the Cys 618 Arg mutation. Through development of a family tree spanning five generations, a familial connection was determined for 28/29 patients, descendants of one large family of Moroccan Jewish descent. Another 4 patients from the MTC registry without available genetic test results belonged to this extended family. Clinical and pathological data pertaining to these 32 patients was analyzed. Nineteen patients (59%) were female; mean age at surgery was 26.6 $\pm$12.8 years. Tumor size was 10.8 $\pm$9.3 mm. Extrathyroidal extension was described in 4/19 (21.0%); vascular invasion in 5/18 (27.8%); multifocality in 17/21 (81.0%) and bilateral lesions in 17/22 (77.3%). Ki67 was mentioned for only one patient and was 3%. Lymph nodes were removed in 8 patients, and metastases found in 3. Extranodal extension was found in 1 case. Three patients had distant metastases at diagnosis. Of 22 patients with one-year follow-up, 11 were cured, 10 had persistent disease and 1 suffered disease-related mortality. Of those with persistent disease, 6 were biochemical, 2 structural and 2 unknown. Surveillance duration was 9.3 $\pm$12.9 years. Recurrence occurred in 4/19 patients (21.2%), 3 with distant metastases. Seven patients had additional therapy: 4 surgery, 2 radiotherapy and 1 tyrosine kinase inhibitors. One more patient died during follow-up; whether his death was disease-related is unclear. Comorbidities included pheochromocytoma in 2 patients, Hirschsprung disease in 2 and primary hyperparathyroidism in 1 patient.
Conclusion
The prevalent RET mutation in Israel is Cys 618 Arg, and almost all cases are linked to one large family of Moroccan Jewish descent. Genotype-phenotype correlation are similar to that described previously with cases of pheochomocytoma and hyperparathyroidism, rendering screening for these conditions essential.

Human malignant pleural mesothelioma (MPM) is a rare but aggressive neoplasm, arising from pleural mesothelial cells, generally due exposure to asbestos. Of note, different growth factors and their receptors are involved in the pathogenesis of MPM and resistance to therapy. Chemotherapy with cisplatin (cis) and antifolates, like pemetrexed (PEM), is the first-line treatment for inoperable MPM. Growth hormone-releasing hormone (GHRH), besides stimulating GH secretion in the anterior pituitary, exerts many peripheral functions, such as stimulation of cell proliferation and survival. GHRH and GHRH receptors (GHRH-Rs) are expressed in different cancer cell types, where they modulate their proliferative effects. Conversely, GHRH-R antagonists were found to inhibit the proliferation of different cancer cells *in vitro* and *in vivo*. Moreover, we recently demonstrated the antitumor activity of GHRH antagonists MIA-602 and MIA-690, in both *in vitro* and *in in vivo* models of MPM. However, the antitumor functions of GHRH-antagonists in combination with cis and PEM (cis/PEM) remain to be elucidated. Thus, in the present study, we assessed the antitumor effects of MIA-690 in combination with cis/PEM *in vitro*, in human biphasic MPM cell line MSTO-211H, and *in vivo*, in mice bearing MPM xenografts. *In vitro*, MIA-690 showed synergistic inhibitory activity with cis/PEM, by reducing cell survival and proliferation at 48 h in MSTO-211H and increasing the chemotherapy-induced apoptosis. *In vivo*, subcutaneous administration of MIA-690, at the dose of 5 µg/d for 4 weeks, potentiated the antitumor activity of cis/PEM by strongly inhibiting the growth of MPM xenografts, as demonstrated by the reduction of tumor volume and weight and inhibition of survival/proliferative markers, as revealed by immunohistochemistry analysis. MIA-690 also influenced the expression levels of cell cycle regulators (cyclinB1, D1 and D2), cell migration effectors (MMP-2 and MMP-9) and epithelial-mesenchymal transition markers (E-cadherin, N-cadherin, and vimentin), compared with cis/PEM treatment alone. Moreover, mice treated with both MIA-690 and cis/PEM showed increased expression of apoptotic molecules, along with a reduction of tumor insulin-like growth factor-I (IGF-I) and vascular endothelial growth factor (VEGF) in tumor xenografts. Collectively, these results further confirm the antitumor role of GHRH antagonists in MPM and suggest the potential therapeutic efficacy of these molecules in combination with chemotherapy, by potentially reducing anticancer drug doses and associated side effects.

SF3B1 inhibition disrupts malignancy and prolongs survival in glioblastoma patients through BCL2L1-splicing and mTOR/ß-catenin pathways imbalances

Miguel E G-Garcia[1,2,3], Antonio C Fuentes-Fayos[1,2,3], Jesus Perez Gomez[1,2,3], Juan M Jiménez-Vacas[1,2,3], Cristobal Blanco-Acevedo[1,4], Rafael Sánchez-Sánchez[1,2,5], Juan Solivera[1,4], Joshua Breunig[6], Manuel D Gahete[1,2,3], Justo P Castaño[1,2,3] & Raul M Luque[1,2,3]

Glioblastoma (GBM; grade IV astrocytoma) is one of the most devastating endocrine-related cancer worldwide based on its locally aggressive behavior and because it cannot be cured by current therapies. Therefore, the identification of novel diagnostic and prognostic biomarkers, and especially efficient therapeutic targets is urgently needed. In this sense, defects in alternative splicing process are associated with poor survival and high aggressiveness in cancer, including GBM. Specifically, splicing factor SF3B1 (splicing-factor-3B-subunit-1), an essential and druggable component of spliceosome (machinery responsible for splicing process), has been identified as a key dysregulated factor in some endocrine-related cancer (e.g. prolactinomas and breast cancer); however, the oncogenic implication of SF3B1, its somatic mutations, and expression profile or its association with molecular features and clinical parameters have not been characterized in GBM, nor its putative therapeutic potential. Therefore, different human cohorts and dataset from different glioma mouse models were analyzed to determine the mutation frequency as well as the gene and protein expression levels between tumor and control samples of SF3B1. SF3B1 expression was also explored at the single cell level across all cell subpopulation and transcriptomic programs. The association of *SF3B1* expression with relevant clinical data in different human cohorts was also analyzed. Moreover, different functional (proliferation/migration/tumorspheres-formation/ VEGF-secretion/apoptosis) and molecular/mechanistic (gene expression/signaling-pathways) assays were performed in different glioblastomas cell models (human primary-cultures and cell-lines) in response to SF3B1 blockade (using pladienolide B treatment). Additionally, tumor onset, formation and progression were monitored in response to SF3B1 blockade in a preclininal mouse model. Our data provide novel evidence demonstrating that SF3B1 is low-frequency mutated in human gliomas (1%) but widely overexpressed in glioblastoma compared with control samples from the different human cohorts and mouse models included in the present study, wherein SF3B1 levels are associated with key molecular and clinical features (e.g., overall survival, poor prognosis and/or drug-resistance). Remarkably, in vitro and in vivo blockade of SF3B1 activity with pladienolide B drastically altered multiple glioblastoma pathophysiological processes (i.e., reduction in proliferation, migration, tumorspheres-formation, VEGF-secretion, tumor initiation and increase in apoptosis) likely by suppressing AKT/mTOR/ß-catenin pathways, causing an imbalance of *BCL2L1* splicing. Together, we highlight

SF3B1 as a potential diagnostic and prognostic biomarker and an efficient pharmacological target in glioblastoma, offering a clinically relevant opportunity worth to be explored in humans.

Splicing factor 3 subunit B1 (SF3B1) inhibition in PRL-secreting PitNETs and cross-talk with dopamine receptor type 2 (DRD2)

Genesio Di Muro[1,2], Federica Mangili[2], Anna Maria Barbieri[2], Emanuela Esposito[2], Donatella Treppiedi[2], Federico Arlati[2], Rosa Catalano[2], Giusy Marra[2], Emma Nozza[2], Maura Arosio[2,3], Giovanna Mantovani[2,3] & Erika Peverelli[2]
[1]University Sapienza of Rome, PhD Program in Endocrinological Sciences, Italy; [2]University of Milan, Department of Clinical Sciences and Community Health, Italy; [3]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Endocrinology Unit, Italy

Somatic mutations in splicing factor 3 subunit B1 (SF3B1) were found in about 20% of PRL-secreting PitNETs. SF3B1 is involved in pre-mRNA splicing and required for assembly of the U2 complex, which is critical for branch site recognition and the early stages of spliceosome assembly. Patients with mutant prolactinomas showed higher PRL levels and shorter progression-free survival compared to wild-type patients. Aims of the present study were: 1) to characterize the genetic profile of a cohort of 14 patients with PRL-secreting PitNETs, searching for somatic mutations in SF3B1 hotspot region; 2) to test the effects of SF3B1 inhibitor pladienolide-B on tumoral lactotroph cells; 3) to investigate dopamine receptor type 2 (DRD2) agonist effects in tumoral lactotroph cells silenced for SF3B1. We found no SF3B1 mutated patients in our cohort. In rat PRL-secreting pituitary tumoral cells MMQ, pladienolide-B was effective in reducing cell proliferation (-40 $\pm$ 10% at 20 nM, $P<0.001$ vs basal), viability (-42 $\pm$ 7% at 10 nM, $P<0.05$ vs basal) and in promoting apoptosis (6-fold increase at 50 nM, $P<0.05$ vs basal). In primary cultured cells from one PRL-secreting PitNET, bearing wild-type SF3B1, pladienolide-B reduced cell proliferation and cyclin D3 expression and increased cell apoptosis. SF3B1 silencing in MMQ cells induced a reduction of DRD2 expression (-51 $\pm$ 13.2%, $P<0.001$ vs control cells). Moreover, in MMQ cells lacking SF3B1, cabergoline completely lost its ability to reduce cell proliferation (-22 $\pm$ 4.8%, $P<0.001$ vs basal), AKT phosphorylation (-31 $\pm$ 24,6%, $P<0.01$ vs basal), cyclin D3 expression (-23 $\pm$ 7,6%, $P<0.05$ vs basal) and to increase p27 (+20 $\pm$ 8,6%, $P<0.05$ vs basal). Interestingly, cabergoline treatment reduced SF3B1 protein expression levels in MMQ cells (-60 $\pm$ 40%, $P<0.05$ vs control cells) and in primary cultured cells from 2 PRL-secreting PitNETs (-43 $\pm$ 6,4%, $P<0.01$). In conclusion, our data demonstrated that SF3B1 inhibitor pladienolide-B exerts antitumoral actions in PRL-secreting PitNET cells bearing wild-type SF3B1. In MMQ cells, SF3B1 silencing reduced DRD2 expression and signaling, and cabergoline negatively regulated SF3B1 expression.

Kisspeptin administration has therapeutic potential for men with low sexual desire by increasing penile tumescence and sexual brain processing

Edouard Mills[1], Natalie Ertl[2], Matt B Wall[2], Layla Thurston[1], Lisa Yang[1], Sofiya Suladze[1], Tia Hunjan[1], Maria Phylactou[1], Bijal Patel[1], Beatrice Muzi[1], Dena Ettehad[1], Jonathan Howard[2], Eugenii A Rabiner[2], Paul Bech[1], Ali Abbara[1], David Goldmeier[3], Alexander Comninos[1] & Waljit Dhillo[1]
[1]Imperial College London, Hammersmith Campus, Section of Endocrinology and Investigative Medicine, London, United Kingdom; [2]Invicro London, London, United Kingdom; [3]Imperial College Healthcare NHS Trust, Sexual Function Clinic, London, United Kingdom

Background
Hypoactive Sexual Desire Disorder (HSDD) is associated with dysfunctional brain activation in regions governing sexual responses, resulting in a deficiency/absence of sexual desire with marked distress. It affects up to 8% of men with detrimental effects on quality of life, interpersonal relationships and fertility, but so far has no licensed treatment options. The reproductive neuropeptide kisspeptin offers a putative therapeutic target owing to its emerging role in modulating reproductive behaviour in animal models and healthy men. However, there are no studies examining its effects in HSDD. To address this, we performed the first clinical study of kisspeptin in men with HSDD.
Methods
We examined the effects of kisspeptin administration (vs placebo) on brain activity during short and long erotic video tasks using functional MRI in 32 men with HSDD (mean $\pm$SEM age 37.9 $\pm$1.5 y, BMI 24.9 $\pm$1.0 kg/m^2). To provide functional and behavioural relevance for the associated fMRI brain responses during the long erotic video, simultaneous penile tumescence and subjective level of arousal were recorded. Participants also completed psychometric and behavioural questionnaires. Standard analysis methods were used for fMRI data from the short videos task, and the long videos task used regressors derived from the subjective arousal and penile tumescence data. The statistical threshold used for both was $Z=2.3$, $P<0.05$ (cluster-corrected).
Results
In response to visual erotic stimuli, kisspeptin administration significantly increased penile tumescence during the long video task compared to placebo, with kisspeptin increasing penile tumescence by 56% ($P=0.002$). Moreover, kisspeptin increased participant-reported happiness about sex ($P=0.02$). During both video tasks, kisspeptin significantly modulated brain activity, compared to placebo, in key structures of the sexual-processing network. In response to short erotic videos, kisspeptin enhanced left middle frontal gyrus and left anterior cingulate activity, and decreased activity in bilateral parahippocampus (all $p<0.05$). During the long video task, kisspeptin enhanced right fusiform gyrus and bilateral visual cortex activity, and decreased left frontal pole, right posterior cingulate and bilateral precuneus activity (all <0.05). Additionally, we observed positive correlations between kisspeptin's effects on aforementioned brain activity and psychometric parameters of sexual desire and arousal (all $P<0.01$).
Conclusion
Collectively, we demonstrate for the first time that kisspeptin administration in men with HSDD increases penile tumescence and psychometric measures of sexual desire and arousal by modulating sexual brain processing. Taken together, our data suggest that kisspeptin-based therapeutics may offer a novel, effective and much-needed clinical strategy for men with HSDD.

Background
Osilodrostat is a potent oral inhibitor of the adrenal enzymes aldosterone synthase and 11b-hydroxylase and decreases glucocorticoid and mineralocorticoid production and secretion. Phase 2 and 3 studies from the osilodrostat clinical trial programme have demonstrated the drug's efficacy and safety in patients with Cushing's disease. Osilodrostat received European Marketing Authorization (MA) for the treatment of Cushing's syndrome (CS) in adults.
Objective
Evaluate the use of osilodrostat for the treatment of CS in clinical practice in France (Autorisation Temporaire d'Utilisation [ATU], post-ATU, post-MA; authorization IDRCB2021A0140140).
Methods
This multicentre analysis included patients with CS who were treated with osilodrostat between 2019 and 2021. Causes of CS, therapeutic approaches, dosages, and efficacy and safety of osilodrostat were analysed in patients where data was available.
Results
Patients ($n=107$) with CS aged 11–85 years were analysed; 68 patients were female and 39 were male. At diagnosis, urinary free cortisol (UFC; median ± standard deviation (SD) [range; n]) was 135 µg/24 h ±1703 (10–27188; $n=79$). Causes of CS in these patients include ACTH-dependent (Cushing's disease [$n=57$]; ectopic [$n=28$]; uncertain [$n=5$]) and ACTH-independent (adrenocortical carcinoma [$n=9$]; macronodular adrenocortical hyperplasia [$n=5$]; adrenocortical adenoma [$n=2$]). UFC levels (median ± SD [range; n]) at the time of initiating osilodrostat therapy were 135 µg/24 h ±1703 (5–10000; $n=78$). Regarding therapeutic approaches (n/N, %), 17/87 patients (20%) received osilodrostat as first-line therapy, whereas 36 patients (41%) received it as second-line therapy. Methods of osilodrostat administration included: titration (59/95, 62%), block and replace (9/84, 11%) and titration followed by block and replace (33/85, 39%). The initial osilodrostat dose (median ± SD [range; n]) was 4.0 mg/day ±8.7 (1–60; $n=96$), whereas the maximum dose was 12.0 mg/day ±18 (1–80; $n=103$). UFC normalization with osilodrostat was achieved in 64/78 patients (82%). Improvements of clinical signs and symptoms were reported in 67/89 patients (75%), and improvement of comorbidities with osilodrostat was reported in 39/62 patients (63%). In terms of safety in patients treated with osilodrostat, adrenal insufficiency was reported in 30/91 patients (33%) and hyperandrogenism was reported in 6/54 patients (11%).
Conclusion
These findings from clinical practice confirm the efficacy of osilodrostat in patients with various aetiologies of CS, in agreement with the European MA. The main side effect observed was adrenal insufficiency, which was expected and related to the mechanism of action of osilodrostat. Use of the block and replace approach may prevent the development of adrenal insufficiency.

HPLC-MSMS steroidogenic profiles in ACTH-dependent Cushing Syndrome patients treated by osilodrostat or metyrapone suggest differences in the spectrum of steroidogenic enzyme inhibition between the two CYP11B1 inhibitors in clinical care

Bonnet Fideline[1,2,3], Jonathan Poirier[4], Anna Vaczlavik[2,3,4], Christelle Laguillier-Morizot[1,2,5], Benoît Blanchet[6], Laurence Guignat[4], Laura Bessiene[4], Léopoldine Bricaire[4], Lionel Groussin[2,3,4], Guillaume Assié[2,3,4], Jean Guibourdenche[1,2,5] & Jerome Bertherat[2,3,4]
[1]Hôpital Cochin-APHP, UF d'Hormonologie, Paris, France; [2]Université de Paris, Paris, France; [3]INSERM, U1016, Paris, France; [4]Hôpital Cochin-APHP, Endocrinologie, Paris, France; [5]INSERM, Physiopathologie et Pharmacotoxicologie Placentaire Humaine : Microbiote Pré & Post Natal, Paris, France; [6]Hôpital Cochin-APHP, Biologie du Médicament et Toxicologie, Paris, France

Introduction
Osilodrostat is a new 11 ß-hydroxylase inhibitor with a mode of action analogue to metyrapone. It has become increasingly used in recent years for treatment of Cushing's Syndrome (CS). However, few in vivo studies are currently available to accurately compare both drugs characteristics. The objective of our study was to compare steroidogenic profiles in patients treated by either Osilodrostat or Metyrapone for ACTH-dependent CS.
Methods
Patients followed in Cochin hospital Endocrinology department between March 2019 and December 2021 for an ACTH-dependent CS, controlled by either Osilodrostat or Metyrapone were included. A serum profile of 5 steroids (cortisol, 11-deoxycortisol, 17-hydroxyprogesterone, androstenedione and testosterone) was determined in high performance liquid chromatography-tandem mass spectrometry (HPLC-MS/MS).
Results
Twenty-five patients treated by Osilodrostat and 14 patients treated by Metyrapone were thus included. Cortisol level was lower in Osilodrostat group (175 [22-421] nmol/l) in comparison to Metyrapone group (307 [68-547] nmol/), $P=0.025$; hypocortisolism (basal 8:00 AM cortisol < 100 nmol/l) being found in 48% of patients treated by Osilodrostat and 7% of patients treated by Metyrapone. 11-deoxycortisol level was higher in patients treated by Metyrapone (80.9 [2.2-688.4] nmol/l) than in patients treated by Osilodrostat (10.3 [0.5-71.9] nmol/l), $P=0.0009$. Similarly, androstenedione level was higher in Metyrapone group (14.9 [2.5-54.3] nmol/l) than in Osilodrostat group (4.0 [0.3-13.3] nmol/l), $P=0.0005$. Testosterone level in women patients was also higher in Metyrapone group (3.3 [0.93-4.82] nmol/l) than in Osilodrostat group (1.31[0.13-5.09] nmol/l), $P=0.0146$. Steroidogenic enzymes activity was evaluated by upstream/downstream steroids ratio, a higher ratio thus reflecting an accumulation of the enzyme substrate, i.e a lower enzymatic activity. CYP11B1 activity, evaluated by 11-deoxycortisol/cortisol ratio, was not different between Metyrapone group (22.4 [0.7-410]) and Osilodrostat group (7.53 [1.0-47.3]), $P=0.1254$. CYP21A2 activity, assessed by 17OHprogesterone/11-deoxycortisol ratio, was significantly decreased in Osilodrostat group (18.6 [4.89-101.9]) in comparison to Metyrapone group (3.1[1.3-31.8]), $P<0.0001$, as well as CYP17A1 activity, evaluated by 17OHprogesterone/androstenedione ratio: 56.9 [17.7-136.5] in Osilodrostat group in comparison to 18.3 [5.8-46.8] in Metyrapone group, $P<0.0001$.
Conclusion
In patients with ACTH-dependent CS, the use of CYP11B1 inhibitors in standard routine care suggest that Osilodrostat has a less specific effect on the inhibition of steroidogenic enzymes than Metyrapone. This might explain a smaller increase in 11-deoxycortisol and in androgens levels in patients treated by Osilodrostat and should be taken in consideration for patients management.

Epigenomic and somatic mutation profile of pituitary adenomas (PAs)/ pituitary neuroendocrine tumors (PitNETs)

Federica Guaraldi[1], Luca Morandi[2], Matteo Zoli[1,2], Alberto Righi[3], Stefania Evangelisti[2], Caterina Tonon[2], Diego Mazzatenta[1,2] & Sofia Asioli[2]
[1]IRCCS Istituto delle Scienze Neurologiche di Bologna, Pituitary Unit, Bologna, Italy; [2]Alma Mater Studiorum - Bologna University, Department of Biomedical and Neuromotor Sciences (DIBINEM), Bologna, Italy; [3]Rizzoli Orthopedic Institute, Anatomopathology and Histopathology Service, Bologna, Italy

Background
Pituitary adenomas (PAs)/Pituitary Neuroendocrine Tumors (PitNETs) are a complex and heterogeneous group of lesions. Genetic and epigenetic studies have been performed to identify predictors of treatment outcome.
Study aim
To profile clinically non-aggressive (NA) and aggressive (A) PAs/PitNETs, and carcinomas for somatic mutations and epigenetic alterations of genes involved in cell proliferation/differentiation, miRNA/lncRNA-post-transcriptional regulators, and therapy targets.
Patients and Methods
64 NA and 41 A PAs/PitNETs (40 males; 21 ACTH-, 50 FSH-/lH-, 16 GH-, 3 GH/PRL-, 12 PRL-secreting; 1 null cell; 2 plurihormonal PIT-1+) and 6 carcinomas (3 males; 3 ACTH-, 2 PRL- and 1 FSH/lH-secreting) treated by endoscopic surgery from 2003 to 2017, with ≥1-year follow-up were included. Clinico-radiological and histological data were collected. Somatic mutations of 17, and DNA methylation of 22 genes were assessed in fresh frozen and/or formalin-fixed paraffin-embedded tumor tissue (20% VAF and 100x coverage in both strands). Ten normal pituitaries were used as control.

Results
6/64 (9.4%) NA and 9/41 (22%) A PAs/PitNETs and 1/6 (16.6%) carcinoma showed ≥1 mutation ($P=0.0024$), involving *TP53* ($n=3$; 2.7%), *NOTCH1* ($n=4$; 3.6%), *AIP* ($n=6$; 5.4%), *USP8* ($n=3$; 2.7%) or *PIK3CA* ($n=3$; 2.7%). Carcinomas presented the highest methylation levels of *PARP15*, *LINC00599*, *MIR193a*, *MIR137HG* and *ZAP70* followed by A and NA PAs/PitNETs ($P<0.05$). *LRRTM1*, *NTM*, *CDH1* were hypermethylated in carcinomas only. *GNAS*, *PDCD1* and *AIP* methylation was higher in NA than A PAs/PitNETs and carcinomas ($P<0.05$). Hypermethylation could silence genes and reduce the expression of PARP15, LINC00599 and miR-193a, thus inducing cancer cells growth and proliferation by modulating p53 expression and related apoptotic pathways in aggressive tumors. *PDCD1* methylation could predict the response to anti-PD1 and PDL-1 inhibitors, as well as the escape of tumor cells from immunological control. Methylation levels of *MAGEA family, UXT* and *FLNA* gens, interacting with the androgen receptor (AR) and p53, differed between males and females in PAs/PitNETs and carcinomas, supporting the role of AR expression and the synergy of epigenetics and somatic gene mutations in pituitary tumorigenesis.
Conclusions
Different profiles of somatic gene mutations and methylation were identified in NA and A PAs/PitNETs, and carcinomas. Altered methylation appears an early event that could contribute to tumor aggressiveness, response to treatment and progression to carcinoma directly, or indirectly by inducing gene mutation. Involvement of X-linked genes could underly gender variability in tumor behavior. These data reinforce the importance of combining molecular analysis with clinico-radiological and pathological data in attempting to predict tumor behavior.

A tumor-borne Angpt2/Tie2 autostimulatory loop controls tumorigenesis

Natalia Pellegata[1], Ninelia Minaskan[1], Sebastian Gulde[1], Hermine Mohr[1], Julia Geppert[1], Maria Rohm[1], Giovanni Vitale[2], Germano Gaudenzi[2], Alessandra Dicitore[2], Schilling Franz[3], Mathias Schillmaier[3], Graeme Eisenhofer[4], Stephan Herzig[1], Federico Roncaroli[5] & Jürgen Honegger[6]
[1]Helmholtz Zentrum München, Institute for Diabetes and Cancer, Munich, Germany; [2]Istituto Auxologico Italiano IRCCS, Milan, Italy; [3]Technical University Munich, Munich, Germany; [4]Technical University Dresden, Dresden, Germany; [5]University of Manchester, Manchester, United Kingdom; [6]Eberhard Karls University Tübingen, Tübingen, Germany

Background
Invasive nonfunctioning (NF) pituitary neuroendocrine tumors (PitNETs) are non-resectable neoplasms associated to frequent relapse and significant comorbidities. As current treatments often fail against NF-PitNETs, identifying actionable therapeutic targets is essential. We focused on the angiopoietin-2 (Angpt2)/Tie2 axis, usually active in endothelial cells (ECs).
Methods
ANGPT2 plasma levels in NF-PitNET patients and healthy controls were measured by ELISA. qRT-PCR and immunohistochemistry assessed Angpt2 and Tie2 expression in rat and human NF-PitNETs. The role of endogenous Angpt2 in PitNET cells was investigated by gene knockdown (siRNA, shRNA) followed by proliferation/apoptosis assays. Xenografts of sh*Angpt2* PitNET cells in zebrafish embryos demonstrated that tumor cell-borne Angpt2 is pro-angiogenic. Proximity ligation assay (PLA) showed Angpt2/Tie2 interaction on primary NF-PitNET cells. Downstream targets activation upon Angpt2-mediated receptor stimulation was assessed by western blotting. Mouse xenografts of CRISPR/Cas9-generated Tie2-knockout PitNET cells proved the role of Tie-2 in pituitary tumorigenesis *in vivo*. Drugs inhibiting Angpt2/Tie2 signaling were tested against primary rat/human NF-PitNET cultures. Treatment of mouse xenografts of PitNET cells with an angiopoietin-neutralizing peptibody (AMG386), followed by MRI imaging, determined the effects of Angpt2/Tie2 inhibition on tumor growth *in vivo*. The efficacy of Angpt/Tie2 inhibition was also assessed in MENX rats, the only spontaneous and autochthonous NF-PitNET model. MENX rats were treated with AMG386 and longitudinally monitored using anatomical and functional (diffusion weighted) MRI.
Results
In NF-PitNET patients, circulating Angpt2 levels are elevated and correlate with tumor aggressiveness. PitNET cells express and secrete bioactive Angpt2, which stimulates tumor cell proliferation *in vitro*, and angiogenesis in zebrafish xenografts *in vivo*. Noteworthy, NF-PitNET cells possess a functional Tie2 receptor, which is activated by Angpt2 and stimulates downstream mitogenic signals. This establishes an autocrine/paracrine stimulatory loop in NF-PitNET cells, as so far only demonstrated in ECs. Tie2 knockout blunts PitNETs growth *in vivo*. Proof-of-principle pharmacological inhibition of Angpt2/Tie2 signaling antagonizes NF-PitNETs *ex vivo* (primary cultures of human/rat tumors) and *in vivo* (mouse xenografts, MENX rats).
Conclusion
The Angpt2/Tie2 axis emerges as exploitable therapeutic target in NF-PitNETs, hence addressing an unmet clinical need. The ability of tumor cells to coopt angiogenic signals classically viewed as EC-specific expands our view on microenvironmental cues essential for tumor progression. Tumor-targeted Angpt2/Tie2 inhibition is a novel concept in anti-cancer strategies applicable to tumors expressing Angpt2/Tie2.

Bone loss is a frequent complication of aromatase inhibitors (AIs) therapy in women with breast cancer. Bone-active drugs are effective in protecting the skeleton from detrimental actions of AIs. However, bone mineral density (BMD) was the primary end-point in most of published studies, whereas data on fractures were scant and mainly limited to denosumab. In this prospective study, we investigated the effects of denosumab, oral bisphosphonates and intravenous zoledronate on risk of morphometric vertebral fractures (VFs; primary end-point) and BMD at lumbar spine, femoral neck and total hip (explorative end-point). To address these aims, 567 consecutive women (median age 62 years, range 28-83) were evaluated for BMD and morphometric VFs at baseline and after 18-24 months of follow-up. The inclusion criteria were: 1) hormone receptor-positive breast cancer with indication to AIs; 2) duration of AIs therapy at study entry ≤12 months. After enrolment, 268 women (47.3%) started denosumab 60 mg subcutaneously every 6 months, 59 (10.4%) oral bisphosphonates (BPs), 56 (9.9%) intravenous zoledronate 5 mg every 12 months, whereas 184 women (32.5%) were not treated with bone-active drugs because of patient preference, contraindications and/or clinical judgment. Vitamin D, with or without calcium, was given to all women during study period. Denosumab was given more frequently to women with pre-existing VFs ($P=0.019$) and/or lower BMD values ($P<0.01$ at all skeletal sites) as compared to women treated with oral BPs or zoledronate. During 18-24 months of follow-up, 54 women (9.5%) developed new morphometric VFs, with incidence being higher in untreated women vs those treated with any bone-active drug (17.4% vs 5.7%; $P<0.001$). Stratifying women for type of anti-osteoporotic medications, risk of VFs resulted to be significantly decreased by denosumab [odds ratio (OR) 0.22, 95% confidence interval (C.I.) 0.11-0.46; $P<0.001$) and zoledronate (OR 0.27, 95% C.I. 0.08-0.91; $P=0.035$) , but not by oral BPs (OR 0.64, 95% C.I. 0.27-1.54; $P=0.317$). All anti-osteoporotic medications induced significant increase in median BMD at any skeletal site, whereas BMD decreased significantly in women who were not treated with bone-active drugs. In conclusion, this prospective study, reflecting the real-life clinical practice, shows that in women exposed to AI therapy, denosumab and zoledronate are more effective than oral BPs in decreasing the risk of VFs during the first 24 months of treatment. Future prospective studies will clarify whether in the long-term also oral BPs

could reduce the risk of fractures in women exposed to estrogen-deprivation therapies.

SGLT2 inhibitor treatment does not increase risk of osteoporotic fractures compared to GLP-1 receptor agonists: a Danish population-based cohort study

Zheer Kejlberg Al-Mashhadi[1,2], Rikke Viggers[3,4], Jakob Starup-Linde[1,2,5], Peter Vestergaard[3,4] & Søren Gregersen[1,2]

[1]Aarhus University Hospital, Steno Diabetes Center Aarhus, Aarhus, Denmark; [2]Aarhus University, Department of Clinical Medicine, Aarhus, Denmark; [3]Aalborg University Hospital, Steno Diabetes Center North Jutland, Department of Endocrinology, Aalborg, Denmark; [4]Aalborg University, Department of Clinical Medicine, Aalborg, Denmark; [5]Aarhus University Hospital, Department of Endocrinology and Internal Medicine, Aarhus, Denmark

Background

Type 2 diabetes mellitus (T2D) is associated with an increased risk of fractures. Research on the effects of sodium-glucose cotransporter 2 (SGLT-2) inhibitors is scarce and unsettled. We aimed to investigate the risk of major osteoporotic fractures (MOF) – i.e., hip, vertebral, humerus, and forearm fractures – with SGLT2 inhibitors compared to glucagon-like peptide 1 (GLP-1) receptor agonists when either is used in combination with metformin.

Methods

We conducted a population-based cohort study using discharge diagnosis codes from the Danish National Patient Registry and data on all redeemed drug prescriptions from the Danish National Prescription Registry. Subjects treated with metformin in combination with either SGLT2 inhibitors or GLP-1 receptor agonists between 2012 and 2018 were identified. Subjects were then propensity-score matched 1:1 based on age, sex, and index date. Survival curves were plotted using the Kaplan-Meier estimator. A Cox proportional hazards model was utilized to estimate crude and adjusted hazard rate ratios (HR) for MOF. Finally, Aalen's Additive Regression (AAR) model was used to examine a possible additive rather than multiplicative effect of SGLT2 inhibitors on fracture hazard while allowing time-varying covariate effects.

Results

We identified 27,543 individuals treated with either combination. After matching, 18,390 individuals were included in the main analysis (9,190 in each group). Median follow-up times were 355 [interquartile range (IQR) 126-780] and 372 [IQR 136-766] days in the SGLT2 inhibitor and GLP-1 receptor agonist group, respectively. The crude HR for MOPF was 0.77 [95% CI 0.56-1.04] with SGLT2 inhibitors compared to GLP-1 receptor agonists. The fully adjusted model yielded an unaltered HR of 0.77 [95% CI 0.56-1.05]. Results were similar across subgroup- and sensitivity analyses. Similarly, the multivariate AAR model yielded a non-significant difference between the two exposure groups.

Conclusion

These results suggest that SGLT2 inhibitors have no effect on fracture risk when compared to GLP-1 receptor agonists. This is in line with results from previous studies.

Impact of preoperative zoledronic acid on hungry bone syndrome and bone health indices in patients with primary hyperparathyroidism after curative parathyroidectomy: a randomized controlled trial

Akanksha Gautam[1], Sanjay Bhadada[2], Anil Bhansali[2], Divya Dahiya[3], Arunanshu Behera[3], Uma Nahar Saikia[4], Ashwani Sood[5] & Tulika Singh[6]

[1]Post Graduate Institute of Medical Education & Research, Chandigarh, Endocrinology, Chandigarh, India; [2]Post Graduate Institute of Medical Education & Research, Chandigarh, Endocrinology , Chandigarh, India; [3]Post Graduate Institute of Medical Education & Research, Chandigarh, Surgery, Chandigarh, India; [4]Post Graduate Institute of Medical Education & Research, Chandigarh, Histopathology , Chandigarh, India; [5]Post Graduate Institute of Medical Education & Research, Chandigarh, Nuclear Medicine , Chandigarh, India; [6]Post Graduate Institute of Medical Education & Research, Chandigarh, Radiodiagnosis , Chandigarh, India

Background

In individuals with primary hyperparathyroidism (PHPT), the utility of preoperative bisphosphonate administration in prevention of post-curative-parathyroidectomy hungry bone syndrome (HBS) and effects on long-term bone accrual are uncertain.

Objectives

To estimate the effect of preoperative administration of single infusion of zoledronic acid (ZA) on occurrence of HBS and gain in bone mineral density (BMD) at one year in individuals with PHPT undergoing curative parathyroidectomy.

Methods

In this single-centre, randomized (1:1), single-blind, placebo-controlled study (CTRI/2019/10/021762), a total of 48 adults (age $>$ 18 years) with PHPT (serum Calcium $\geq$ 11 mg/dl) were enrolled. Prior to parathyroidectomy ($\leq$ 2 weeks), participants received either a single intravenous infusion of 5 mg ZA ($n=24$) or placebo ($n=24$). Post-curative-parathyroidectomy, participants were monitored for occurrence of HBS until discharge. HBS was defined by the presence of hypocalcemia (Ca$<$ 8.5 mg/dl) and hypophosphatemia ($P<$ 2.7 mg/dl) with rise in alkaline phosphatase (ALP) ($>$5%) on any day after surgery. BMD (Hologic Discovery 4500) and trabecular bone score (TBS) were assessed at baseline and one year after surgery. In addition, bone turnover markers (CTX, P1NP) were assessed at baseline, first week, 3-, 9- and 12- months post-surgery. Occurrence of HBS was assessed using binary logistic regression model. Changes in BMD and BTM were assessed using linear mixed model for repeated measures.

Results

Forty five out of 48 participants had succesful curative parathyroidectomy. HBS occured in 6 (27.3%) individuals in ZA and 6 (26.1%) in placebo group [OR: 1.06 (0.28 - 3.98);$P=0.928$]. The odds for developing HBS were comparable after adjusting for baseline severity and serum 25(OH)D levels ($P=0.075$). Individuals in ZA group had a higher gain in BMD at lumbar spine (7.54%; 95% CI, 0.06 to 15.02; $P=0.048$), comparable gain at neck of femur (9.74%; 95% CI, - 5.005 to 24.49; $P=$ 0.190) and a fall in BMD at distal radius (3.29% ; 95% CI, -10.17 to 2.31; $P=0.008$). Rise in TBS was comparable between the two groups ($P=0.396$). The higher gain in BMD at lumbar spine was paralleled by a higher decline in CTX (27.8%; 95% CI, -48.44 to -7.12; $P=0.009$) in ZA group while ALP (10.9%; 95% CI, -23.39 to 1.44; $P=0.082$) and P1NP levels remained comparable (9.50%; 95% CI, -22.36 to 41.37; $P=0.360$).

Conclusion

In PHPT, preoperative administration of single infusion of ZA is associated with increased bone mineral accrual at lumbar spine without significant effect on occurrence of HBS.

Is the "rebound phenomenon" following Denosumab discontinuation a risk factor for Zoledronic acid acute phase adverse reactions?

Marta Zampogna[1], Giorgia Grassi[1], Alberto Ghielmetti[1], Serena Palmieri[2], Maura Arosio[1] & Cristina Eller Vainicher[2]

[1]University of Milan, Department of Clinical Sciences and Community Health, Italy; [2]Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Unit of Endocrinology, Italy

Background

Zoledronic acid (ZOL) administration may cause acute phase adverse reactions (APR), which manifest with fever, malaise, bone and muscular pain, headache

and/or gastrointestinal disturbances. Previous data suggest that high N-terminal propeptide of type 1 collagen (P1NP) and low 25,OH-vitaminD (VitD) levels are associated with higher incidence of APR, while the previous use of bisphosphonates is a protective factor. Lately, ZOL has been frequently used to mitigate the "rebound phenomenon" following Denosumab (Dmab) discontinuation. The aim of our study is to evaluate whether the use of ZOL in patients discontinuing Dmab (postDmab) may be associated with an increase in incidence and severity of APR, as compared with patients without prior antiosteoporotic therapy (naïve) and the presence of possible factors associated with APR.

Methods

we retrospectively evaluated 112 patients (56 postDmab and 56 naïve) treated with ZOL 5 mg intravenously for osteoporosis in our center during the last 24 months. Bisphosphonates treatment preceding ZOL administration, including previous ZOL infusions, was considered an exclusion criterion. All patients were taking vitamin D and calcium. In all patients we evaluated femoral neck (FN) and lumbar spine (LS) bone mineral density (BMD), C-terminal telopeptide (CTX) and VitD levels.

Results

PostDmab patients were older (71.4±8.7 vs 65.1±11.4 years, $P=0.001$), had higher BMD (LS T-score -2.3±0.8 vs -3.1±1.2, $P=0.0001$, FN T-score -2.0±0.8 vs -2.4±0.8, $P=0.011$) and lower CTX levels (452±350 vs 630±307 pg/ml $P=0.008$) as compared to naïve patients, while the prevalence of fractures (56.3 vs 43.8% $P=0.333$; respectively postDmab and naïve) and the VitD levels (40.4±13.9 vs 42.8±23.1 ng/ml, $P=0.509$; respectively postDmab and naïve) were comparable in the two groups. No difference was found in the overall APR rate (65.3 vs 58%, $P=0.156$; respectively postDmab and naïve) or in the moderate-severe APR rate (34.7 vs 42%, $P=0.156$ respectively postDmab and naïve) between the two groups. The logistic regression analysis showed a significant association between CTX levels and the occurrence of moderate-severe APR, regardless of age, group (naïve or postDmab) and VitD levels (OR 1.002, 95% CI 1.000-1.003, $P=0.027$).

Conclusions

In our cohort of ZOL treated patients we found a higher incidence of APR than reported in literature without significant differences between postDmab and naïve patients. In our cohort of VitD sufficient patients, CTX seems to be the only factor significantly associated with an increased risk of moderate-severe APR post ZOL infusion.

Key4OI: Development and implementation of a standard set of outcome measures for osteogenesis imperfecta

Anton Franken[1] & Dagmar Mekking[2]
[1]Isala Hospital Zwolle, Endocrinology, Netherlands; [2]Care4brittlebones, Netherlands

Key4OI : Development and implementation of a Standard set of Outcome measures for Osteogenesis Imperfecta. Osteogenesis Imperfecta (OI) is a genetic disorder also known as 'brittle bone disease'. The clinical manifestation of OI shows a wide variation. Therefore, care for patients with OI requires an interdisciplinary approach. The effectiveness of particular interventions and treatment protocols of interdisciplinary teams is not clear due to a non-standardized and wide variation of patient outcomes thus making the comparison of outcome measures available in the literature difficult. In 2018 the Key4OI project was started, an international interdisciplinary working group of 27 experts used a consensus-driven modified Delphi approach to develop a set of global outcome measures for patients with OI. More than 400 different outcome measures were identified in our literature search. After three Delphi rounds, 24 domains were selected. After the focus group sessions with members from OI community, the number of domains were reduced to 15. A consensus was reached on the measuring instruments to cover these domains for both children and adults. The entire approach was in line with the International Consortium for Health Outcomes Measurement ICHOM methodology. The Key4OI project resulted in a standard set of outcome measures focused on the needs and wishes of individuals with OI and their families. This outcome set will enable healthcare teams and systems to compare and to improve their care pathways and quality of care world. Implementation was started in 5 different countries (6 hospitals): China, Norway, USA, Canada and the Netherlands (Isala Zwolle and UMC Utrecht). Various other countries will start implementation in 2022. Anton Franken, D. Mekking on behalf of the international Key4OI expertgroup.

Dose-range analysis of the effects of the long-acting parathyroid hormone analog AZP-3601 versus PTH(1-34) delivered by daily injection or continuous infusion on blood calcium levels and bone metabolism in thyroparathyroidectomized (TPTX) rats

Cagri Aksu[1,2], Michael D Culler[3] & Thomas Gardella[1,2]
[1]Massachusetts General Hospital, Boston, United States; [2]Harvard Medical School, Boston, United States; [3]Amolyt Pharma, Écully, France

AZP-3601, a long-acting PTH/PTHrP(1-36) analog, is a candidate new treatment option for hypoparathyroidism (HP). As compared to conventional PTH(1-34), AZP-3601 binds with higher affinity to the R0 conformation of the PTH-1 receptor, resulting in prolonged signaling and sustained elevations in blood calcium (Ca^{++}) in vivo, despite a very short circulating half-life. We assessed whether repeated injection of AZP-3601 into TPTX rats at doses aimed to normalize serum Ca^{++} levels would produce different effects on bone than PTH(1-34) administered either intermittently or continuously.

Methods

Male S-D rats at age 9 weeks and 2 weeks after TPTX surgery received either a daily sc injection of AZP-3601 at doses of 1.0, 2.0 or 4.0 nmol/kg, daily sc injection of PTH(1-34) at 50, 100 or 150 nmol/kg, or continuous infusion of PTH(1-34) via ALZET mini pump at 1.5, 2.0 or 3.0 nmol/kg/day ($n=8$/group) for 16 days. TPTX controls received vehicle injections or infusion. Tail vein blood Ca^{++} was analyzed on days 7 and 14 at 6 h post-injection. Rats were euthanized on day16 (24 h post injection) and blood and femurs collected for analysis.

Results

Each treatment modality resulted in dose-dependent increases in blood Ca^{++} levels. Optimal doses for raising blood Ca^{++} to normal range (1.2-1.4 mM vs 0.9-1.1 mM in TPTX-vehicle controls, $P<0.001$) on days 7 and 14 were identified as 1.0 nmol/kg for AZP-3601 daily injection, 50 nmol/kg for PTH(1-34) daily injection and 3.0 nmol/kg/day for PTH(1-34) continuous infusion. Effects on bone markers and uCT parameters at these optimal doses were as follows: Continuous infusion of PTH(1-34) significantly increased serum levels of the bone formation marker P1NP ($P=0.03$) and the bone resorption markers CTX1 ($P=0.02$) and TRAP-5b ($P=0.03$), and decreased distal femur trabecular (Tb) bone volume relative to tissue volume (BV/TV, $P=0.002$), as well as mid-femur cortical thickness (Ct.Th $P=0.01$). Daily injection of PTH(1-34) significantly increased serum P1NP ($P<0.001$) and TRAP-5b ($P=0.001$), and increased distal femur trabecular BV/TV ($P=0.01$) as well as mid-femur cortical thickness($P=0.02$). Daily injection of AZP-3601 caused no significant change in these bone turnover and structural parameters.

Conclusion

At doses that similarly normalized blood Ca^{++} levels in TPTX rats, continuous infusion of PTH(1-34) was bone-catabolic, daily injection of PTH(1-34) was bone-anabolic and daily injection of AZP-3601 was bone-neutral. The distinct mechanism used by AZP-3601 may lead to less impact on bone, as compared to either daily injection or sustained, continuous delivery of PTH(1-34), when used as chronic treatments for HP.

Chan School of Public Health, Department of Environmental Health, Boston, United States; [9]University of Southern Denmark, OPEN, Odense, Denmark

Background
Perfluoroalkyl substances (PFAS) are endocrine disrupting chemicals, with elimination half-lives ranging from four to eight years. Experimental studies found PFAS able to interfere with thyroid hormone-binding proteins. During the first 20 weeks of gestation (GW), the fetus is reliant on placental transfer of maternal thyroid hormones, mainly free thyroxine (FT4). However, previous studies investigating associations between exposure to PFAS and thyroid hormone status mainly focused on blood samples from late pregnancy or umbilical cord with mixed findings.
Objectives
To investigate associations between concentrations of PFAS and FT4 and thyroid-stimulating hormone (TSH) in early pregnancy.
Methods
In Odense Child Cohort (OCC), a single-center study, we measured maternal pregnancy serum concentrations of five PFAS: perfluorohexane sulfonic acid (PFHxS), perfluorooctane sulfonic acid (PFOS), perfluorooctanoic acid (PFOA), perfluorononanoic acid (PFNA), perfluorodecanoic acid (PFDA); and FT4 and TSH in 1,048 pregnant women at median gestational week 12 (25th, 75th percentile: 10, 15). Multivariate linear regression models were performed to estimate associations between concentrations of PFAS and FT4 and TSH.
Results
Included women had a mean age of 30.2 ($\pm$ 4.5 SD) years and median pre-pregnancy BMI of 23.5 (5th, 95th percentiles: 19.2, 32.5) kg/^{2}, and 58.7% were nulliparous. A doubling in PFOS, PFOA, and PFNA concentrations was associated with an increment in FT4 concentration by 1.85% (95% CI: 0.66%, 3.05%), 1.29% (95% CI: 0.21%, 2.39%), and 1.70% (95% CI: 0.48%, 2.94%), respectively, in adjusted analyses. A statistically significant dose-response relationship was observed across exposure quartiles for PFOS, PFOA, and PFNA in the association with FT4. No association was found between concentrations of PFAS and TSH in adjusted analyses.
Conclusion and persepectives
Exposure to PFOS, PFOA, and PFNA was associated with higher FT4 concentrations in women during early pregnancy. Our observed associations between exposure to PFAS and FT4 concentrations were small in magnitude, nonetheless, the effects may be greater in populations with higher concentrations of PFAS exposure. The clinical significance of these findings remains to be elucidated. At population level, the demonstrated potential disruption of maternal thyroid hormone status in response to PFAS exposure during early pregnancy may affect offspring neurodevelopment. Hence, the findings are of general public interest, which supports the necessity of a follow-up of offspring in the OCC to assess putative long-term implications on neurodevelopment.

Effect of legacy and new generation PFAS on thyrocyte function

Luca De Toni[1], Andrea Di Nisio[1], Stefano Dall'Acqua[2], Stefania Sut[2], Maria Santa Rocca[3], Alberto Ferlin[1] & Carlo Foresta[1]

[1]University of Padova, Department of Medicine, Italy; [2]University of Padova, Department of Pharmacological Sciences, Italy; [3]Padova University Hospital, Italy

Perfluoroalkyl substances (PFASs) have been claimed as thyroid disrupting chemicals since the exposure to several PFASs was significantly associated with thyroid hormones derangements. Demographics such as sex, age, and disease status likely influence the associations between PFASs exposure and thyroid hormones since major hypothyroidism effects were observed among pregnant women and infants. This study aims to evaluate of the possible impact of legacy and new-generation PFAS exposure on the thyroid stimulating hormone (TSH) receptor (THSR)-mediated effects on available cell models of thyrocytes. Based on their surfactant properties, PFAS are supposed to interfere with the cell function through the alteration of the biophysical properties of plasma membrane. FRTL-5 normal rat thyroid follicular cell line was exposed to C6O4, perfluorooctanoic-acid (PFOA) or perfluoro-octan-sulphonate (PFOS) at a concentration ranging from 0 ng/ml (CTRL) to 100 ng/ml for 24 hours and the possible cell accumulation was evaluated by LC-MS/MS. The cell content of all tesetd PFAS was below the limit of detection and, accordingly, membrane fluidity evaluated by Merocyanin 540 (MC540) showed no obvious variation showed no variation compared to CTRL. The quantification of intracellular cAMP levels upon stimulation with 10 mIU/ml of TSH for 30 minutes showed a significant reduction, compared to CTRL sample, when cells were exposed for 24 hours exposure to PFAS. A dose-dependent effect detected for PFOA whilst, for C6O4 and PFOS, a sharp blunt of cAMP was observed at the lowest concentration tested. The possible interaction of TSHR with PFAS was evaluated by computational docking methods, addressing the possible binding of C6O4 or PFOA to TSHR extracellular domain. Molecular dynamics also showed that the receptor bound by C6O4 or PFOA displayed major conformational differences related to the unbound receptor. Specifically, the root-mean-square deviation (RMSF) profile of the atomic positions in LEU100-GLN170 range, the most involved in the binding to TSH, showed a modified flexibility than the unbound structure, particularly for PFOA. The cell iodide uptake upon 10 mIU/ml TSH stimulation was then evaluated with the Sandell-Kolthoff (SK) reaction. Stimulation with TSH was associated with a strong and significant increase of the intracellular iodide levels in CTRL conditions. Differently, the exposure to PFOA was associated with a significant reduction of iodide uptake at the highest concentration tested of 10 ng/ml, whilst C6O4 and PFOS were essentially unaffected. Further gene expression experiments are planned to clarify whether this effect is mediated by a down-regulation of downstream event related to TSHR-signaling.

Transcriptional profiling of developing male rat perineum and phallus following exposure to the anti-androgenic fungicide triticonazole

Monica Kam Draskau[1], Camilla Lindgren Schwartz[1], Bertrand Evrard[2], Aurélie Lardenois[2], Andrew Pask[3], Frédéric Chalmel[2] & Terje Svingen[1]

[1]National Food Institute, Technical University of Denmark, Kgs Lyngby, Denmark; [2]Université de Rennes, Inserm, EHESP, Irset (Institut de recherche en santé, environnement et travail), Rennes, France; [3]School of BioSciences, University of Melbourne, Melbourne, Australia

Androgen signaling is essential for male reproductive development and masculinization during fetal life. Developmental exposure to endocrine disrupting chemicals, not least those that disrupt androgen action, can lead to reproductive disorders such as cryptorchidism, hypospadias, and poor fertility. In rodent toxicity studies, as well as human epidemiological studies, a general biomarker for compromised fetal androgen signaling is a shorter

anogenital distance (AGD) in male offspring. Some outstanding questions, however, is if AGD is strictly sensitive to anti-androgenic effects or if other signaling pathways are involved such as estrogen signaling. Similarly, penis development and hypospadias formation also involve additional signaling pathways, but which pathways that are vulnerable to developmental exposure to endocrine disruptors are not well characterized. Therefore, we need a better molecular understanding of how these tissues are regulated and vulnerable to chemical exposures. Triticonazole, an agricultural azole fungicide, inhibits androgen receptor activity in vitro and induces short AGD in male rat offspring following gestational exposure. Though triticonazole has anti-androgenic properties, we previously showed that intrauterine exposure does not affect the transcriptome of the fetal rat testes. We thus investigated the transcriptional effects in the androgen-sensitive fetal male rat perineum and phallus. Pregnant Sprague Dawley rats were exposed via oral gavage to triticonazole (450 mg/kg bw/day) or corn oil (control) from gestational day (GD) 7-21. Fetuses (n=11-12) were collected at GD17 or GD21 and perineum and phallus were isolated. Bulk RNA barcoding and sequencing (BRB-seq) was used to analyze the transcriptomes. The transcriptomes of the developing rat perineum and phallus changed significantly during late gestation, showing distinct regional differences between these adjacent tissues and revealing 2,703 differentially expressed genes (DEGs). The transcriptional changes induced by triticonazole exposure (190 DEGs) were different between perineum and phallus, but also between different stages of development. Interestingly, DEGs not only included several androgen receptor (AR) target genes, but also estrogen receptor (ER) target genes. Our results highlight the importance of considering chemical mode of action and spatiotemporal effects when using transcriptomics approaches in characterizing complex in vivo adverse outcomes in toxicity studies. These data furthermore constitute a rich resource for studying the spatiotemporal gene networks that are involved in the development of rat perineum and phallus and the regulatory networks that can be disrupted upon exposure to xenobiotics that prevent normal masculinization of the male fetus and lead to reproductive disorders.

[1]Università Federico II di Napoli, Dipartimento di Medicina Clinica e Chirurgia, Sezione di Endocrinologia, Unità di Andrologia e Medicina della Riproduzione e della Sessualità Maschile e Femminile (FERTISEX-CARES), Naples, Italy; [2]Università degli Studi di Napoli Federico II, Dipartimento di Scienze Chimiche, Naples, Italy; [3]University of Campania "Luigi Vanvitelli", Medical Statistics Unit, Naples, Italy; [4]Università Federico II di Napoli, Unesco Chair for Health Education and Sustainable Development, Naples, Italy

Campania Region has been facing waste management crisis since 1980, characterized by urban, toxic and industrial waste illegal disposal, burying and incineration. Cadmium (Cd) is consistently shown to affect male reproductive function by multiple mechanisms, mostly elucidated in experimental models. The aim of the current single-center, observational, cross-sectional cohort study was to evaluate the prevalence of testis morphostructural alterations in a large cohort of men living in 3 municipalities of Campania Region (Acerra, Afragola, Giugliano) belonging to the high-environmental impact area "Land of Fires", by addressing the potential association with seminal Cd (sCd) levels. Study cohort included 465 males (age range: 14-50 yrs mean: 29.5±7.23 yrs). Morphostructural testis characteristics were assessed by ultrasound and sCd determination was performed in 385 samples by inductively coupled plasma-mass spectrometry. Prevalences of testis morphostructural alterations, unilateral or bilateral, included varicocele (35.4%), hydrocele (34.8%), parenchymal structure inhomogeneity (19%), hypotrophy (14.6%), microlithiasis (2.5%), solid lesions >5 mm (0.2%). Participants with detectable sCd levels (n=128) displayed significantly reduced mean testicular volume (16.56 ± 4.68 vs 17.66 ± 4.34; P=0.0153) and higher prevalence of hypotrophy (21% vs 10%; P=0.0059) and varicocele I-V° grade (47.5% vs 29.5%; P=0.0008), but not clinically relevant varicocele III-V grade (18% vs 11%, P=0.09), together with a slightly higher parenchymal structure prevalence of inhomogeneity (25.8% vs 16.7%; P=0.059) compared to participants with undetectable sCd levels (n=257). Furthermore, a significant difference in mean testicular volume was detected when comparing participants with sCd levels above (n=49) and below median value (n=79) and undetectable sCd levels, respectively (14.88 ± 3.79 vs 17.22 ± 5.03 vs 17.66 ± 4.34; P< 0.001). sCd level was persistently correlated with mean testicular volume after correction for the presence of clinically relevant varicocele (r=-0.185; P=0.001). sCd levels was identified as the best predictor of mean testicular volume in linear regression analysis performed by setting sCd, smoking habit, age and BMI as independent variables. ROC curve analysis highlighted that a sCd level >0.76 µg/l correctly identified testicular hypotrophy with a 60% sensibility and 70% specificity. In conclusion, the current study demonstrated for the first time, in a large cohort of adult males living in high-environmental impact areas of Campania Region, an inverse relationship between sCd levels and mean testicular volume and prevalence of varicocele, independently from age, BMI and smoking habit, therefore further strengthening the concept of gonadal toxicity exerted by Cd, potentially explained by Cd-induced damage to testicular vascular endothelium.

Decoding the role of environmental cadmium exposure in thyroid disorders

Aleksandra Buha[1], Dragana Javorac[1], Katarina Baralic[1], Stefan Mandic-Rajcevic[2], Djurdjica Maric[1], Evica Antonijevic-Miljakovic[1], Danijela Djukic-Cosis[1], Milos Zarkovic[3], Biljana Antonijevic[1] & Zorica Bulat[1]

[1]University of Belgrade - Faculty of Pharmacy, Department of Toxicology, Belgrade, Serbia; [2]Institute of Social Medicine and School of Public Health and Health Management, Belgrade, Serbia; [3]Department of Endocrinology, Diabetes and Metabolic Diseases, Belgrade, Serbia

As a ubiquitously present metal, cadmium (Cd) represents a matter of great concern, especially considering its potential thyroid disrupting capacity. The study evaluated the connection between this environmentally relevant metal exposure and thyroid hormone levels. The DecodExpo study enrolled 425 participants (207 males and 218 females) with various disorders (236 participants) and healthy controls (189 participants). Collected blood samples were digested, and Cd levels were determined by flame atomic absorption method (AAS GTA 120 graphite tube atomizer and FAAS, Agilent technologies, Santa Clara, CA, USA). In contrast, thyroid-stimulating hormone (TSH) and free thyroxine (FT4) were measured in serum. The dose-response relationship between Cd in thyroid hormone disturbances was elucidated using a novel Benchmark dose (BMD) approach previously proposed as applicable to human data by the EFSA guidance. The Benchmark response (BMR) was set at 10% in the modeling procedure, expressed as an additional risk in% - an absolute change in response frequency divided by the non-affected fraction in the control population. PROAST 70.1 software was used for the calculations. Out of 435 participants, 76 had various thyroid disorders, and nearest-neighbor matching was performed to select the closest eligible healthy control unit paired with each patient with a thyroid disorder. Blood Cd levels were then compared between the two newly established

groups: cases, and controls using the Man-Whitney-Wilcoxon test. The statistical analyses were performed using the R language and environment for statistical computing with additional packages. The BMD calculations revealed the following confidence interval for FT4 1.22-915 µg/l for men and 0.784-721 µg/l for women, while confidence intervals obtained for TSH were even wider. Although dose dependence was observed for Cd's relationship with investigated hormones, the intervals calculated were wide, suggesting a high level of uncertainty. When comparing Cd levels in two established groups, the medium measured Cd blood level was 2.185 µg/l in cases while measured levels were 1.794 µg/l in corresponding controls, with no statistical differences observed between the Cd levels in these two groups. However, lower confidence intervals of BMD calculated for FT4 and TSH in both sexes were lower than the medium blood Cd levels obtained for the entire study, i.e., 1.8 µg/l (0.03-5.80 µg/l), which could suggest an additional risk of thyroid hormone disturbances due to Cd environmental exposure. Even though inconclusive, the results of this study urge the need for further investigations to elucidate the role of environmental exposure to Cd in thyroid disorders.

Iodine nutrition among adolescent Faroese comply with recommendations – are we home-safe?

Herborg Líggjasardóttir Johannesen[1], Stig Andersen[2], Kári Rubek Nielsen[3], Pál Weihe[4], Maria Skaalum Petersen[4] & Anna Sofía Veyhe[4]
[1]The National Hospital of the Faroe Islands, Department of Endocrinology and Medicine, Torshavn, Faroe Islands; [2]Aalborg University, Department of Clinical Medicine,, Aalborg, Denmark; [3]The National Hospital of the Faroe Islands, Department of Gasteroenterology and Medicine, Torshavn, Faroe Islands; [4]The Faroese Hospital System, Department of Occupational Medicine and Public Health, Torshavn, Faroe Islands

Introduction
Iodine nutrition is critical for human health. In recent years the main focus was on the developing brain during pregnancy. In addition, iodine nutrition is essential for growth and development during adolescence. Iodine nutrition was recently low within the recommended range among adult Faroese living on local, iodine-rich marine food items. Dietary habits among young generations are drifting away from local foods, and this raises a concern that led us to perform the first study of iodine nutrition among Faroese teenagers.
Method
We surveyed 14-year olds aiming for the number of participants recommended for a 90% precision of the estimated iodine nutrition level: Urin from one hundred twenty-nine girls ($n=65$) and boys ($n=64$) sampled in iodine-free containers. Iodine was measured using standard laboratory methods using the ceri/arsen method after alkaline ashing and creatinine. We calculated the iodine/creatinine ratio to adjust for dilution. A food frequency questionnaire recorded intake of iodine-rich foods.
Results
The median urinary iodine concentration was 166 µg/l, creatinine adjusted 124 µg/g. Iodine was in recommended range in 102 urine samples (79%), above the recommended range in 22 (17%), and in the range of insufficiency in 4%. No single sample suggested severe iodine deficiency. The urinary iodine concentration was markedly higher in those who reported higher "fish dinners per week" than those who reported limited or no fish intake.
Conclusion
Our nationwide study demonstrated Faroese teenagers to be iodine replete according to the WHO recommendations. However, the Faroese may have adapted to a high iodine intake from the formerly frequent intake of marine foods. Dietary habits change with new generations, and surveying iodine deficiency disorders is needed. In addition, the changing dietary habits emphasise the need for continuous monitoring of iodine nutrition.

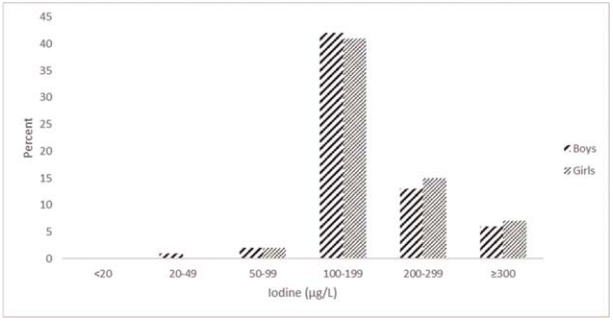

Figure 1 Proportions of urinary iodine concentrations among 14-year-old Faroese boys and girls, from a population-based sample of 129 participants divided into the following groups: moderate (20-49), mild deficiency (50-99), adequate (100-199), slightly increased (200-299) and excess (300+).

Single-cell molecular and functional mapping of POMC neurons in obesity: a multi-modal approach

Stéphane Léon[1], Vincent Simon[1], Thomas H Lee[1], Samantha Clark[1], Nathalie Dupuy[1], Yves Le Feuvre[1], Xavier Fioramonti[2], Daniela Cota[1] & Carmelo Quarta[1]
[1]University of Bordeaux, INSERM, Neurocentre Magendie, U1215, Bordeaux, France; [2]University of Bordeaux, INRAe, NutriNeuro, UMR 1286, Bordeaux, France

The brain plays a crucial role in maintaining the body's energy needs, a process involving the activity of a group of hypothalamic neurons that express the neuropeptidergic marker pro-opiomelanocortin (POMC). POMC neuronal dysfunction can cause obesity and its associated metabolic sequelae. However, this population of neurons is highly diverse at a molecular and functional level, and whether or not such heterogeneity is implicated in disease establishment or progression has yet to be elucidated. Here, using a lineage-tracing approach in combination with histological and electrophysiological tools, we have characterized POMC neuronal cells at a single-cell resolution in control of lean and diet-induced obese (DIO) mice. Thanks to this genetic strategy, we 'traced' with a reporter protein POMC neurons in adult mice, thus studying these neuronal cells independently from the expression of their main marker POMC. Different histological techniques, including immunohistochemistry, fluorescent in-situ hybridization, and RNAscope, have been used to cluster genetically 'traced' POMC neuronal cells based on their expression of the main marker POMC. These different approaches consistently allowed the identification of a previously uncharacterized sub-population that expresses negligible POMC mRNA and protein levels, which we named Ghost-POMC neurons. We also observed that Ghost-POMC neurons are insensitive to acute nutritional cues (fasting and refeeding) relative to 'classic' POMC positive neurons. Intriguingly, DIO mice presented an increased number of Ghost-POMC neurons relative to control animals. Furthermore, we developed an approach that combines whole-cell patch-clamp of traced POMC neurons with the subsequent molecular profiling of the patched cell by single-cell qPCR. Thanks to this approach, we observed that DIO leads to electrical alterations only in a fraction of POMC neurons expressing undetectable levels of POMC mRNA, which is reminiscent of the Ghost population previously identified by histological techniques. Thus, Ghost-POMC neurons might constitute a novel subpopulation of POMC neurons that undergo dysfunction in response to prolonged dietary cues, perhaps contributing to obesity establishment or progression.
Keywords: POMC neurons; heterogeneity; neuroanatomy; electrophysiology.

Success in implementing changes in macronutrients intake in a high-protein and high-unsaturated fatty acids dietary intervention: 36-months results of the NutriAct randomized controlled multi-center trial

Laura Pletsch-Borba[1], Charlotte Wernicke[1], Nina Meyer[1], Thu Nguyen[1], Anne Pohrt[2], Christiana Gerbracht[3], Andreas Pfeiffer[1], Joachim Spranger[1] & Knut Mai[1]
[1]Charité Universitätsmedizin Berlin, Endocrinology and Metabolism, Berlin, Germany; [2]Charité Universitätsmedizin Berlin, Institute of Biometry and Clinical Epidemiology, Germany; [3]Human Study Center, German Institute of Human Nutrition Potsdam-Rehbrücke, Germany

Background & Aims
NutriAct is a 36-month randomized controlled multi-center trial aiming to analyze the effects of a dietary pattern focusing on a high-protein and high-unsaturated fatty acids (UFA) intake on healthy aging. We aimed to explore changes in intake of macronutrients and determine factors associated with a successful modulation of dietary pattern after 36 months in elderly community dwelling participants.
Methods
502 participants were randomized into a usual care control group including dietary recommendations of the German Nutrition Society or an intervention group, which used supplementation of rapeseed oil and specifically designed foods as well as repetitive advices to implement a food pattern based on high intake of predominantly plant proteins and UFA. Food intake was repeatedly assessed by 3-day food records at months 0, 3, 6, 12, 24 and 36 months. Linear regression models were carried out to investigate differences in changes in macronutrients intake between the intervention arms and determinants of modulation of dietary pattern during the intervention in 36 months.
Results
148 intervention and 164 control participants (median age 66 y, 36% males) with available food records at baseline and at month 36 and were included. The intervention resulted in higher intake of protein, mono- and polyunsaturated fatty acids (MUFA and PUFA) and fiber, and lower carbohydrate and saturated fat consumption (all $P < 0.05$). While individuals who were already at baseline closer to the NutriAct pattern also achieved a diet closer to the proposed pattern at month 36, the strongest relative changes of dietary behavior were seen in those with dietary patterns further away from the proposed pattern at baseline. Sex, age, baseline BMI, education, comorbidities, smoking, cognitive status and shared household were not associated to a higher implementation of the proposed diet.
Conclusions
A successfully modification of dietary pattern was achieved by the intervention within 36 months. Baseline dietary habits were substantial determinants predicting change in dietary pattern.

Table. Changes in macronutrients intake between baseline and month 36 between intervention and control groups

Macronutrient	Beta coefficient (95% CI)	*P*-value
Protein (%E)	2.35 (1.44, 3.25)	<0.01
Total fat (%E)	2.70 (1.00, 4.39)	<0.01
Carbohydrate (%E)	-4.83 (-6.60, -3.05)	<0.01
Sat. Fatty acids (%E)	-2.30 (-3.24, -1.32)	<0.01
PUFA (%E)	3.57 (2.70, 4.44)	<0.01
MUFA (%E)	0.82 (0.08, 1.60)	0.03
Fiber (%E)	3.64 (1.72, 5.56)	<0.01

Glucose-dependent insulin secretion is regulated by mitochondrial-associated cannabinoid receptor type 1 (mtCB1)

Camille Allard[1], Philippe Zizzari[1], Samantha Clark[1], Nathalie Dupuy[1], Francisco-Javier Bermudez-Silva[2], Concepción Lillo Delgado[3], Luigi Bellocchio[4], Giovanni Marsicano[4], Carmelo Quarta[1] & Daniela Cota[1]

Type 2 diabetes is among the most prevalent chronic diseases worldwide. Further research is needed to identify new mechanisms that may help preserve the function of insulin-secreting pancreatic β-cells. The cannabinoid receptors type 1 (CB1) and their endogenous ligands, endocannabinoids, exert a key role in regulating of glucose homeostasis, β-cells function, and insulin secretion. Intriguingly, CB1 is not only located at the plasma membrane (pmCB1), but also at the mitochondrial membrane component (mtCB1), albeit the relative contribution of subcellular CB1 signaling on β-cell function and glucose control has yet to be determined. This study aimed to uncover the relative role(s) of pmCB1 and mtCB1 in β-cell physiopathology, with a particular focus on the differential impact on insulin secretion and mitochondrial function. For this purpose, we used an animal model expressing a mutant form of CB1 (named DN22-CB1) which lacks in vivo mitochondrial localization and functions but retains pmCB1-related signaling. DN22-CB1 mice present no difference in body weight and insulin sensitivity compared to control littermates, nor when fed chow or a hypercaloric high-fat diet (HFD). However, chow-fed DN22-CB1 mice are hyperglycemic after an overnight fast, and following a glucose load. Hyperglycemia in DN22-CB1 mice is then further worsened under HFD feeding. Regardless the diet, DN22-CB1 mice display reduced in vivo plasma insulin relative to controls. Glucose-stimulated insulin secretion (GSIS) data obtained ex-vivo from isolated islets of chow-fed DN22-CB1, full CB1-KO and control littermates suggest that pmCB1 and mtCB1 act as Ying-Yang partners to influence insulin secretion. Indeed, CB1KO islets display an increased GSIS, whereas GSIS and mitochondrial respiration is blunted in DN22-CB1 islets, with no significant changes in cytosolic calcium signaling. Our work pinpoints a novel molecular mechanism whereby subcellular CB1-dependent signaling orchestrate mitochondrial functions and glucose-dependent insulin secretion in β-cells to influence systemic glucose homeostasis. These findings might have implications for type 2 diabetes pharmacotherapy, thus resurrecting the interest in the use of CB1 receptor modulators in metabolic diseases.

Variants in obesity-related genes in a population with early-onset obesity

Patrick Kleyn, Ilia Ichetovkin & Ida H Moeller
Rhythm Pharmaceuticals, Boston, United States

Introduction
Genetic testing can improve the diagnosis of rare genetic diseases of obesity and identify patients who may benefit from targeted therapeutic intervention. For example, patients with genetic defects in the melanocortin-4 (MC4R) pathway may present with severe early-onset obesity and hyperphagia. Historically, however, genetic testing in patients with obesity has been limited. The Uncovering Rare Obesity® diagnostic genetic testing program aims to enhance access to genetic testing for these patients. The frequency of rare genetic variants in this clinical patient population is currently unknown.
Methods
We sequenced 8599 individuals with severe, early-onset obesity as part of the US-based Uncovering Rare Obesity® program. Genes selected include those with well-established associations with obesity, as well as genes associated with the MC4R pathway. In this program, we sequenced 7811 individuals for 40 genes, and recently expanded the gene panel to include an additional 39 genes and the 16p11.2 chromosomal region; 788 individuals have been sequenced on the broader panel. Yield estimates were weighted by the number of individuals sequenced for each gene.
Results
Integrating across the two panels using weighted yield estimates, 54.6% of sequenced individuals had variants that may qualify them for commercial or investigational treatment with the MC4R agonist setmelanotide. An additional 9.9% of individuals had variants not eligible for setmelanotide treatment, but that may support a genetic diagnosis of obesity. Overall, 2.7% of individuals carried pathogenic or likely pathogenic variants that also met mode of inheritance criteria (2 or more alleles in autosomal recessive conditions and 1 or more alleles in autosomal dominant conditions).
Conclusions
In this selected cohort of individuals with severe, early-onset obesity, 64.5% carried potentially clinically relevant variants. As additional data become available about the investigational genes and obesity, and/or as new obesity-related genes are identified, these estimates may change. Genetic testing of patients with severe obesity, particularly those with a history of early-onset

obesity suggestive of a potential genetic origin, may therefore be an important component of understanding the etiology of these patients' phenotypes, and may potentially impact the course of care for these patients.

Metabolic-associated fatty liver disease (MAFLD) is a growing cause of hepatocellular carcinoma (HCC), but the molecular mechanisms associated with the pathological progression from MAFLD to HCC are still to be fully elucidated. The genomic and transcriptomic profile of HCC samples have been widely described; however, the proteomic landscape of MAFLD-derived HCC samples is mostly unknown. Here, we sought to perform the first quantitative proteomic analysis of HCC samples from different aetiologies using a representative, well-characterized cohort of patients. To that end, cytosolic and nuclear proteome of liver tissues from HCC patients ($n=42$; HCC vs adjacent tissue) and healthy controls ($n=5$) were determined by SWATH-MS-based proteomics and the results were analyzed using different bioinformatics tools. Non-targeted proteomics revealed the dysregulation of the cytosolic ($n=507$ proteins) and nuclear ($n=925$ proteins) tumor proteomes. Enrichment analysis revealed altered cellular functions such as mRNA processing, including mRNA splicing. Indeed, the dysregulation of the splicing machinery was confirmed in two retrospective human cohorts [cohort 1: HCC vs adjacent ($n=93$); cohort 2: HCC vs adjacent ($n=58$), cirrhosis ($n=39$), and healthy livers ($n=5$)] and in different *in silico* HCC cohorts. Specifically, from the 94 splicing factors identified in the proteomic analysis, 31 were validated in the retrospective and *in silico* cohorts, and were associated with key clinical parameters of aggresiveness (tumoral diameter, survival). Interestingly, some of these splicing factors (ej. KHSRP) were associated to metabolic alterations such as diabetes. When comparing between aetologies, we identified cellular pathways (ej. "nucleotide excision repair", EIF4 and p70S6K signalling) speciffically dysregulated in MAFLD-derived HCC patients, and a battery of more than 20 splicing factors specifically dysregulated in this aetiology [e.g. SNRPD1 and LSM2, two critical components of the small nucleolar ribonucleoproteins (snRNPs) U1/U2/U4/U5 and U6]. Accordingly, culstering analysis defined a HCC subgroup with lower survival and higher recurrence that was associated to the dysregulation of the splicing machinery and included all patients with MAFLD-derived HCC. Finally, *in vitro* assays (proliferation, colonies/tumorspheres) were performed in liver cancer cell lines (HepG2, Hep3B, SNU-387) after silencing *SNRPD1* and *LSM2* with specific siRNAs. Remarkably, *in vitro* silencing of these splicing factors significantly reduced proliferation and dedifferentiation capacity in cancer cells. Our study demonstrates the usefullness of quantitative proteomics for the identification of tumoral subgroups in HCC and the potential of the splicing machinery as a tool for HCC management, specially in less described aetiologies, such as MAFLD.

Opposite actions of LEAP-2 and ghrelin in energy homeostasis

Sabela Casado Masa[1,2,3], Tadeu De Oliveira Diz[1,3], Marta Varela Miguéns[1], Carlos Diéguez González[1,2,3] & Sulay Tovar Carro[1,2,3]

[1]Centro Singular de Investigación en Medicina Molecular y Enfermedades Crónicas (CIMUS)-Universidad de Santiago de Compostela, Fisiología, Santiago de Compostela, Spain; [2]Centro de Investigación Biomédica en Red de la Fisiopatología de la Obesidad y la Nutrición (CIBERobn), Spain; [3]Instituto de Investigación Sanitaria de Santiago de Compostela (IDIS), Santiago de Compostela, Spain

Liver-expressed antimicrobial peptide 2 (LEAP-2) has been recently characterized as an endogenous GHSR1a antagonist. LEAP-2 is produced mainly in the liver, and it was described that an acute ghrelin administration blocks food intake, GH release and normalize glucose levels during chronic caloric restriction. For this reason, it could be considered as a key endocrine factor in the regulation of systemic energy metabolism. Nevertheless, the exact mechanism of action is still unknown. Our aim was to investigate the central LEAP-2 effects in energy homeostasis in mice with standard diet and in a ghrelin resistance mice model induced by diet. We used male C57BL/6 mice fed standard or high fat diet (60% fat, 12 weeks). We performance an acute or chronic ICV administration of vehicle, ghrelin, LEAP-2 or ghrelin and LEAP-2. Food intake, body weight and circulating cholesterol and leptin plasma levels were measured. Human HEPG2 hepatocytes treated with oleic acid were used and they were co-treated with LEAP-2. Hepatic fat accumulation was analysed using oil red-O staining. Genes related to glucose and lipid metabolism were studied by qPCR. Statistical analysis conducted through t-student and ANOVA. The results obtained showed that LEAP-2 inhibits food intake, and body weight in all the mice models studied and in an acute and chronic treatment. Moreover, chronic treatment is able to decrease the orexigenic response of ghrelin when they are co-administered. Furthermore, LEAP-2 decreases leptin and cholesterol plasma levels, and decreases the liver lipid content. When we analysed human hepatocytes treated with LEAP-2, they exhibit a lower lipid accumulation with a reduction in the expression of genes of gluconeogenesis and *de novo* lipogenesis in standard conditions and under oleic acid effect. As a conclusion, chronic central administration of LEAP-2 in mice antagonizes the major effects of ghrelin in vivo and the co-administration with ghrelin attenuates the ghrelin orexigenic and obesogenic effects, in a diet independent manner. Moreover, it decreases fat accumulation directly in human hepatic cells. These novel results place LEAP-2 as a counter-regulatory hormone in the ghrelin system, and as a promising therapeutic target in the treatment of obesity, MAFLD and other metabolic diseases.

Thr92Ala polymorphism of the type 2 deiodinase (DIO2) is associated with higher risk of iatrogenic thyrotoxicosis in thyroidectomized subjects treated with levothyroxine and liothyronine

Gisella Boselli[1,2], Gianluca Margiotta[1,2], Rossella Corleto[1,2], Maria Laura Monzani[1,2], Andrea Craparo[1,2], Michela Locaso[1,2], Samantha Sperduti[1,3], Manuela Simoni[1,2], Vincenzo Rochira[1,2], Daniele Santi[1,2] & Giulia Brigante[1,2]

Introduction

Hypothyroidism treatment is classically based on levothyroxine (LT4). However, 10% of hypothyroid patients treated with LT4 complain of hypothyroidism symptoms, despite normal thyroid stimulating hormone (TSH) serum levels. This "peripheral hypothyroidism" has been linked to decreased availability of free triiodothyronine (fT3), likely related to single nucleotide polymorphisms (SNP) in deiodinase genes (*DIO*), reducing enzymatic activity. Since *Thr92Ala-DIO2* was associated to altered responsiveness to LT4, combined levothyroxine/liothyronine (LT4/lT3) therapy was suggested to improve quality of life in hypothyroid patients encoding *Thr92Ala-DIO2*.

Aims

To evaluate the influence of *Thr92Ala-DIO2* variant on thyroid therapeutic compensation in thyroidectomized subjects treated with LT4 or LT4/lT3.

Methods

An interim analysis of a prospective, randomized, placebo-controlled, double-blinded clinical trial was performed. Totally thyroidectomized patients treated with LT4 and with TSH levels within reference range in the previous 3 months were enrolled. Subjects were randomized in two groups: personalized-combined-twice-daily therapy with LT4/lT3 at 13-20:1 ratio (study group) and LT4 + placebo (control group). Subjects were evaluated three times during the 6-month treatment. Iatrogenic thyrotoxicosis and hypothyroidism rates were assessed at each visit, measuring serum levels of TSH, fT4 and fT3. DNA was extracted from blood samples and the DIO2 genotype was analysed by Sanger's sequencing. The *Thr92Ala-DIO2* rate was calculated in both groups.

Results

A total of 139 patients (age 55.6±12.1 years, TSH 1.3±1.4 microIU/ml) were enrolled, 70 in the study (age 55.1±10.9 years) and 69

in the control group (age 56.0±13.4 years). *Thr92Ala-DIO2* frequency (11.4%) was similar to general population (12-36%). Drop-out rate did not differ between groups (11.4 vs 14.5%, respectively, $P=0.591$) and no difference was found in biochemical thyroid function examinations (considering also fT3/fT4 ratio) and LT4 pro-Kg dosage comparing study and control groups at baseline. Combined LT4/lT3 therapy resulted in more frequent iatrogenic thyrotoxicosis than LT4 monotherapy (9.8% vs 2.2%; $P<0.05$), with a significantly higher incidence in *Thr92Ala-DIO2* carriers. More frequent dose adjustments were required in the study group compared to controls (44.5% vs 22.5%; $P<0.001$) and, among cases, in those with *Thr92Ala-DIO2 compared to wild-type* (52.0% vs 37.6%; $P<0.05$).

Conclusion

Thr92Ala-DIO2 variant seems to have no influence on LT4 monotherapy effectiveness. In our interim analysis, carriers of *Thr92Ala-DIO2* are at higher risk of iatrogenic thyrotoxicosis when treated with LT4/lT3: this result surprisingly suggest an increased enzymatic activity in SNP carriers. Accordingly, the management of these patients is more challenging, requiring more frequent dose adjustments in the first six months of therapy.

What you choose makes the difference: the first medical therapy for amiodarone-induced thyrotoxicosis has significant implications on cardiovascular events and hospitalizations

Daniele Cappellani[1], Giada Cosentino[1], Riccardo Morganti[2], Luca Manetti[1], Luigi Bartalena[3] & Fausto Bogazzi[1]

[1]University of Pisa, Department of Clinical and Experimental Medicine, Pisa, Italy; [2]University Hospital of Pisa, Unit of Statistics, Pisa, Italy; [3]University of Insubria, Department of Medicine and Surgery, Varese, Italy

Context

Amiodarone is a widely used anti-arrhythmic medication, however associated with a 15-20% rate of thyroid adverse effects. Amiodarone-induced thyrotoxicosis (AIT) is a complex disease due to diagnostic difficulties and therapeutic challenges. AIT patients often receive initial therapy for thyrotoxicosis before admission to a referral center. Whether the first-line medical therapy (i.e. therapies for thyrotoxicosis at first diagnosis of AIT) may affect the outcome of AIT patients is unknown.

Study design

Single-center historical-prospective cohort study of 313 AIT patients admitted to our university referral center for amiodarone-induced thyroid disorders.

Methods

Clinical and biochemical data at first diagnosis, at a referral center, and during the course of AIT were collected. The medical figures responsible for the first approach to the disease were recorded. Primary outcomes were cardiovascular (CV) events and hospitalizations. First-line therapies were appropriate when included glucocorticoids for type 2 AIT and methimazole for type 1 AIT at the approved dosage, either alone (optimal medical therapy, OMT) or in combination (right-dose combination therapy, RCT). Other therapies were considered not appropriate, including no therapy. Duration of exposure to thyrotoxicosis was the time from first diagnosis of AIT to its remission.

Results

34.5% patients received appropriate therapy (28.1% OMT and 6.4% RCT), whereas non-appropriate therapies accounted for 65.6% of cases: specifically most patients originally approached by general practitioners and cardiologists received no therapy at all (56.9% and 50% respectively), whereas inappropriate therapies for the AIT-type (i.e. glucocorticoids for type 1 AIT and methimazole for type 2 AIT) was the most common therapy for patients originally approached by endocrinologists outside the referral center. CV events, and hospitalizations were more frequent in patients who received non-appropriate therapies (33.2% vs 4.5%, and 24.9% vs 6.5%, respectively; $P<0.0001$ for both). Appropriate therapies reduced serum thyroid hormone concentrations ($P=0.018$) at variance with non-appropriate therapies. The duration of exposure to thyrotoxicosis was longer in patients receiving non appropriate therapies and was a risk factor for arrhythmias (HR 1.004, $P=0.0008$), MACEs (HR 1.004, $P=0.020$) and hospitalizations (HR 1.006, $P<.0001$).

Conclusions

The first medical therapy of AIT influences the exposure to thyrotoxicosis and the occurrence of cardiovascular events and hospitalizations.

PD-1/PD-L1 inhibitors and immune-related thyroid toxicity according to pre-existing thyroid dysfunction and TPO antibody levels: a single centre experience

Giovanni Gruosso[1], Alice Anna Nervo[1], Sara Basile[1], Enrica Migliore[2], Valentina D'Angelo[1], Matteo Ferrari[1], Anna Roux[1], Alessandro Piovesan[1] & Emanuela Arvat[1]

[1]Azienda Ospedaliero-Universitaria Città della Salute e della Scienza di Torino, Oncological Endocrinology Unit, Torino, Italy; [2]Azienda Ospedaliero-Universitaria Città della Salute e della Scienza di Torino, Cancer Epidemiology Unit, Torino, Italy

Background

Immune checkpoint inhibitors (ICIs) have modified the outcome of several advanced malignancies. Thyroid dysfunctions (DYSTHYR) are the most common endocrine immune-related adverse events (IRAEs) during treatment with the programmed cell death protein-1 (PD-1) and its ligand (PD-L1) inhibitors. Data regarding predictive biomarkers enabling stratification of DYSTHYR risk are still limited.

Patients and methods

We retrospectively analyzed patients who started treatment with PD-1/PD-L1 inhibitors between 2017 and 2020 at Città della Salute e della Scienza Hospital (Department of Oncology). Both the onset of new DYSTHYR during ICI and the worsening of pre-existing DYSTHYR were recorded; patients with central hypothyroidism were excluded. In subjects without pre-existing hormonal thyroid alterations, it was evaluated the relationship between thyroid peroxidase antibody (Ab-TPO) level before the start of ICI and the onset of DYSTHYR during treatment. These patients were divided into two groups (MED-TPO+ and MED-TPO-) using the median Ab-TPO titer of the population as a cut-off value.

Results

In our cohort (median age 67 years, 70.7% males, 49.4% lung cancer, 95.4% anti PD-1 therapy), we observed a high frequency of DYSTHYR (80 out of 324 patients; 24.7%); thyrotoxicosis was detected in 7.7% of the population, while hypothyroidism occurred in 21% of subjects (after a median time of 1.8 and 3.7 months, respectively). Among cases with pre-existing thyroid hormonal alterations (14.5% of the sample), the worsening of DYSTHYR was found in 42.6% of cases after the start of ICI; the risk of DYSTHYR was significantly higher in comparison to patients without a thyroid disease history (OR 2.68 at univariate analysis, P 0.03). Baseline Ab-TPO levels were available for 97 patients (Ab-TPO median value 12 U/ml). Mean AbTPO level in the group with DYSTHYR during ICI (42.5 U/ml) was significantly higher than AbTPO titer in patients without DYSTHYR (16.1 U/ml, $P=0.0003$). DYSTHYR after the start of ICI occurred in 33.9% of MED-TPO+ patients vs 7.9% of MED-TPO- subjects ($P=0.003$); a significantly increased risk of developing DYSTHYR was observed in MED-TPO+ patients when compared to MED-TPO- cases (OR 5.98 at univariate analysis; $P=0.007$).

Conclusion

Our data confirm the high frequency of DYSTHYR (mostly hypothyroidism) during PD1/PD-L1 inhibitors. We observed a greater risk of DISTHYR during ICI in patients with pre-existing thyroid function alterations and in case of higher baseline Ab-TPO level. These results may help the oncologist to identify the patients who are most likely to require an endocrinologist consultation during ICIs.

Association of thyroid function and TPO positivity with the risk of postpartum depression: a population-based cohort study and systematic review

Federica Sileo[1,2], Joris Osinga[3,4], Edward Visser[3,4], Arash Derakhshan[3,4], valeria citterio[1,2], Luca Persani[1,2] & Tim Korevaar[3,4]

[1]University of Milan, Milan, Italy, Department of Biotechnology and Experimental Medicine, Milan, Italy; [2]IRCCS Istituto Auxologico Italiano, Milan, Italy, Lab of Endocrine and Metabolic Research, Department of Endocrine and Metabolic Diseases, Milan, Italy; [3]Erasmus Medical Center, Postbus 2040, 3000 CA, Rotterdam, The Netherlands, Department of Internal Medicine, Rotterdam, Netherlands; [4]Erasmus Medical Center, Postbus 2040, 3000 CA, Rotterdam, The Netherlands, Academic Center for Thyroid Diseases, Rotterdam, Netherlands

Background

Postpartum depression (PPD) is a common mental health disorder with a major impact on maternal health and wellbeing and offspring development. Thyroperoxidase antibody (TPOAb) positivity is a major risk factor for

postpartum thyroiditis and via this link, it is hypothesized that TPOAb positivity is a risk factor for PPD. However, the results of currently available single center studies are heterogeneous and affected by major study limitations.
Objective
To examine the association of TPOAb and thyroid function with the risk of PPD.
Methods
In the Generation R Study, a population-based prospective birth cohort in Rotterdam, The Netherlands, we measured TSH, FT4 and TPOAb in blood samples collected between 8-18 weeks of pregnancy. Postpartum depressive symptoms were assessed with the Edinburgh Postpartum Depression Scale (EPDS) at 2 months postpartum and with the Brief Symptom Inventory (BSI) at 2, 6 and 36 months postpartum. In addition, we performed a systematic review of literature assessing the association of thyroid function and/or TPOAb positivity with risk of PPD.
Results
There was no association of TSH or FT4 levels with the risk of postpartum depression (log_TSH OR:0.79, 95%CI 0.56-1.13, $P=0.20$; fT4 OR:1.02, 95%CI 0.96-1.08, $P=0.57$). There was also no association of TPOAb positivity with PPD (OR:0.79, 95%CI 0.39-1.19, $P=0.39$). Additional analyses assessed an impaired thyroidal response to hCG stimulation and defined the combined effects of a high hCG with either a high TSH or low FT4 as an alternative marker of TPOAb positivity. We identified that an impaired thyroidal response to hCG stimulation was associated with a lower risk of PPD (P for interaction TSH $=0.04$ and FT4 $=0.06$). In our systematic review, ten out of 1219 identified articles were included: four studies showed an association of TPOAb positivity with PPD, two showed an association of thyroid function with PPD, the remaining studies showed no association of either thyroid function or autoimmunity with PPD.
Conclusions
Our original study is by far the largest study on this topic showing that neither TPOAb positivity nor TSH or FT4 were associated with PPD. Our systematic review revealed high heterogeneity and suboptimal methodological quality in the current literature, but overall does not support a link with PPD. Although TPOAb positive women should be monitored for postpartum thyroiditis, there does not seem to be an indication to screen for postpartum depression. Further research should focus on other factors potentially involved in the etiology of PPD.

Positive correlation of thyroid nodule cytology with molecular profiling – analysis of over 4000 nodules from multicenter study and systematic literature review

Idit Tessler[1], Isaac Shochat[2], Oded Cohen[3], Richard J Payne[4] & Galit Avior[1]
[1]Sheba Medical Center, Department of Otolaryngology Head and Neck Surgery, Ramat Gan, Israel; [2]Hillel Yaffe Medical Center, Hadera, Israel; [3]Hebrew University, Jerusalem, Israel; [4]Sir Mortimer B. Davis-Jewish General Hospital, McGill University, Department of Otolaryngology Head and Neck Surgery, Montréal, QC, Canada

Objectives
Despite the increasing role of molecular profiling, the association between mutation expression and pre-operative cytology for thyroid nodules has not been established.
Methods
We collected data on patients who underwent molecular profiling of thyroid nodules in Bethesda categories III to VI from two tertiary academic hospitals and via systematic literature review. We tested the associations between Bethesda categories and molecular mutation stratified by risk levels, according to the 2015 ATA guidelines. When thyroidectomy was preformed, we also evaluated association with postoperative diagnosis and aggressivity of disease based on histopathological variants, nodal metastasis or extra-thyroidal extension.
Results
We analyzed data from 452 nodules in our institutional cohort and 3912 nodules from the systematic literature review. A significant positive correlation was found between Bethesda categories and mutations, demonstrated by an increase in the intermediate to high-risk mutation rate in the higher BSRTC categories (Rs $=$ 0.660, $P\leq$ 0.001). In the institutional cohort malignancy rate for BSRTC III and IV was 56.7% and 75.7%, respectively. The most common mutation was BRAFV600E, with 95.9% (93/97) of those patients in Bethesda category V or VI ($P<.001$). All had confirmed thyroid cancer on pathology, with aggressive tumor behavior in most (60%). Patients with low-risk mutation, as H, K or N RAS alterations showed an association with Bethesda categories III and IV ($P\leq.01$). In mutation-negative nodules of BSATC III to VI who underwent surgery, we found a lower incidence of aggressive thyroid cancer compared to those with an identified mutation (12.6% vs 44.3%, $P<.01$).
Conclusion
We found positive correlation between cytology results and molecular testing. These findings may provide clinicians with better interpretation for BSRTC results and may contribute to the identification of aggressive thyroid nodules associated with indeterminate Bethesda categories.

A new grading system for medullary thyroid cancer

Alessandro Prete[1], Carla Gambale[1], Liborio Torregrossa[2], Valeria Bottici[1], Virginia Cappagli[1], Fulvio Basolo[2], Rossella Elisei[1] & Antonio Matrone[1]
[1]Unit of Endocrinology, Department of Clinical and Experimental Medicine, Pisa, Italy; [2]Unit of Pathology, Department of Surgical, Medical, Molecular Pathology and Critical Area, Pisa, Italy

Introduction
medullary thyroid carcinoma (MTC) is a neuroendocrine thyroidal cancer. World Health Organization recognizes a grading system for almost all neuroendocrine tumors; however, a shared grading system for MTC is still lacking. We performed a clinical and pathological review of 257 MTCs to evaluate which histologic features have an impact on the disease specific survival and to propose a new grading system.
Method
We retrospectively reviewed clinical data of 257 consecutive patients with sporadic MTC, surgically treated at the Endocrine Surgery Unit and followed at the Endocrine Unit of the University Hospital of Pisa, from 2000 to 2018. In this cohort, MTC histopathologic variants (classical, follicular, papillary, oncocytic, clear cell, small cell and spindle cell), desmoplastic reaction (fibrosis $\geq$ 10%), number of mitosis for 10 high-power field (x10HPF), Ki67 percentage and necrosis were evaluated.
Results
Patients were followed for a median time of 9.3 years. The MTC variants were distributed as follows: 164/257 (63.3%) classical variant, 50/257 (19.3%) spindle cell variant and 43/257 (17.4%) other variants with a frequency $<5\%$ each. Desmoplastic reaction was present in 159/257 (61.9%). Number of mitosis and Ki-67 percentage higher than 2 were present in 57/257 (22.2%) and 97/257 (37.7%), respectively. Necrosis was present in 19/257 samples (7.4%). According to Kaplan-Meier analysis, MTC with desmoplastic reaction, mitosis number >2, Ki-67 $>2\%$ or necrosis had lower disease specific survival ($P<0.001$). After preliminary analysis, we proposed the following grading system composed by desmoplastic reaction and Ki-67 percentage: high grade (presence of desmoplastic reaction and Ki-67 $>2\%$) and low grade (all other combinations). At Kaplan-Meier analysis, high grade MTC had lower disease specific survival compared to low grade (74.7% vs 98.6%, $P<0.001$). Intriguingly, this grading system was able to predict DSM, both in intrathyroidal (stage I-II) ($P=0.034$) and extrathyroidal (stage III-IV) MTCs ($P<0.001$).
Conclusions
In our large MTC series, presence of desmoplastic reaction and necrosis, mitosis number $\times$10HPF >2, and Ki-67 $>2\%$ were negative prognostic factors for DSM. Grading system composed by Ki-67 $>2\%$ and desmoplastic reaction was able to identify the MTCs with the worst prognosis, both in lower (I-II) than in more advanced (III-IV) stages.

Klinik und Poliklinik IV, Munich, Germany; [15]Motol University Hospital, Department of Pediatrics, Prague, Czech Republic; [16]Istituto Superiore di Sanità, National Centre for Rare Diseases, Rome, Italy; [17]Erasmus Medical Centre, Department of Internal Medicine, Academic Centre for Thyroid Diseases, Rotterdam, Netherlands

Introduction
The European Registries for Rare Endocrine Conditions (EuRRECa) was created in collaboration with the European Reference Network on Rare Endocrine Conditions (Endo-ERN), the European Society for Paediatric Endocrinology and the European Society of Endocrinology to support the needs of the endocrine community.
Aim
To describe the patient population and data entered in the EuRRECa Core Registry between June 2019 and December 2021.
Methods
Core Registry clinical contributors are invited to register new and existing cases of endocrine conditions seen in their centres. Diseases are organized in eight main condition groups. A core data set and a condition-specific data set collect information regarding demographics and diagnosis. Generic Patient-Reported Outcome Measures (PROMs) are available for clinicians and patients to complete. Patients can access the platform, view their data and complete outcomes.
Results
Twenty centres from 12 countries have registered cases. To date, a total of 644 cases have been added to the registry, 238 (36%) in the sex development and maturation condition group, 160 (24%) in the pituitary group, 153 (23%) in the calcium and phosphate group, 51 (8%) in the adrenal group, 24 (4%) in the thyroid group, 23 (3%) in the genetic endocrine tumour syndrome group, 10 (1%) in the growth and obesity group and 5 (0.7%) in the disorders of glucose and insulin metabolism. Of 664 cases, 183 (28%) were within the age range 0-9 years, 140 (22%) within 10-17 years and 321 (51%) over 18 years. The median age was 19 (0, 88) with 341(52%) cases over the age of 18 yrs. Of 664 cases, 442 (67%) were under active follow-up. One-hundred and thirteen (17%) had expressed an interest in using the patient platform; 76 (67%) had been sent an invitation to join the platform and of these, 18 (24%) activated their account. Thirty-two EQ-5D outcomes have been completed, 28 (87%) in cases of mineral conditions and 2 (6%) in pituitary and. Of these, 26 (94%) have been completed by clinicians and 2 by patients.
Conclusion
The EuRRECa Core Registry has shown its ability to collect information on a very wide range of endocrine conditions in patients of all ages. The additional functionality for collecting patient reported and clinician reported outcomes has now been tested and can be used for studying long-term clinical outcomes for rare endocrine conditions.

Genetic cause of POI are common, the case for next generation sequencing?

Elinor Vogt[1,2], Eirik Bratland[3], Eystein Sverre Husebye[4,5], Sigridur Bjornsdottir[6], Siren Berland[5] & Marianne Øksnes[4,5]
[1]University of Bergen, Medicine, Bergen, Norway; [2]Haukeland University Hospital / Health Bergen, Norway; [3]Haukeland University Hospital / Health Bergen, Genetics, Norway; [4]University of Bergen, Medicine, Bergen, Norway; [5]Haukeland University Hospital / Health Bergen, Medicine, Norway; [6]Nya Karolinska, Sweden

Context
Premature ovarian insufficiency (POI) affects approximately 1-3% of women. Clinical presentations are heterogeneous and the underlying etiologies remain unknown in the majority of cases.
Objective/aim
To characterize presentations of POI and to evaluate the distribution of underlying etiologies in women with newly diagnosed POI of unknown cause.
Design
Prospective study of 100 women with newly diagnosed POI. Autoimmunity was examined by radio immune assays of autoantibodies associated with POI, i.e. 21-hydroxylase (21 OH), cholesterol side-chain cleavage enzyme (SCC), 17α-hydroxylase (17 OH), and NALP5. Extensive chromosomal and genetic analyses were performed in all, including FMR-1 premutation sequencing and next generation sequencing (NGS) of 100 POI associated genes.
Results
Three percent had autoimmune POI based on the presence of 21OH and SCC autoantibodies. Copy number profiling or chromosome analysis revealed X-chromosome abnormalities in 5%, and a large deletion on chromosome 8 in one patient. FMR-1 premutations were identified in 3%. NGS analysis found genetic variants classified as likely causes of POI in approximately one third of cases. These included genes SOHLH2, STAG3 and EIF4ENIF1. Furthermore, several patients carried highly suspicious variants of unknown significance (VUS) in genes such as SOX8, BUB1B and C14ORF39. One patient with primary amenorrhea was homozygous for a rare missense variant in MCM8. A family history of POI was less common (10% vs 28% vs *P* 0.040) and fewer women reported previous pregnancies (38% vs 61%, *P* 0.041), in genetic compared to idiopathic POI. FSH levels were higher in genetic compared with idiopathic POI (53.4 (4.0-149.2] vs 37.3 [1.6-120] IU/l, *P* 0.043]. There were no significant differences between the groups in frequency of primary amenorrhea (15%), timing of menarche (13 [9-17] years) or age at secondary amenorrhea (33 [12-3] years). A larger proportion of women with African heritage carried a VUS (9/17).
Conclusion
In women with newly diagnosed POI, screening for chromosomal abnormalities and FMR mutations identified genetic etiology in 8%, whereas the extensive NGS panel revealed a possible underlying genetic etiology in more than one third, actualizing the discussion of which tests should be a part of diagnostic screening in clinical practice.

Defective Notch1/Jag1 signaling impacts GnRH development and contributes to hypogonadotropic hypogonadism

Cotellessa Ludovica[1,2,3], Marelli Federica[2], Paolo Duminuco[1], Bartoloni Lucia[4], Adamo Michela[4], Nelly Pitteloud[4], Luca Persani[1,2], Marco Bonomi[1,2], Paolo Giacobini[3] & Vezzoli Valeria[1]

Lille, Inserm, CHU Lille, U1172 -LilNCog(JPARC) – Lille Neurosciences & Cognition, F-59000, Lille, France, Lille, France; [4]Lausanne University Hospital, Service of Endocrinology, Diabetology, and Metabolism, Lausanne University Hospital, Lausanne, Switzerland

The precise development of the Gonadotropin Releasing Hormone (GnRH) neurons is essential for the proper function of the hypothalamic-pituitary-gonadal axis, as GnRH is the master regulator of reproductive functions in vertebrates. Mutations in genes involved in the development of GnRH neurons are associated with Congenital Hypogonadotropic Hypogonadism (CHH), a heterogeneous genetic disorder characterized by hypogonadism, lack of puberty onset, and infertility, which is named Kallmann Syndrome (KS) when the disease associates with anosmia. In this study, we identified in two European cohorts of CHH/KS patients rare missense variants in the NOTCH1 ligand gene *JAG1*. It is already reported in the literature the key role of the Notch signaling in the development of the olfactory system in both mouse and drosophila; therefore, considering the intimate connection between the olfactory and GnRH systems we studied its possible role in the development of the GnRH system. We first performed multiplex fluorescent in situ hybridization combined with immunofluorescence to assess the expression pattern of *JAG1* and its receptors *NOTCH1*, *NOTCH2*, *NOTCH3* and *NOTCH4* in human fetal sections of the nasal compartment during the first trimester of gestation. We showed that those molecules were expressed along the GnRH migratory pathway as well as by GnRH neurons, suggesting a paracrine and/or autocrine mechanism. Taking advantage of the zebrafish model, we observed that *jag1a*, *jag1b*, *notch1a*, and *GnRH3* (homologous of the mammalian GnRH1) were expressed in the olfactory placodes of zebrafish embryos. Moreover, we report that pharmacological and genetic inhibition of *jag1b* altered the development of the GnRH3 neurons and the olfactory scaffold used for their migratory process. Functional *in vitro* validation of the *JAG1* variants identified in CHH patients revealed that some were retained into the cytoplasm and did not reach the cell membrane. We also showed that some variants

did not properly activate the Notch Responsive Element, suggesting that they are loss-of-function mutations. Combining morphological analysis *in vivo*, together with genetic manipulation in zebrafish and human genetic analysis, we provide compelling evidence that Notch1/Jag1 signaling plays a role in the development of GnRH neurons and propose that Notch1/Jag1 signaling insufficiency may contribute to the pathogenesis of CHH in humans.

Sex-chromosome dosage effects on circular RNA: A circular transcriptome-wide study of Turner and Klinefelter syndrome across different tissues

Emma Bruun Johannsen[1], Jesper Just[1], Mette Viuff[1], Jens Fedder[2], Anne Skakkebæk[1,3] & Claus H Gravholt[1,4]

[1]Aarhus University Hospital, Department of Molecular Medicine, Aarhus, Denmark; [2]Odense University Hospital, Odense, Denmark; [3]Aarhus University Hospital, Department of Clinical Genetics, Aarhus, Denmark; [4]Aarhus University Hospital, Department of Endocrinology, Aarhus, Denmark

Background

Turner syndrome (45,X; TS) and Klinefelter syndrome (47,XXY; KS) present with a range of clinical features due to copy number aberrations of the X chromosome. The underlying genetics of these syndromes have revealed karyotype-dependent transcription and methylation patterns, and implicated genes that escape X chromosome inactivation (XCI). Alterations in the expression pattern of non-coding RNAs has previously been reported in TS and KS, yet the landscape of circular RNAs (circRNAs) has never been investigated. These endogenous circularized RNAs have the potential to facilitate regulatory processes, thereby affecting transcription, translation and epigenetics, and may contribute to the TS and KS phenotype.

Methods

Primary samples of blood, muscle and adipose tissue were collected from individuals with TS ($n=33$) and KS ($n=22$) and from males ($n=16$) and females ($n=44$) of normal karyotype. The circRNAs were identified and quantified from RNAseq data from these samples, using a combination of three different circRNA identification pipelines (CIRI2, CIRCexplorer2 and circRNA_finder). CircRNA differential expression, interaction prediction and functional enrichment analysis was carried out to describe the nature of the circRNA profile in KS and TS.

Results

Differential expression was observed throughout the genome in all tested tissues. The host-genes of these circRNAs were associated with known phenotypic traits. Furthermore, several differentially expressed circRNAs had the potential to sponge certain miRNAs and these miRNAs were predicted to interact with genes that were differentially expressed between TS and females and KS and males. CircRNAs arising specifically from the PAR-genes, displayed a general pattern of opposing expression with up-regulation in TS and down-regulation in KS, which was similar to that of their respective host-genes. Furthermore, we observed that CircRNA-miRNA-mRNA networks may compensate for altered X-chromosome dosage of the PAR-genes.

Conclusion

The present study shows pervasive changes in the circRNA transcriptome throughout three different relevant tissues in Turner and Klinefelter syndrome. It extends our understanding of TS and KS genomics, being is not only limited to changes in the mRNA transcriptome and methylome. The conceptual picture of these syndromes is clearly much more complex than hitherto thought and future studies will need to include multiple tissues, more components of the endogenous ceRNA complex, as well as the epigenome. We propose that the phenotype of these syndromes shall be seen through a lens of a complicated multi-tissue framework with multiple genomic mechanisms causing, regulating and compensating the resultant output – the patient.

Luteinizing hormone (LH)- and choriogonadotropin (hCG)-induced internalization of the receptor (LHCGR) is responsible for hormone-specific signaling

Elia Paradiso[1], Clara Lazzaretti[1], Sara D'Alessandro[1,2], Samantha Sperduti[1,3], Neena Roy[1], Elisa Mascolo[1], Lara Baschieri[1,2], Claudia Anzivino[1,3], Manuela Simoni[1,3,4] & Livio Casarini[1,3]

Introduction

Luteinizing hormone (LH) and human choriogonadotropin (hCG) regulate reproduction through binding the same receptor (LHCGR). They act via activation of G protein- and β-arrestin-dependent signals, resulting in ligand-specific pattern of signaling cascades and LHCGR internalization into endosomal vesicles. Previous studies differentiated the action of these two hormones in LH-related proliferative signals and hCG-related steroidogenic signals.Aim. We compared the role of LHCGR internalization in determining LH- and hCG-specific signals.

Methods

Ligand-specific patterns of LHCGR trafficking and signaling were evaluated in HEK293 cells overexpressing the receptor and specific bioluminescence resonance energy transfer (BRET) biosensors, with or without internalization blockade by Dynasore. LH- and hCG-induced LHCGR internalization and trafficking were evaluated over 30 min, determining the interaction between receptor and endosomal type-specific markers RAB-GTPases (Rab) 5, 7, and 11, as well as β-arrestin 2. Ligand-specific receptor coupling to Gs, Gi, and Gq protein, and related cAMP, extracellularly-regulated kinases 1 and 2 (ERK1/2), and intracellular Ca^{2+} increase were evaluated as well. Results were compared by Kruskal Wallis test and Dunn's post-test; $P<0.05$; $n=4$-8.

Results

The interaction between LHCGR and markers of internalization/localization into early endosome, i.e. β-arrestin 2 and Rab5, is markedly more induced upon cell treatment with hCG, with than LH ($P<0.05$; $n=4$). Conversely, LH induces preferential LHCGR-Rab11 interaction, indicating the routing of the receptor toward recycling in cell membrane ($P<0.05$; $n=4$), while no hormone-specific LHCGR-Rab7 interaction was found ($P\geq 0.05$; $n=4$). Interestingly, LHCGR trafficking is modulated by the blockade of internalization with Dynasore. Under this condition, hCG-induced LHCGR-β-arrestin 2/Rab5, as well as LH-induced LHCGR-Rab11 interactions were lost ($P\geq 0.05$; $n=4$), suggesting missing ligand-specific receptor trafficking. Moreover, Dynasore treatment increases LH-, but not hCG-induced LHCGR-Rab7 interaction, indicating ligand-specific routing toward the degradation pathway. Hormone-specific trafficking reflects the downstream signaling pattern. hCG has higher efficacy than LH in inducing Gs- and Gq coupling to LHCGR ($P<0.05$; $n=8$), reflecting more pronounced activation of cAMP and intracellular Ca^{2+} increase ($P<0.05$; $n=4$), as two molecules upregulating the synthesis of gonadal steroids. Cell treatment with Dynasore did neither change the hCG-related G protein coupling to LHCGR, nor cAMP production, while it decreased intracellular Ca^{2+} increase. Conversely, LH was more effective than hCG in inducing LHCGR coupling to Gi protein ($P<0.05$; $n=8$), preferentially activating proliferation-related ERK1/2 downstream signaling ($P<0.05$; $n=4$). However, LH-induced LHCGR-Gi coupling and ERK1/2 activation were inhibited by Dynasore ($P\geq 0.05$; $n=4$).

Conclusion

We conclude that LH-related proliferative and hCG-linked steroidogenic signals require hormone-specific trafficking of the receptor.

Analysis of cardiovascular comorbidities and events in a cohort of transgender people during GAHT

Lorenzo Marinelli, Andrea Camandona, Chiara Michela Crespi, Domiziana Magistri, Ezio Ghigo & Giovanna Motta

Università Degli Studi Di Torino Dipartimento Scienze Mediche, Torino, Italy

Introduction

According to the DSM-5, gender dysphoria (GD) is defined as a distress that results from an incongruence between one's sex assigned at birth and one's gender identity. This condition may require gender-affirming hormone therapy (GAHT), in order to reduce distress. GAHT, however, is not free from side effects and it could increase the risk of onset of new pathological conditions.

Aim of the study

To evaluate cardiovascular comorbidities and events in a cohort of patients with GD taking GAHT.

Subjects and methods

We enrolled subjects with GD [assigned male at birth (AMAB) and assigned female at birth (AFAB)] who were regularly followed by the local gender team in Molinette Hospital, Turin (Italy), between February 2007 and July 2021. For each

patient, at each access anthropometric parameters, smoking habit and a cardiovascular assessment (arterial hypertension, diabetes, dyslipidaemia, ACS, stroke, DVT) were recorded. A baseline analysis of the whole cohort was carried out; subsequently an evaluation of cumulative incidence of comorbidities during GAHT was performed. Finally, mortality was assessed in terms of SMR (standardized mortality ratio - ratio between observed and expected death).
Results
We enrolled 613 patients, 380 transgender-AMAB with a median age of 33.9 years [22.04-45.85] and 233 transgender-AFAB, aged 27.4 years old [22.01-39.54], observed for a median follow-up time of 43.50 [17-72.25] and 41.50 [19-74] months, respectively. Only transgender-AMAB showed a significant weight gain (+2 Kg after 24 months). At baseline, 39% of transgender-AMAB and 39.1% of transgender-AFAB were active smokers; no significant difference during follow-up was recorded. During observation time, new cases of arterial hypertension ($n=12$), diabetes ($n=4$) and dyslipidaemia ($n=28$) were recorded in transgender-AMAB, while 12 new cases of arterial hypertension, 2 of diabetes and 21 of dyslipidaemia were reported in transgender-AFAB. Three cases of DVT were registered within transgender-AMAB. One case of ACS and one stroke were described in transgender-AFAB group. Finally, 4 deaths were recorded in the transgender-AMAB group (1.04%) and 1 in the transgender-AFAB group (0.42%). In both groups, SMR was higher than age-matched cisgender women [AMAB SMR: 1.32 (IC 95% 0.42-3.19); AFAB SMR: 1.26 (IC 95% 0.04-3.91)].
Conclusions
Although transgender-AFAB and AMAB enrolled were relatively young and not fully representative of the general transgender population, during GAHT an increase of main cardiovascular comorbidities was observed. Thus, our data highlight the need of a proper follow-up and medical monitoring to manage these new conditions and to prevent the onset of major cardiovascular events.

Development of [18F]AldoView as the first highly selective aldosterone synthase PET tracer for imaging of patients with primary hyperaldosteronism

Kerstin Sander[1], Tom Kurzawinski[1,2], Thibault Gendron[3], Klaudia Cybulska[3], Fatih Sirindil[4], Junhua Zhou[4], Tammy Kalber[5], Mark Lythgoe[5], Morris Brown[4], Bryan Williams[6] & Erik Arstad[1]
[1]University College London, Centre for Radiopharmaceutical Chemistry, London, United Kingdom; [2]University College Hospital, Endocrine Surgery, London, United Kingdom; [3]University College London, Centre for Radiopharmaceutical Chemistry, United Kingdom; [4]Barts and The London School of Medicine and Dentistry, London, United Kingdom; [5]University College London, Centre for Advanced Biomedical Imaging, London, United Kingdom; [6]University College Hospital, Biomedical Research Centre, London, United Kingdom

Background
Inappropriately high aldosterone in patients with primary hyperaldosteronism (PHA) is due to increased aldosterone synthase (CYP11B2) activity. Selective in vivo imaging of overexpressed CYP11B2 in adrenals with positron emission tomography (PET) has not yet been achieved due to close homology of enzymes involved in aldosterone and cortisol (CYP11B1) synthesis.
Aim
Synthesize a fluorine-18 labelled highly selective CYP11B2 inhibitor, [^{18}F] AldoView, and assess its potential for the detection of aldosterone producing adenomas (APAs) and aldosterone producing cell clusters (APCCs) with PET in patients with PHA.
Methods
[^{18}F]AldoView was synthesised in high radiochemical yields using a proprietary radiochemistry platform.[1] Dynamic PET/CT imaging, biodistribution studies and metabolite analysis was performed in wild type female BALB/c mice. [18F] AldoView binding to CYP11B2 was characterised by quantitative phosphorimaging in tissue sections prepared from adrenalectomy specimens of patients with PHA, Cushing, phaeochromocytoma and incidentaloma. CYP11B2 specific immunohistochemistry (IHC) was performed in directly adjacent sections.
Results
In mice, [^{18}F]AldoView showed a favourable pharmacokinetic profile, including rapid distribution and clearance. In tissue sections, [^{18}F]AldoView binding was visually consistent with CYP11B2 IHC staining. Specific tracer binding to CYP11B2 positive areas ranged from 8.6 to 19.1 kBq/cm^2 and was evenly distributed across tissue identified as APA, in contrast to cortex, which had diffuse patterns with hot spots in keeping with APCCs. There was no evidence of elevated tracer uptake in CYP11B2 negative areas in patients with or without PHA (3.2±1.1 kBq/cm^2 and 2.6±1.8 kBq/cm^2, respectively).[2]
Conclusion
Our results strongly suggest that [^{18}F]AldoView can image CYP11B2 expression in human adrenals and could become first highly selective radioactive tracer to be used to stratify patients with PHA for adrenalectomy.

Early post-operative ACTH-stimulated aldosterone predicts long-term biochemical outcome in primary aldosteronism

Denise Bruedgam[1], Christian Adolf[1], Holger Schneider[1], Verena Wegmann[1], Paul Schwarzlmueller[1], Lisa Mueller[1], Finn Holler[1], Benjamin Lechner[1], Laura Handgriff[1], Roland Ladurner[2], Sinan Deniz[3], Tracy Ann Williams[1,4], Felix Beuschlein[1,5], Martin Reincke[1] & Daniel Heinrich[1]
[1]LMU Klinikum Innenstadt, Medizinische Klinik und Poliklinik IV, München, Germany; [2]LMU Klinikum Innenstadt, Klinik für Allgemein-, Viszeral- und Transplantationschirurgie, Campus Innenstadt, Klinikum der Universität München, München, Germany; [3]LMU Klinikum Innenstadt, Klinik und Poliklinik für Radiologie, München, Germany; [4]Division of Internal Medicine and Hypertension, Department of Medical Sciences, University of Turin, Turin, Italy; [5]University Hospital of Zürich, Klinik für Endokrinologie, Diabetologie und Klinische Ernährung, Zürich, Switzerland

Introduction
Primary aldosteronism (PA) is the most common surgically curable cause for endocrine hypertension. Patients with unilateral aldosterone-producing adenoma undergo adrenalectomy (ADX). Clinical and biochemical outcome is assessed 6-12 months after ADX according to PASO consensus. To reduce unnecessary follow-up visits and change in medication for diagnostic purposes for potentially cured patients after ADX, a prediction tool is needed. Previous research had shown greater ACTH-responsiveness in unilateral disease. Thus, we analyzed if early post-operative ACTH-stimulated aldosterone can predict PASO outcomes.
Methods
We prospectively included 100 patients of the German Conn's registry from 2015-2021, who underwent ADX and post-operative ACTH stimulation tests. 6-12 months after ADX we assessed blood pressure and biochemical remission according to PASO criteria. In addition, serum cortisol and plasma aldosterone concentrations (PAC) were measured before and 30 min after the application of 250 µg Synacthen® within the first week after ADX. We used ROC (receiver operating curve) analysis and paired baseline and stimulated PAC and serum cortisol to PASO outcomes.
Results
81% of the patients had complete, 13% partial and 6% absent biochemical remission at 6-12 months after ADX. Complete clinical remission was observed in 28%. There was a significant correlation between biochemical outcome and ACTH-stimulated PAC values ($P=0.01$, $r=0.53$). Using 58.5 pg/ml as a cut-off, post-operative stimulated PAC had high sensitivity (95%) and reasonable specificity (74%) for predicting partial or absent biochemical remission at 6-12 months after ADX. Additionally, stimulated PAC AUC (area under the curve) values (0.89; CI 0.82-0.96) were significantly higher ($P=0.03$) than baseline PAC AUC ($P=0.28$). In contrast, baseline and stimulated serum cortisol levels were less useful (baseline cortisol AUC 0.60; CI 0.45-0.74), stimulated cortisol AUC 0.67; CI 0.54-0.80, ($P=0.01$; $P=0.01$). Blood pressure outcome AUC for baseline and stimulated serum cortisol and PAC ranged from 0.56-0.66, indicating a low predictive value.
Conclusions
In our series, low post-operative ACTH-stimulated PAC was predictive of biochemical remission after ADX. As post-operative ACTH stimulation tests are used to detect adrenal insufficiency, concurrent stimulated PAC measurements should be included in routine care. If confirmed, this approach could reduce follow-up visits to assess biochemical outcome.

11-oxygenated C19 steroids are the predominant androgens responsible for hyperandrogenemia in Cushing's disease

Hanna Nowotny[1], Frederick Vogel[1], Martin Bidlingmaier[1], Leah Braun[1], Martin Reincke[1], Lea Tschaidse[1], Matthias Auer[1], Christian Lottspeich[1],

James M Hawley[2], Jo Adaway[2], Brian Keevil[2], Katharina Schilbach[1] & Nicole Reisch[1]
[1]Klinikum der Universität München, Medizinische Klinik und Poliklinik IV, München, Germany; [2]Manchester University Foundation NHS Trust, Manchester Academic Health Sciences Centre, Department of Clinical Biochemistry, Manchester, United Kingdom

Background
Symptoms of hyperandrogenism are common in patients with Cushing's disease (CD), but they cannot be sufficiently explained by measured concentrations of circulating androgens. In this study we analyzed the contribution of 11-oxygenated (11o×C19) androgens to hyperandrogenemia in female patients with CD as well as the influence of treatment with steroidogenesis inhibitors osilodrostat and metyrapone on 11o×C19 and classic androgens.
Methods
In this single-center study, we assessed saliva day profiles of 23 females with treatment naïve CD, 26 female controls, 5 females with CD treated with metyrapone and 5 treated with osilodrostat for cortisol, cortisone, androstenedione (A4), 11-hydroxyandrostenedione (11OHA4), testosterone (T) and 11-ketotestosterone (11KT) by liquid chromatography tandem mass spectrometry as well as morning baseline levels of gonadotropins and estradiol, sex hormone-binding globulin, cortisol and dehydroepiandrosterone sulfate (DHEAS) in serum and adrenocorticotropic hormone in plasma.
Results
Treatment naïve females with CD showed significantly elevated areas under the curve (AUC) of 11OHA4 and 11KT throughout the day compared to controls (11OHA4 mean rank difference (mrd) 18.13, $P=0.0002$; 11KT mrd 17.42; $P=0.0005$) whereas A4, T and DHEAS were comparable to controls. Patients with more symptoms of hyperandrogenism displayed higher concentrations of 11o×C19 androgens and had significantly lower SHBG concentrations. Gonadotropin levels were normal in all patients with CD (LH 7.18 U/l (SD 14.28 U/l); FSH 7.68 U/l (SD 12.0 U/l)) and did not correlate with any other parameters. Treatment with osilodrostat and metyrapone efficaciously blocked 11oxC19 androgen synthesis. In metyrapone but not in osilodrostat treatment a trend towards increased concentrations of T and significantly increased A4-concentrations were observed (A4 mrd 23.07, $P=0.0119$).
Conclusion
Hyperandrogenemia in CD is predominantly caused by excess of 11o×C19 androgens. Due to lower compensatory increase of A4 and T, osilodrostat seems to be more suitable for treatment of females with CD and hyperandrogenism than metyrapone.

Classic and 11-oxygenated androgens in serum and saliva across adulthood and the menstrual cycle – a mass spectrometry-based cross-sectional study

Punith Kempegowda[1,2], Lina Schiffer[1], Jo Adaway[3], Fozia Shaheen[1], Andreas Ebbehoj[4,5], Sumitabh Singh[4], Alessandro Prete[1,2], James M Hawley[1,3], Alice J Sitch[6], Brian Keevil[3], Irina Bancos[4], Angela Taylor[1] & Wiebke Arlt[1]
[1]University of Birmingham, Institute of Metabolism and Systems Research, United Kingdom; [2]Queen Elizabeth Hospital Birmingham, United Kingdom; [3]Wythenshawe Hospital, Department of Clinical Biochemistry, United Kingdom; [4]Mayo Clinic, Division of Endocrinology, Metabolism, Diabetes and Nutrition, Department of Internal Medicine, United States; [5]Aarhus University, Department of Clinical Medicine, , Aarhus, Denmark; [6]University of Birmingham, Institute of Applied Health Research, Birmingham, United Kingdom

Objective
Quantify classic and 11-oxygenated androgens in serum and saliva and determine variations across age, sex, body mass index (BMI), menstruation and hormonal contraception use.
Methods
Morning serum samples were collected from 292 healthy volunteers (125 men, 22-95 years; 167 women, 21-91 years). Morning saliva was collected from 83 healthy volunteers (51 women, 32 men). 25 individuals (12 women, 13 men) also collected a 7-timepoint diurnal saliva profile; the 12 women also collected morning saliva on seven consecutive days during both follicular and luteal phase. The following steroids were quantified by liquid chromatography-tandem mass spectrometry: classic androgens and their precursors (dehydroepiandrosterone sulfate [DHEAS], dehydroepiandrosterone [DHEA], androstenedione [A4], testosterone [T], dihydrotestosterone [DHT]), and 11-oxygenated androgens and their precursors (11-hydroxy androstenedione [11OHA4], 11-keto androstenedione [11KA4], 11-hydroxy testosterone [11OHT], 11-keto testosterone [11KT]). Data were pooled Descriptive statistics and non-parametric tools were used for each variable to obtain median, IQR and significance (p-values). Multiple linear regressions were performed to delineate the distinct effects of age and BMI in a sex-specific analysis
Results
Age: In serum, DHEAS, DHEA, and A4 decreased with age in both men and women, while 11OHA4, 11KA4, 11OHT, 11KT remained stable. Sex: Serum concentrations of DHEA, A4, and 11-oxygentated androgens were similar in men and women while, as expecteded, T and DHT were higher in men. 11OHA4 levels were the highest of all 11-oxygenated androgens and were higher than A4 and similar to DHEA levels. BMI: There were no associations of DHEAS, DHEA, A4, 11OHA4 and 11KA4 with BMI. After adjusting for age, 11KT positively correlated with BMI in men (change/kg/m^2 (95% CI)=3.05(0.08, 6.03), $P=0.044$), while the relationship between 11OHT and BMI was not significant. Menstruation status: Saliva classic and 11-oxygenated androgens showed a clear diurnal pattern in men and in the follicular phase in women, but in the luteal phase only 11-oxygenated androgens showed diurnal variation. Postmenopausal women had lower serum DHEAS, DHEA, A4, T, and 11KA4 ($P<0.001$) compared to premenopausal women. 11OHT and 11KT were increased in postmenopausal compared to premenopausal women ($P<0.001$ and $P=0.005$, respectively). Impact of contraception: Women on hormonal contraceptives had lower T and 11-KT concentrations in saliva, but not in serum.
Conclusion
While classic androgens decline with age and are subject to menstrual cycle-dependent variation, 11-oxygenated androgens form a stable pool during adulthood. While all other measured androgens decreased after menopause, 11OHT and 11KT increased, which may have clinical implications for diagnostic work-up of hormonal pathologies.

Adrenal nodular disease is a frequently increasing in the general population with an incidence that reaches almost 10% in the seventh decade of life. More and more evidences show these lesions discovered through diagnostic imaging (CT, MRI) performed for other medical problems (incidentalomas). New radioimaging techniques, exploiting the quantitative variables of imaging, permit to identify an hypothetical pathological tissue. We have applied this potential in a retrospective series of 72 patients of both sexes with single adrenal lesion >1 cm in dimension with adrenal incidentalomas followed at our center. Patients were studied following ESE/ENSAT current criteria practice guideline in order to exclude any hormonal hypersecretion considering in this study only not secreting and cortisol secreting adrenal masses by dexamethasone-suppression test (DST). Based on cortisol value they were divided in two groups: functioning (32) and non-functioning (40) adrenal incidentalomas with cortisol values >50 nmol/l and <50 nmol/l respectively. Machine learning concept, through different algorithms offers the possibility to study several biological processes obtaining quantitative information from imaging and correlating it with outcomes. Radiomics is an emerging technique that translates radiological images into quantitative data to yield biological information and permits an in depth radiological characterization, thus improving diagnosis, decision support, and follow up monitoring. It is a multistage process in which features based on shape, pixel densities, and texture are extracted from CT or MR images. Each incidentaloma was studied in the preliminary non-contrast phase with a specific software (Mazda), surrounding a region of interest within each lesion. 314 features were extrapolated. Mean and standard deviations of features were obtained and the difference in means between the two groups was statistically analyzed. ROC curves were used to identify an optimal cut off for each variable and a prediction model was constructed via multivariate logistic regression with backward and stepwise selection. A 11-variables prediction model was constructed and a ROC curve was used to

differentiate patients with high probability of functioning incidentalomas. Using a specific threshold value we obtained a sensitivity of 93.75% and a specificity of 100% in diagnosing functioning incidentaloma. Based on these results, CT texture analysis appears a promising tool in the diagnostic definition of adrenal incidentalomas.

Introduction

Pheochromocytomas and paragangliomas (PPGLs) exhibit an up to 20% malignancy rate. Various clinical, genetic, and pathological features have been proposed as predictors of malignancy. However, until present there are no robust indices to reliably predict metastatic PPGLs.

Aim

The aim of the present study was to prospectively validate the value of methoxytyramine as risk marker of metastatic disease and establish a machine learning (ML) model, based on clinical and biochemical features, to reliably predict malignancy in patients with PPGLs.

Methods

This study included retrospective data of 493 patients for the generation and training of ML models. Data of 295 patients prospectively enrolled in the multicenter international PMT-Study were used for the validation of the predictive value of methoxytyramine and the external validation of the selected ML model. The predefined features for selection analysis were sex, age at initial diagnosis, locations and size of tumor(s), previous history of PPGL, presence of SDHB mutation, plasma normetanephrine, metanephrine and methoxytyramine.

Results

Receiver operating characteristic curves indicated that plasma methoxytyramine using an optimal cutoff of 33 pg/ml provided an accurate biomarker for detecting patients with metastatic PPGLs. After feature selection and the use of 4 different models, ensemble trees model, which comprised 9 features, had the greatest discriminatory ability with an AUC of 0.9938 (95% CI:0.9903-0.9951). The ensemble trees model was validated externally and ranked based on the balanced accuracy with an AUC of approximately 0.9261 (95% CI:0.9293-0.9381).

Conclusion

Our study confirms in a prospective series the value of methoxytyramine as a strong predictor of metastatic PPGLs. Importantly we demonstrate predictive ML models, as the first effective, non-invasive and highly accurate approach to predict malignant disease in patients with PPGLs, providing immediate guidance to clinicians for individualized patient management and follow-up strategies.

Pheochromocytomas and paragangliomas (PPGL) are catecholamine-producing neuroendocrine tumors that display the highest heritability rate among all human tumors. Genomic analyses revealed the existence of 2 main clusters of PPGL, i.e. cluster 1 containing SDHx- and VHL-mutated tumors which do not produce epinephrine, and cluster 2 including epinephrine-secreting PPGL related to RET, NF1, TMEM127 and MAX mutations. Early diagnosis and treatment of PPGL is crucial to prevent adrenergic crises, especially in pregnant patients with previously undiagnosed pheochromocytoma (PCC). In this context, PCC are associated with a high risk of maternal or fetal complications due to catecholamine excess triggered by tumor compression induced by fetus growth, or labor and delivery. However, it is known that surges in plasma catecholamines may also occur during early gestation suggesting that pregnancy may also activate the secretory activity of PPGL through the involvement of non-mechanical factors, such as gestational hormones. Herein, we report a case of silent PCC in a pregnant woman with the first symptoms of catecholamine excess appearing during the first trimester and a life-threatening adrenergic myocarditis occurring at 31 weeks of gestation. Genetic analysis revealed the presence of a heterozygous germline RET variant of uncertain significance. The fact that the first symptoms of catecholamine excess had occurred during the first trimester of pregnancy led us to conduct in vitro studies to investigate the effects of estradiol and hormone chorionic gonadotropin (hCG) on epinephrine secretion by cultured cells derived from the patient's tumor. Expression of LH/hCG receptor (LHCGR) was searched for in the tumor and an additional series of 12 PCC by RT-qPCR and immunohistochemistry. LHCGR expression was also analyzed in silico in the PPGL cohorts of the COMETE network and The Cancer Genome Atlas (TCGA) databases. hCG stimulated epinephrine secretion by primary cultured PCC cells. The tumor expressed the LHCG receptor, which was colocalized with catecholamine-producing enzymes. LHCGR expression was also detected in 5 out of a series of 12 PCCs. In silico studies revealed that PPGL display the highest expression levels of LHCGR mRNA among the 32 solid tumor types of TCGA cohort. Interestingly, expression of LHCGR was higher in cluster 2 than in cluster 1 PPGL. These data show that PCC can express functional LHCG receptor. Consequently, pregnancy may activate catecholamine production by previously silent PCC as early as the first trimester of gestation especially in women with gene mutations that predispose to cluster 2 epinephrine-secreting PCC.

Peripheral facial paralysis as first manifestation of hypophysary glioma: a case report

Jéssica Maria Telles[1], Laura Vilas Boas[2], Thielsen Cardoso da Silva[2], Gabrielle Andrusko dos Santos[1], Matheus Kowal Rosales[1], Bruno Melquíades da Rocha[2] & Mirnaluci Paulino Ribeiro Gama[1]

[1]Hospital Universitário Evangélico Mackenzie, Brazil; [2]Evangelical Mackenzie Faculty of Parana, Brazil

Introduction

Low-grade pituitary gliomas are extremely rare neoplasms, originating from the pituicytes of the posterior pituitary or infundibulum. The incidence of these tumors increases with age and peaks in the seventh decade of life. Gliomas are primary brain tumors of the supporting glial cells of the central nervous system, which derive from neuroglial stem cells or progenitor cells. They are responsible for nearly 30% of all primary brain tumors and 80% of all malignant tumors, as well as the majority of deaths from primary brain tumors. The clinical manifestation is mainly through visual impairment, due to optic nerve compression, headache, and pituitary deficits.

Case report

A 16-year-old female patient presented with left peripheral facial paralysis, with no change in the imaging tests, with spontaneous improvement. Evolved with progressive headache, severe nasal congestion, bilateral visual acuity alteration, and right peripheral facial paralysis, associated with findings of a tumor in the sellar topography, dilatation of the supratentorial ventricular system, and diffuse meningeal impregnation, suggestive of the spread of the pathology. She underwent a ventriculoperitoneal shunt and subsequent transsphenoidal excision of the mass (4.9 × 2.6 × 2.5 cm) which was successfully performed. Anatomopathological analysis showed a round cell neoplasm with fibrillar background and low-grade hyalinized vessels, suggestive of glial neoplasm. In the early postoperative period, developed diabetes insipidus, treated with desmopressin acetate nasal spray 0.1 mg/ml twice a day, and

hypothalamic obesity. In the outpatient follow-up, a diagnosis of panhypopituitarism was made, consisting of hypogonadotropic hypogonadism, central adrenal insufficiency, and central hypothyroidism, and replacement of estradiol valerate 2 mg + levonorgestrel 0.25 mg, hydrocortisone 17.5 mg, and levothyroxine 123 mg/day was initiated. The patient remains under outpatient follow-up, in good general condition, asymptomatic, and with good control of complications.

Conclusion

Although pituitary tumors are the most commonly found intracranial neoplasms, the low-grade pituitary glioma presented by the patient is an extremely rare pathology. However, as it has the potential to manifest in several forms, which go far beyond those described in the literature, it should always be considered in the differential diagnosis of pituitary neoplasms, given its potential for complications and the need for early radical treatment aimed at healing the patient.

Objectives

The novel coronavirus disease-2019 (COVID-19) is the fastest-spreading disease worldwide, with over 380 million cases and 5 million deaths. The presence of diabetes mellitus (DM) in patients with COVID-19 was associated with mortality, acute respiratory distress syndrome, disease progression. COVID-19 was progressed with some hematological disorders, especially lymphopenia. Studies implicated that neutrophil-to-lymphocyte ratio (NLR) level can be a reliable marker in showing the severity of COVID-19 disease. A routine hematology analyzer measures the percentage of large unstained cells (%LUCs), reflecting activated lymphocytes and peroxidase-negative cells. In previous studies, the%LUCs was found to be associated with disease progression in patients with HIV. This study aims to investigate whether the%LUCs and NLR parameters are associated with disease progression in diabetic patients with COVID-19.

Materials and Methods

The data of the patients hospitalized in the Infectious Diseases Service and Intensive Care Unit with a COVID-19 in Ankara City Hospital between 15.03.2020 and 15.07.2020 were collected in our retrospective study. This study included 656 patients with COVID-19, 131 with DM, and 525 with the DM-free control group. White blood cell (WBC) count, neutrophils, neutrophil percentage, lymphocytes, lymphocyte percentage, LUCs,%LUCs, NLR, platelets, hemoglobin which was taken within the first 24 hours after admission, and history of DM were noted from the records.

Results

The mean age was 61.29 ± 13.81 years in the diabetic patient group and 44.37 ± 17.14 years in the non-diabetic control group with COVID-19, which was significantly higher in the diabetic group ($P < 0.001$). NLR, WBC count, neutrophils, and neutrophil percentage were statistically significantly higher in patients with DM (respectively, $P < 0.001$, $P = 0.008$, $P = 0.008$, $P = 0.003$, and $P = 0.049$). There were no significant differences between the groups regarding lymphocyte, platelet, LUCs, and%LUCs values ($P > 0.05$).

Conclusion

There are studies in the literature that a decrease in%LUCs value and an increase in NLR are indicators of severe disease in COVID-19. Our study did not detect a difference in%LUCs value in diabetic patients, but our study is a preliminary study. Analysis of the data with clinics continues with more patients.

Discovery of microRNA biomarkers in circulation and bone tissue from a type-2 diabetes mellitus rat model under different anti-osteoporotic treatments

David Carro Vázquez[1], Lejla Emini[2], Martina Rauner[2], Christine Hofbauer[2], Johannes Grillari[3], Richard Eastell[4], Lorenz C Hofbauer[2] & Matthias Hackl[1]
[1]TAmiRNA GmbH, Wien, Austria; [2]Dresden University of Technology, Department of Medicine III and Center for Healthy Aging, Dresden, Germany; [3]Ludwig Boltzmann Institut, Department of Experimental and Clinical Traumatology, Wien, Austria; [4]The University of Sheffield, Academic Unit of Bone Metabolism, and Mellanby Centre for Bone Research, Sheffield, United Kingdom

Metabolic changes in Type-2 Diabetes-Mellitus (T2DM) make patients more prone to develop osteoporosis and delayed bone healing. We hypothesize that microRNAs could be involved in the underlying mechanism and used as biomarkers in this context. To test this hypothesis, we analyzed microRNAs in samples from Zucker Diabetic Fatty (ZDF) rats, a T2DM model with reduced bone healing and bone mass. 11-week-old male ZDF and wildtype rats with a femur subcritical defect were treated with placebo, anti-sclerostin, PTH and insulin treatments for 12 weeks. After the treatment, metabolic and bone phenotype parameters of all the rats were measured and serum and ulna samples were obtained ($n =$ 4-5 per group). RNA isolation and small RNA next generation sequencing (NGS) were performed using serum and ulna samples for untargeted genome-wide miRNA analysis. Significantly (adj. $P < 0.2$) regulated miRNAs identified by NGS were further analyzed with the online tool miRnet 2.0 for miRNA target network construction and with the FANTOM5 browser for cell-type enrichment analysis. Our results show that insulin induced a strong dysregulation of circulating miRNAs mainly involved in metabolism, and even rescued seven circulating miRNAs in the ZDF model (rno-miR-802-5p, rno-miR-122-3p, rno-miR-375-3p, rno-miR-27a-5p, rno-miR-31a-5p, rno-miR-192-5p, rno-miR-122-5p). Anti-sclerostin caused a less intense miRNA dysregulation in serum but affected miRNAs shown to be enriched in bone tissue, rescuing particularly one of those miRNAs (rno-miR-145-5p). PTH treatment did not produce any effect on circulating neither on bone miRNAs in the ZDF rats, most probably due to a blunting effect of diabetes over the PTH. Altogether, this study shows the enhancement effect on bone mass and bone regeneration potentially caused by dysregulation of bone miRNAs and of the rescue of circulating miRNAs in ZDF rats under the three analyzed treatments.

The effect of multiple passes to the same thyroid nodule in the fine needle aspiration biopsy session on obtaining adequate and/or the AUS/FLUS cytological result

Fatma Dilek Dellal Kahramanca[1], Fatma Neslihan Cuhaci Seyrek[2], Afra Alkan[3], Oya Topaloglu[2], Reyhan Ersoy[2] & Bekir Cakir[2]
[1]Ankara City Hospital, Endocrinology and Metabolism, Ankara, Turkey; [2]Ankara Yildirim Beyazit University, Faculty of Medicine, Endocrinology and Metabolism, Ankara, Turkey; [3]Ankara Yildirim Beyazit University, Faculty of Medicine, Biostatistics, Ankara, Turkey

Aim

To determine whether multiple fine needle passes to the same thyroid nodule in the fine needle aspiration biopsy (FNA) session affect sufficient and/or atypia of undetermined significance/follicular lesion of undetermined significance (AUS/FLUS) cytological result.

Materials and Methods

Ultrasonography (US) and cyto-histopathology results of the nodules of patients who were diagnosed with thyroid nodules and underwent FNA between May-August 2021 were retrospectively analyzed. The nodules were divided into two groups according to the number of needle passes performed in the same FNA session as those with one pass (one-pass group) and those with two or three passes (multiple-passes group). The two groups were compared in terms of cytological adequacy and the rate of AUS/FLUS diagnosis as well as US features and TIRADS scores.

Results

A total of 1500 thyroid nodules of 708 patients (575 female and 133 male) were included in the study. The mean age of the patients was 51.57 ± 12.51 years. 1409 (93.9%) nodules were performed one pass, and 91 (6.1%) were performed two ($n = 85$) or three passes ($n = 6$). While the cystic/mixed nodule ratio and macrocalcification rate were higher in the multiple-passes group, the rates of coalescent nodules and presence of halo were higher in the one-pass group ($P = 0.001$, $P = 0.039$, $P = 0.006$, and $P = 0.040$, respectively). TIRADS 3 score was higher in multiple-passes group ($P = 0.001$). The adequacy and AUS/FLUS ratios were similar in the two groups.When nodules with macrocalcifications and cystic/mixed structures were evaluated as two separate subgroups, the adequacy and AUS/FLUS ratios were similar in one-pass and multiple-passes groups.

Conclusion

Two or three passes to thyroid nodules have similar cytological adequacy and AUS/FLUS ratios compared to one pass.Although more passes are performed in

Features	One-pass ($n=1409$)	Multiple-passes ($n=91$)	P
Cystic/mixed structure [n (%)]	87 (6.2)	14 (15.4)	**0.001**
Presence of macrocalcification [n (%)]	119 (8.4)	14 (15.4)	**0.039**
Presence of peripheral halo [n (%)]	250 (17.7)	8 (8.8)	**0.040**
Coalescence [n (%)]	149 (10.6)	1 (1.1)	**0.006**
TIRADS Category			**0.003**
3	73 (5.2)	12 (13.2)	**0.001**
4a	702 (49.8)	40 (44.0)	0.278
4b	579 (41.1)	32 (35.2)	0.265
4c	55 (3.9)	7 (7.7)	0.078
5	0 (0.0)	0 (0.0)	
Cytological sufficiency [n (%)]	1033 (73.3)	65 (71.4)	0.694
AUS/FLUS cytology [n (%)]	240 (17.0)	9 (9.9)	0.103

cystic/mixed and macrocalcified nodules estimating that the material would be insufficient with macroscopic on-site evaluation, needle insertion of two or three times does not contribute to the adequacy and also the AUS/FLUS ratio compared to one pass.

Engaging the Endocannabinoid System in Neuroendocrine Neoplasms (NENs) potentiates treatment outcomes and null drug resistance

Shani Avniel- Polak[1], David Polak[2], Kira Oleinikov[1], David J Gross[1], Ori Wald[3], Uzi Izhar[3], Haggi Mazeh[4], Yotam Drier[5] & Simona Glasberg[1]
[1]Hadassah Medical Organization, Hebrew University of Jerusalem, Department of Endocrinology and Metabolism, Neuroendocrine Tumor Unit, ENETs Center of Excellence, Jerusalem, Israel; [2]Hadassah Medical Organization, Hebrew University of Jerusalem, Department of Periodontics, Dental Medicine Faculty, Jerusalem, Israel; [3]Hadassah Medical Organization, Hebrew University of Jerusalem, Department of Cardiothoracic Surgery, Jerusalem, Israel; [4]Hadassah Medical Organization, Hebrew University of Jerusalem, Department of Surgery, Mount Scopus, Jerusalem, Israel; [5]Hadassah Medical Organization, Hebrew University of Jerusalem, The Lautenberg Center for Immunology and Cancer Research, Faculty of Medicine, Jerusalem, Israel

Introduction
Patients with unresectable NENs are offered a variety of non-curable therapeutic options, which eventually fail due to drug resistance. Increasing evidence suggest an anticancer trait of cannabinoids, via cellular pathways including mTOR, known to be associated with drug resistance development. Still, limited data exist on the anti-cancer effects of cannabinoids in NENs.
Aims
To understand the possible anti-tumor role of the cannabinoids and the endocannabinoid system in NENs, and their ability to overcome resistance to everolimus.
Materials and methods
The endocannabinoid receptors expression on NENs cell lines of lung (NCI-H727) and pancreatic (BON1) origin and on human samples was examined using FACS/immunofluorescence staining and RNA-Seq. Cells were treated with multiple cannabinoids extracts with different chemical profile. Viability and apoptosis were examined using WST-1 and Annexin/PI. Endocannabinoid receptors blocking with specific antagonists examined cannabis extracts -induced toxicity. The effect of everolimus $\pm$ cannabis extracts/ endocannabinoid receptors antagonists on cell viability was examined.
Results
The endocannabinoid receptor CB1, but not CB2, is highly expressed in NEN cell lines and tumor samples. The expression of other endocannabinoid receptors (TRPV1, TRPV2, PPARα and PPARγ) is heterogeneous. 50 cannabis extracts were initially tested, identifying 6 cannabis extracts that significantly reduced cell viability by ~40% via CB1. Also, CB1 blocking vigorously decreased cells viability and increased apoptosis. Cells viability decreased by 15% with everolimus alone; this effect was enhanced when cannabis extracts and mainly when CB1 antagonists were added (by 33% and 59%, respectively). Even more, combining everolimus with endocannabinoid receptor blocking in a NEN mouse model showed synergistic effect with impressive decrease in tumor size.
Conclusions
Our preliminary results suggest that modulation of endocannabinoid system seems promising in NENs models, mostly via the endocannabinoid receptor CB1. Addition of cannabis extracts /CB1 antagonist to everolimus may have synergistic effects that might lead to a novel and efficient modality to treat NEN and diminishes the development of drug resistance.

Excessive bilateral adrenal hyperplasia associated with aldosterone synthase (CYP11B2) deficiency

Aristidis Diamantopoulos[1], Panagiotis Mourelatos[1], Amalia Sertedaki[2], Efthimia Botoula[1], Dimitra Vassiliadi[1] & Stylianos Tsagarakis[1]
[1]"Evangelismos" General Hospital of Athens, Greece, Department of Endocrinology, Diabetes and Metabolism, National Expertise Center for Rare Endocrine Disorders and member of the Endo-ERN, Athens, Greece; [2]"Agia Sofia" Children's Hospital, Athens, Greece, First Department of Peadiatrics, Division of Endocrinology, Metabolism and Diabetes, Medical School, National and Kapodistrian University of Athens, Athens, Greece

Introduction
Congenital adrenal hyperplasia (CAH) encompasses a group of enzymatic defects in cortisol biosynthesis resulting in adrenal hyperplasia through chronic compensatory ACTH stimulation. Aldosterone synthase deficiency, however, is associated with normal cortisol secretion and there are no reports on whether it may be associated with adrenocortical hyperplasia.
Case Presentation
A 37-year-old, Greek female was referred for further investigation of excessive diffuse bilateral adrenal hyperplasia discovered during investigations for post-partum weight gain (25 kg), fatigue, hirsutism, easy bruising, and depression associated with borderline cortisol status abnormalities (cortisol post-1mg dexamethasone: 100 nmol/l, basal ACTH: 7.3 pg/ml and 24-h urinary free cortisol (UFC): 1.32$\times$ULN; androgens, as well as 17-hydroxyprogesterone, were normal). In infancy, the patient was erroneously diagnosed with CAH when she presented with failure to thrive, hyponatremia and hyperkalemia. She was treated with methylprednisolone and fludrocortisone until the age of 2, when she was re-evaluated with a Cosyntropin Stimulation Test (CST) with normal basal and stimulated cortisol levels (0'/30': 811/822 nmol/l). Aldosterone was 13 ng/dl with PRA$>$40 ng/ml/h and 11-Deoxycortisol 2,2 ng/ml. On repeated testing, aldosterone was 15,6 ng/dl, PRA: 2,2 ng/ml/h, 17OHPR: 0,2 ng/ml and the diagnosis of pseudo-hypoaldosteronism was made. Subsequently, the patient had normal growth and pubertal development; she had oligomenorrhea until pregnancy and subsequently normalization of menstrual cycles. The coding regions of *CYP11B2*, *CYP21A2* and *CYP11B1* genes underwent Sanger sequencing.
Results
On physical examination, she had no clinical stigmata of Cushing's Syndrome. Cortisol post-dexamethasone was borderline (63 nmol/l) without any other features of hypercortisolism (normal midnight serum cortisol and UFC). Basal aldosterone levels were 5/4.4 ng/dl with marginally elevated renin levels (56/40 mcU/ml). Given her PMH we performed a CST, in which she had a normal cortisol response, a borderline increase of 17-OH PRG (0'/30': 7/30.2 nmol/l) but a remarkable lack of aldosterone response (0'/60':6.3/6.9 ng/dl). We suspected *CYP11B2* gene deficiency, which was confirmed by genetic testing, that revealed compound heterozygosity for two pathogenic variants (p.T185I and p.E255X). No mutations were identified in *CYP21A2* and *CYP11B1* genes.
Conclusion
To our knowledge, this is the first report that associates diffuse bilateral adrenal hyperplasia with *CYP11B2* deficiency, a rare defect that is usually diagnosed during infancy and improves with age so that adults are asymptomatic. Our patient presented with impressively enlarged adrenals without discrete nodules and no other evident cause of adrenal hyperplasia.

Background
Molecular mechanisms underlying the pathogenesis of adrenocortical adenomas (ACAs) and autonomous cortisol secretion remains frequently unexplained despite previous comprehensive genomics studies.
Aim
To gain novel insights into molecular pathogenesis of adrenocortical tumours by investigating transcriptome profiles of ACAs at single-nuclei resolution (snRNA-Seq), using adult human normal adrenal glands (NAGs) as reference.
Methods
We isolated single nuclei from 6 NAGs and 12 ACAs, including 7 cortisol-producing adenomas (CPAs) and 5 endocrine inactive adenomas (EIAs) with different genetic background. snRNA-Seq was performed using inDrop™ technology. Data analysis, integration and exploration was performed using Seurat R package. Pathway enrichment analysis was performed using pathfindR withKEGG pathways as reference. Transcriptome profile from ACA was integrated with NAG using anchor pairs between the two datasets. Identification of tumour- and mutation-specific cell subpopulations (i.e. clusters) was done by differential gene expression analysis.
Results
Within the NAGs, we identified different satellite clusters of immune, myeloid and vascular origin, in addition to main clusters representing the three adrenal cortex zones, medulla and capsule. We also identified two subpopulations potentially representing adrenocortical and adrenomedullary progenitor cells, located within and underneath the capsule. Comparative analysis of the transcriptional profiles of NAGs and ACAs revealed the presence of six ACA-specific clusters, namely four "tumour-specific" (TC1-4), "tumour microenvironment" (TME), and one cluster overexpressing genes of cholesterol pathway (Chol-upreg). Specifically, the TC1 was mostly found in 2 *CTNNB1*-mutated samples (one EIA and one CPA), where a significant overexpression of *AFF3*, *FTO* and *ISM1*, as well as genes of spliceosome (fold enrichment, FE = 7.6), ECM-receptor interaction (FE = 7.3) and Hippo signaling (FE = 2.8) pathways were observed. The TC2 cluster was more abundant in EIA and characterized by overexpression of genes like *MMP26*, *SP100* and *EIF4H*, as well as genes of NOD-like receptor (FE = 3.6) and IL-17 signaling pathway (FE = 3.5) associated with tumour promotion. The Chol_upreg cluster was largely represented in CPAs and characterized by a very high expression of genes associated to steroid biosynthesis (FE = 34.2) and cortisol synthesis and secretion (FE = 9.5), including *HMGCS1*, *SQLE* and *FDX1*. The remaining clusters (TME, TC3-4) were quite homogeneously distributed in all ACAs, independently from mutational status (2 *PRKACA*-, 1 *GNAS*-, 6 *CTNNB1*-, 3 no driver-mutation) and cortisol secretion.
Conclusion
Our human adult NAG single-cell atlas represents a unique source for investigations of adrenal diseases and allowed us to investigate the molecular heterogeneity of ACAs at single-cell level, showing the presence of specific cell populations associated with cortisol secretion and genetic background.

YI3

Generalization of TSH and FT4 reference intervals in pregnancy: an individual participant data meta-analysis

Joris Osinga[1,2], Arash Derakhshan[1,2], Consortium on thyroid and pregnancy working group on reference intervals [3], Robin Peeters[1,2] & Tim Korevaar[1,2]
[1]Erasmus University Medical Center, Department of Internal Medicine, Rotterdam, Netherlands; [2]Erasmus University Medical Center, Academic Center for Thyroid Diseases, Rotterdam, Netherlands; [3]Multiple, Nepal

Objective
Defining thyroid function test abnormalities in pregnancy is complicated by changes in maternal physiology. Ideally, reference intervals (RIs) should be population-based and pregnancy-specific. Large methodological differences between published reports limit the adoption of such RIs into clinical practice.
Methods
The study was performed in the Consortium on Thyroid and Pregnancy. In line with current consensus and the 2017 American Thyroid Association guidelines, cohort-specific RIs based on the 2.5th and 97.5th percentiles were calculated after exclusion of participants with pre-pregnancy thyroid disease, thyroid medication use and TPOAb positivity. To evaluate current recommendations and methodological variations, RIs were also calculated using the above mentioned methods and eight different methodologies often encountered in literature; 1) using the 5th to 95th percentiles, 2) without excluding TPOAb positivity, and using additional exclusion criteria defined as 3) exclusion of TgAb-positivity 4) pre-pregnancy diabetes mellitus, 5) essential hypertension, 6) obesity 7) active smoking, or 8) any pregnancy complications.
Results
The final study population comprised of $n = 63{,}198$ participants from 22 cohorts. Between cohorts, the upper limit for TSH calculated according to the current consensus ranged from 2.24 to 6.02 mU/l in the first trimester, from 2.67 to 6.15 mU/l in the second trimester and from 3.03 to 6.13 mU/l in the third trimester. Not excluding TPOAb positive participants led to a rise of the upper limits of TSH in all cohorts, especially in the first (+17.4% average, range +1.6 to +30.3%) and second (+9.8% average, range +0.6 to +32.3%) trimester. The use of the 95th percentile led to considerable changes in upper limits, varying from -10.8% to -21.8% for TSH and -1.2% to -13.2% for FT4 across all trimesters. All other additional exclusion criteria led to less than 3.5% variability around the 97.5th percentile, without a trend towards increase or decrease.
Conclusion
The large variability in reference limits between cohorts stress the importance of hospital- and pregnancy specific RIs. Furthermore, our data emphasize the importance of excluding TPOAb-positive participants and the use of appropriate percentiles cut-offs. Additional exclusions frequently encountered in literature did not affect TSH or FT4 reference intervals during pregnancy, indicating that the majority of published studies can be implemented into clinical practice despite methodological differences and future studies can adapt simplified study setups to define valid RIs.

The role of miR-335-5p in the differentiation of thyroid cancers with BRAF mutation

Valeria Pecce[1], Antonella Verrienti[1], Marialuisa Sponziello[1], Giorgio Grani[1], Simone Bini[1], Sebastiano Filetti[2] & Cosimo Durante[1]
[1]Sapienza University of Rome, Translational and Precision Medicine, Rome, Italy; [2]Sapienza University of Rome, Unitelma

The most frequent mutation in papillary thyroid carcinoma (PTC) is the p.V600E of the *BRAF* gene. This mutation leads to the aberrant activation of the RAS / BRAF / MEK / ERK pathway and consequently to the under-regulation of thyroid-specific genes, resulting in uncontrolled growth and de-differentiation of cancer cells. In this work, we analyzed the transcriptomics data produced by the TCGA project using a network approach. The analysis led to the identification of regulatory genes, called switch genes, involved in the network changes between mutated *BRAF* papillary carcinomas and normal thyroid tissues. In particular, we identified 227 switch genes. Within the network generated by these genes, 63 were found to be targets of the same microRNA, the mir-335-5p. The role of this microRNA was then investigated through an *in vitro* study. We selected two primary cell lines and four immortalized lines of thyroid cancer, all of them carrying the *BRAF* mutation, which showed lower levels of mir-335-5p expression compared with normal control cells. A synthetic microRNA was transfected in all six cell lines. After transfection, the analyses showed an increase in *TSHR*, *PAX8*, and *NIS* expression in the two primary cell lines and in three out of four immortalized lines. Furthermore, all the studied lines showed an increased iodine uptake following treatment with mir-335-5p. Moreover, we obtained organoids by growing the transfected lines in a semi-solid culture medium. We studied the morphology of the 3D structures generated before and after the transfection of miR-335-5p, the interaction among organoid cells and extracellular matrix components, and the protein levels of thyroid-specific genes through immunofluorescence. Our results led us to conclude that the restoration of the intracellular levels of mir-335-5p could have a role in promoting the re-differentiation of thyroid tumors with *BRAF* mutation.

[1]AP-HP, Service d'endocrinologie et diabète de l'enfant, ERN BOND, ERN for rare endocrine disorders, Platforme d'expertise des maladies rares, Hôpital Bicêtre Paris Saclay, Le Kremlin-Bicêtre, France; [2]Department of Clinical Sciences and Community Health, University of Milan, Milan, Italy; [3]Endocrinology Unit, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; [4]AP-HP, Centre de Référence des maladies rares du métabolisme du Calcium et du Phosphate, filière OSCAR, Paris, France; [5]Université de Paris Saclay, INSERM, U1185, Le Kremlin-Bicêtre, France

Since the first description of pseudohypoparathyroidism (PHP) a remarkable clinical variability was observed. In 2016 a new classification of this group of diseases have been published by the European Network on PHP and related disorders, proposing "inactivating PTH/PTHrP signaling disorder" (iPPSD) as a new term that encompasses all the clinical entities. PHP and related disorders vary in clinical presentation and disease severity, and clinical features usually develop during mid and late childhood. There are only few reports in literature about neonatal PHP, describing hypocalcemic seizures in late neonatal period. To our knowledge no others neonatal complications are described as associated to iPPSD. The aim of this study is to analyse a large cohort of iPPSD patients and to investigate early history of the disease, with special focus on neonatal complications. We collected data from 136 patients diagnosed with iPPSDs and in regular follow-up at the Endocrinology Unit of Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico (Milan, Italy) and at the Pediatric Endocrinology Unit of Hôpital Bicêtre (Paris, France). We have retrospectively collected data about birth, and we have then investigated the rate of neonatal complications occurring within the first month of life. Then, we have subdivided neonatal complications in several categories (respiratory, cardiac, neurological, gastrointestinal, metabolic, multiple districts, others) and we have assessed the number of complications for each patient. We analysed data from 83 children and 53 adults with diagnosis of iPPSD (mean age 18 $\pm$ 11 years). In our cohort 55.9% of patients were diagnosed with iPPSD2 (PHP1A) and 17.6% with iPPSD3 (PHP1B), 11.8% of patients suffered from acrodysostosis type 1 or 2 and 2.2% had a mutation of *PTHR1* (iPPSD1). In 12.5% of cases we couldn't find any mutations (iPPSDx). At least one neonatal complication occurred in 36% of patients (49/136). iPPSD2 patients represent the majority of our cohort and 47% of them experienced neonatal complications, being the category the most affected ($P=0.001$). At univariate analysis neonatal complications in iPPSD patients correlate with the risk of developing neurocognitive impairment ($P=0.01$) and constipation ($P=0.04$) later in life. Moreover, 38.9% iPPSD2 patients who developed neonatal complications had $>$ 2 complications at birth. We could also identify recurrent complications among iPPSD2 patients: 8 of them (10.5%) developed neonatal hypoglicemia and 13 (18.4%) experienced transient respiratory distress. To now we can conclude that iPPSD and especially iPPSD2 newborns need special care at birth, for the risk of developing neonatal complications.

Introduction
In Primary Bilateral Macronodular Adrenal Hyperplasia (PBMAH), cortisol secretion may be consecutive to physiological stimuli, through the illegitimate expression of G-protein coupled receptors (GPCR) in adrenocortical cells. The most characterized is the overexpression of GIP receptor (GIPR) leading to food-dependent Cushing syndrome (FDCS) but it has not been associated with the consecutive inactivation of ARMC5 responsible for 25% of PBMAH. This work aimed to investigate the molecular heterogeneity of PBMAH and its genetic causes.
Methods
A multi-omics analysis (transcriptome, methylome, miRNome, SNP array and exome sequencing) was performed on PBMAH tissues from 36 operated patients.
Results
The integrative analysis revealed three molecular groups with different clinical features: G1, 16 patients with PBMAH due to ARMC5 inactivating variants; G2, 6 patients with FDCS; and G3, 14 patients with a less severe phenotype. Exome sequencing identified germline truncating variants of KDM1A in 5 G2 patients, constantly associated with a somatic loss of the KDM1A wild-type allele on 1p, leading to a loss of KDM1A expression both at mRNA and protein levels ($P=1.2\times10\text{-}12$ and $P<0.01$, respectively). G2 tumors are characterized by a specific pathological aspect including a large proportion of eosinophilic cells compared to G1 and G3 ($P<0.001$). The transcriptome analysis allows to show specific expression profiles of GPCR: G1/ARMC5 tumors showed a relative overexpression of the vasopressin receptors AVPR1A and AVPR1B compared to the two other groups (fold-change [FC] $=7.39$, $P<0.001$ and 3.98, $P<0.001$, respectively) but a lower expression of AVPR2 (FC$=0.43$, $P=0.015$); G2/KDM1A tumors showed a dramatic overexpression of GIPR compared to the two other groups (FC$=105.02$, $P<0.001$) but also of the adrenergic receptors ADRA1D and ADRA2A (FC$=2.93$, $P=0.027$ and 9.99, $P<0.001$, respectively) and of the LH/hCG receptor (LHCGR) (FC$=12.20$, $P<0.001$); G3 tumors showed a slight overexpression of the adrenergic receptors ADRA1B (FC$=3.49$, $P=0.001$) and in few tumors ADRA1D, AVPR2 and LHCGR were highly expressed suggesting molecular heterogeneity in G3.
Conclusion
This study reveals three distinct molecular groups of PBMAH with specific expression profiles of GPCR and identifies KDM1A inactivation as the genetic cause of FDCS. Besides GIPR, KDM1A inactivation seems to drive the overexpression of the LH/hCG receptor, potentially responsible for Cushing syndrome associated with pregnancy and menopause. KDM1A tumors present specific pathologic aspects including a large proportion of eosinophilic cells. ARMC5 and KDM1A genetic screening can now be offered for all PBMAH cases, opening the way to earlier diagnosis and improved management.

Background
The risk of a second brain tumour following radiotherapy for pituitary adenoma or craniopharyngioma in adults is currently unclear. Studies are methodologically limited by small patient sample size, few case events, selection biases or the use of inappropriate controls.
Objective
To ascertain whether radiotherapy delivered to adults with pituitary adenoma or craniopharyngioma is associated with an increased second brain tumour risk using appropriate methodology.
Design
Multicentre, retrospective cohort study involving six adult endocrine centres.
Methods
4,292 patients with pituitary adenoma or craniopharyngioma detected until 31st December 2013 were identified from departmental registries. Patients with one image, unknown radiotherapy exposure status, genetic predisposition, history of brain tumour prior to study entry, or aged <18 years at the time of radiotherapy, were excluded ($n=598$). Recipients of proton or stereotactic radiotherapy ($n=81$) were also excluded from statistical analyses, such that data were explored for 930 patients exposed to conventional, 3D-CRT or IMRT and 2,683 controls. Follow-up was defined by imaging dates from the time of radiotherapy until last imaging in the exposure group, and from the time of pituitary tumour detection until last imaging in the control group.
Results
Over 43,887 patient-years (12,674 radiotherapy, 31,213 controls), second brain tumours were reported in 58 patients (27 radiotherapy, 31 controls): 6 were malignant (4 radiotherapy, 2 controls, and 52 benign (23 radiotherapy, 29 controls). Older age at pituitary tumour diagnosis and radiotherapy exposure were associated with increased risk of second brain tumour (HR 1.036, 95%CI 1.018-1.055, $P<0.0001$ and HR 1.744, 95% CI 1.040-2.927, $P=0.035$, respectively), but tumour type and sex were not. After adjusting for age, radiotherapy exposure was associated with an increased risk of second brain tumour (HR 1.728, 95%CI 1.029-2.902, $P=0.031$). Cumulative probability of second brain tumour at 20 years was 4.2% and 2.1%, for the radiotherapy group and control group, respectively. Incidence rate ratio of irradiated versus controls was 2.15 (95%CI 1.27-3.60, $P=0.005$). Median latency after radiotherapy was 8.1 years (7.5-27.3) for malignant and 17.2 years (3.0-50.8) for benign tumours, respectively.
Conclusions
This is the first study assessing the risk of a second brain tumour in a cohort of non-selected irradiated adults and appropriate controls with confirmed long-term imaging surveillance. The risk of second brain tumour following radiotherapy (conventional, 3DCRT or IMRT) for pituitary tumours is increased, although less than previously reported. Our results inform clinical practice and provide data to be used when counselling patients on the risks of radiotherapy.

AKR1D1 knockdown identifies 7α-hydroxy-3-oxo-4-cholestenoic acid (7-HOCA) as a driver of metabolic dysfunction and hepatocellular cancer risk in patients with non-alcoholic fatty liver disease (NAFLD)

Nikolaos Nikolaou[1,2], Anastasia Arvaniti[2,3], Fabio Sanna[2], Ragazzon da Conceição[2], Niall Dempster[2], Laura Gathercole[3] & Jeremy Tomlinson[2]
[1]University of Cambridge, Department of Pathology, Cambridge, United Kingdom; [2]University of Oxford, Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, United Kingdom; [3]Oxford Brookes University, Department of Biological and Medical Sciences, Oxford, United Kingdom

Non-alcoholic fatty liver disease (NAFLD) is a spectrum of disease ranging from simple intrahepatic lipid accumulation to fibrosis, cirrhosis, and hepatocellular carcinoma (HCC). 5β-reductase (AKR1D1) is a liver enzyme that catalyses a fundamental step in bile acid (BA) synthesis. Both BAs and BA intermediates are established as potent regulators of metabolic and proliferative phenotype. We have hypothesised that AKR1D1 plays a crucial role in NAFLD and HCC. Human liver biopsies and serum samples were obtained from healthy subjects and patients with established NAFLD, cirrhosis and HCC. Alterations in BA synthesis and composition were determined by LC-MS. Genetic manipulation of AKR1D1 (siRNA/shRNA) was performed in human hepatoma HepG2 cells. Effects on BA synthesis, fatty acid metabolism, cell cycle, proliferation and DNA damage were determined by LC-MS, qPCR, western blotting, flow cytometry, RNA-sequencing, ILab biochemistry analyser, and single cell gel electrophoresis (comet assay). Total serum BA and BA intermediate levels were significantly elevated across NALFD disease severity, with a particular increase in the concentration of the AKR1D1 substrate 7α-hydroxy-3-oxo-4-cholestenoic acid (7-HOCA) [control: 182.1 ± 14.9 ($n=19$) vs HCC: 350.6 ± 37.4 nM ($n=20$), $P=1e\text{-}4$). In line with this, *AKR1D1* expression was significantly decreased in liver biopsies from patients with advancing steatosis, fibrosis, inflammation and HCC. In HepG2 cells, AKR1D1 knockdown decreased primary BA and increased 7-HOCA concentrations. RNA-sequencing analysis in AKR1D1-knockdown cells identified dysregulated pathways impacting lipid metabolism, cell cycle and proliferation, consistent with increased intracellular triglyceride accumulation and decreased fatty acid oxidation. In addition, AKR1D1 knockdown induced DNA damage, downstream resulting in cell cycle arrest at G1/S phase, impaired cell proliferation and enhanced apoptosis, suggesting a role for 7-HOCA in liver cell health. Confirming this, RNA-sequencing and subsequent pathway enrichment analysis in wild-type, 7-HOCA-treated HepG2 cells revealed a transcriptional profile similar to the one observed following AKR1D1 knockdown, with increased lipid and decreased proliferative gene expression, accompanied by enhanced DNA damage. Complementing these findings, pharmacological inhibition of AKR1D1 using three novel AKR1D1 inhibitors (identified through a high-throughput drug screen of $>$ 300,000 compounds) similarly impaired proliferative gene expression and cell proliferation. In conclusion, AKR1D1 expression is decreased in patients with NAFLD and HCC, and results in increased accumulation of its substrate, 7-HOCA, with downstream detrimental effects on hepatic triglyceride metabolism, fatty acid oxidation and cell proliferation. Taken together, these data demonstrate the crucial role of 7-HOCA in NAFLD/HCC progression and reveal the potential of AKR1D1 manipulation for hepatoprotective therapies.

Acute kidney injury: a strong risk factor for hypoglycaemia in hospitalized patients with type 2 Diabetes

Ana Carreira[1], Pedro Castro[2], Filipe Mira[2], Miguel Melo[1], Isabel Paiva[1], Pedro Ribeiro[3] & Lèlita Santos[3]
[1]Centro Hospitalar e Universitário de Coimbra, Department of Endocrinology, Diabetes and Metabolism, Coimbra, Portugal; [2]Centro Hospitalar e Universitário de Coimbra, Department of Nephrology, Coimbra, Portugal; [3]Centro Hospitalar e Universitário de Coimbra, Department of Internal Medicine, Coimbra,Portugal

Introduction
Acute Kidney Injury (AKI) is highly prevalent during hospitalization of patients with type 2 diabetes (T2D), and has been associated with increased risk of hypoglycaemia in Intensive Care Units. However, this association in non-critically ill patients is less clear and evidence on the impact of AKI's severity and duration on hypoglycaemia is lacking.
Objectives
To assess the impact of AKI and its severity and duration on the risk of hypoglycaemia during hospitalization of non-critically ill patients with T2D.
Methods
Retrospective cohort study of patients with T2D, hospitalized in Internal Medicine wards, from 01/01/2018 to 31/12/2019. AKI was defined as an increase in serum creatinine by ≥ 0.3 mg/dl in 48 hours or ≥ 1.5 times baseline within 7 days, and hypoglycaemia as blood glucose concentration <70mg/dl. Glomerular filtration rate (GFR) was calculated by CKD-EPI equation and patients with chronic kidney disease (CKD) stage ≥ 4 were excluded. 239 hospitalizations with AKI were obtained (Group 1) and an equivalent number without AKI was randomly selected (Group 2). Binary logistic regression was used to control for confounding factors and ROC curve analysis to determine cut-off values for AKI's duration.
Results
478 cases were analysed, with mean HbA1C of 7.4 ± 1.6%, 36.0% previously treated with insulin. Patients with AKI were older (82.7 ± 7.9 vs 80.3 ± 10.1 years, $P=0.004$) and had lower basal GFR (59.0 ± 17.3 vs 70.7 ± 19.1, $P<0.001$). The prevalence of hypoglycaemia was higher in Group 1 (40.2% vs 15.9%, $P<0.001$) and the risk increase was sustained when adjusted for confounding factors (including previous insulin therapy and insulin therapy protocol during hospitalization), with a 4.5 times greater risk of hypoglycaemia in the presence of AKI (95%CI: 1.9-10.3). AKI's severity was associated with mortality but not with hypoglycaemia. In contrast, each day of AKI's duration was associated with an increase of 15% on the risk of hypoglycaemia and 16% on the risk of 30-day mortality, independently of its severity. A cut-off of 5.5 days of AKI was obtained for increased risk of hypoglycaemia and mortality. Globally, patients with hypoglycaemia had 4.4 times greater risk of death in 30 days (95%CI: 2.4-8.1).
Conclusion
AKI was an important risk factor for hypoglycaemia in non-critically ill hospitalized patients with T2D, and its prevalence was superior in elderly patients with CKD. The duration of AKI was the main factor increasing the risk of hypoglycaemia and mortality. These results highlight the need to define specific protocols to avoid hypoglycaemia and its burden in patients with AKI.

The developing rat thyroid gland transcriptome is sexually dimorphic and exhibit dynamic changes from fetal life to prepuberty

Louise Ramhøj[1], Anna Rosenmai[1], Aurélie Lardenois[2], Bertrand Evrard[2], Marta Axelstad[1], Frédéric Chalmel[2] & Terje Svingen[1]
[1]Technical University of Denmark, National Food Institute, Kgs. Lyngby, Denmark; [2]Univ Rennes, INSERM, EHESP, Irset, Rennes, France

Lifelong thyroid health depends on establishment of thyroid gland structure and function during early life development. However, thyroid development can be disrupted and lead to early- or adult life thyroid disorders. Still, the molecular machinery underpinning thyroid gland development remains poorly understood, particularly after the onset of fetal thyroid function. Here we used bulk-RNA-barcoding and sequencing (BRB-seq) to map the thyroid gland transcriptome as it undergoes transcriptional reprogramming after the onset of fetal thyroid gland function. We found 1619 differentially expressed genes (DEGs) during rat thyroid gland development from gestation day 21 to postnatal days 3, 6, 16 and 22. The DEGs partitioned into 6 clusters that display distinct temporal transcriptional patterns. Highly expressed genes in fetuses and neonates were primarily related to cell division, development and morphogenesis. This immaturity of the thyroid gland, even after the onset of thyroid function, was verified histologically, as the fetal thyroids displayed a dense structure with very little follicular lumen. Later on in postnatal development, as thyroid hormone concentrations peak, thyroid gland structure was more mature with larger follicles. This was also reflected in the postnatal transcriptome where genes important for thyroid hormone synthesis, such as *Tpo, Slc5a5(NIS)* and *Nkx2-1*, were upregulated. In addition to the temporal DEGs, we identified 205 DEGs between males and females. Some of these DEGs were related to thyroid hormone synthesis, *Tg, Duox1* and *Duox2*, but the enriched terms also showed that developmental processes as well as the immune system and response to hormones was different between males and females. Thus, it is possible that these differences mediate a sex-specific susceptibility to external stressors such as environmental chemicals. Our results show that, even after the onset of thyroid function, the thyroid gland is still developing with a distinct and sexually dimorphic transcriptional landscape. Disruptions to this transcriptional reprogramming could alter development and thus susceptibility to thyroid disorders in adult life.

Background
Pancreatic Neuroendocrine Tumors (PanNETs) are highly prevalent in Multiple Endocrine Neoplasia type 1 (MEN1) and one of the main causes of mortality. Conventional imaging is the mainstay of PanNET screening/surveillance in MEN1. This study aims to assess the diagnostic accuracy of conventional pancreatic imaging studies and to determine the added value of pancreatic fine needle aspirations (FNA) for the diagnosis of MEN1-related PanNETs.
Methods
Patients were included from the population-based MEN1 database of the DutchMEN Study Group from 1990–2017 ($n=445$). Magnetic resonance imaging (MRI), computed tomography (CT), endoscopic ultrasound (EUS), FNA, and surgical resection specimens were obtained. For diagnostic accuracy assessment patients with a PanNET diagnosis >1990 were included if both index and reference test were available. To assess diagnostic accuracy, the first imaging (CT, MRI or EUS) of the pancreatic head and the first imaging of the pancreatic body/tail were considered the index test. For specific comparison of diagnostic accuracy between MRI and CT in the modern era, the first MRI or CT between 2010 and 2017 was the index text. The reference standard was a composite of surgical histopathology and if histopathology was unavailable radiological follow-up.
Results
413 patients underwent 3477 imaging studies. Median radiological follow-up was 8.4 yrs. Time trends show an increasing number of scans/patient, and a preference for MRI in the last decade. Overall diagnostic accuracy of the combined conventional imaging was good with a positive (PPV) and negative predictive value (NPV) of 88.9% (76.0-95.6) and 92.8% (89.4-95.1) for PanNET located in the pancreatic head and 92% (85.3-96.0) and 85.3% (80.5-89.1) in the body/tail. For comparison of MRI vs CT, PPV and NPV for tumors located in the head were 100%(76.0-100) and 87.1%(76.3-93.6) (MRI) vs 60%(22.9-88.4) and 70.4%(51.3-84.3) (CT). PPV and NPV for tumors located in the body/tail were 91.3%(72.0-98.8) and 87.0%(75.3-93.9) (MRI) vs 100%(74.9-100) and 77.8%(54.3-91.5) (CT). FNA was performed of 34 lesions in 33 patients. FNA diagnosis was PanNET in 24 (all confirmed PanNET by histology (10) or follow-up (14)), normal/cyst/unrepresentative in 6 (all confirmed PanNET by follow-up), and adenocarcinoma in 4 (2 confirmed, 2 PanNET).
Conclusion
Diagnostic accuracy for the diagnosis of PanNET was higher for MRI compared to CT and MRI should be the preferred (non-invasive) imaging modality for PanNET screening/surveillance in MEN1. The high diagnostic accuracy of pancreatic imaging and the sporadic occurrence of pancreatic adenocarcinoma question the need for routine (EUS-guided) FNA.

Role of the transcription factor HHEX in inner adrenal cortex homeostasis and response to progesterone signaling

Typhanie Dumontet[1], Kaitlin Basham[2], Antonio Lerario[1], Christina Bothou[3], Bjoern Brixius[1], Adina F Turcu[1], Felix Beuschlein[3] & Gary D Hammer[1]
[1]University of Michigan, Arbor Arbor, United States; [2]University of Utah, Salt Lake City, United States; [3]University of Zurich, Zurich, Switzerland

The adrenal glands serve as central organs of the endocrine system by producing steroid hormone essential for organismal homeostasis. Mechanisms ensuring proper adrenal homeostasis and function are therefore crucial for maintaining human life. ACTH, released by the pituitary corticotrope, is required for the differentiation of the inner part of the adrenal cortex (the zona fasciculata) and the resultant stimulation of cortisol production. Perturbation of ACTH signaling can lead to diverse pathologic manifestations such as adrenal hyperplasia, hypertrophy, hormone overproduction or adrenal insufficiency. For example, elevated ACTH is a characteristic of patients suffering from Congenital Adrenal Hyperplasia (CAH), a set of defects in cortisol synthesis due to autosomal recessive mutations in genes encoding steroidogenic enzymes. To study the complexity of the ACTH-responsive cell population in the adrenal cortex, we performed single-cell RNAseq of the steroidogenic lineage in the adult mouse adrenal. We identified *Hhex* as a transcription factor with a restricted expression to the ACTH-responsive zona fasciculata. Although the role of HHEX in adrenal biology is completely unknown, a meta-analysis identified a germ-line variant of uncertain significance near the gene *HHEX* associated with increased adrenal androgen production in humans. Interestingly, we have also observed an increase in Hhex expression in a mouse model of CAH. Together with our scRNAseq data, we hypothesized that HHEX contributes to the unique function of the ACTH-responsive inner cortex. To define the role of HHEX in adrenal homeostasis, we generated Hhex knockout mouse models. KO mice exhibited progressive adrenomegaly by 15 weeks of age, accompanied by hypertrophy, most prominent in the inner cortex. Expression of the transcription factor *Nr5a1/Sf1* and steroidogenic enzymes involved in corticosterone production were significantly upregulated at 6 weeks old, prior to adenomegaly. For insights into the signaling pathways controlled by HHEX, we analyzed global transcriptional changes during loss of *Hhex* and found dramatic downregulation of members of the membranous progesterone receptor family (PAQR). PAQR signaling has been implicated in the downregulation of cAMP, a primary mediator of ACTH signaling. Thereby, we speculate that down-regulation of PAQR and subsequent increased ACTH sensitivity could drive the increase in steroidogenesis in *Hhex* KO mice. These findings suggest that HHEX provides a unique autocrine/paracrine intra-adrenal feedback to ACTH-driven cAMP signaling by upregulating PAQR in a unique progesterone-responsive cell population in the inner cortex. As a result, we are currently assessing the implication of HHEX in contributing to the hypertrophy and steroidogenic phenotype observed in CAH.

[1]Centro Hospitalar do Tamega e Sousa, Endocrinology, Penafiel, Portugal; [2]Centro Hospitalar de Tras-os-Montes e Alto Douro, Endocrinology, Vila Real, Portugal; [3]Centro Hospitalar do Tamega e Sousa, Gynaecology and Obstetrics, Penafiel, Portugal; [4]Maternidade Bissaya Barreto, Centro Hospitalar e Universitário de Coimbra, Obstetrics, Coimbra, Portugal

Introduction
Women with gestational diabetes (GD) have an increased risk of developing future type 2 diabetes *mellitus* (T2DM). A reclassification oral glucose tolerance test (OGTT) is currently recomended in the postpartum period. However, most studies report a compliance rate below 50% and as low as 23%.
Objectives
We aimed to study predictors of missing postpartum OGTT in women with GD.
Materials and Methods
Retrospective study based on the national register of GD. Included women followed between 2012 and 2017. Excluded women with fetal losses and missing data on age, educational level, BMI, previous history of GD, abortion or arterial hypertension, family history of T2DM, treatment, delivery and obstetric/neonatal complications. Women with and without OGTT were compared. A logistic regression model was used to study factors associated with absence of OGTT: variables with different distribution between groups were included in the analysis.
Results and Conclusions
We studied a total of 14081 women, 4324 (30.7%) had missed postpartum OGTT. Women without OGTT were younger, more frequently foreigners, had higher BMI, more often had had previous GD, multiparity, twin pregnancies and preterm deliveries and they were less frequently diagnosed in the 1st trimester. Newborns from women without OGTT were more often macrossomic and had neonatal hypoglycemia. In the multivariate analysis, age [OR 0.96 (IC 95%: 0.95-0.96), $P<0.001$], BMI ≥ 30 kg/m^2 [1.13 (1.04-1.23), $P=0.004$], preterm delivery [1.35 (1.18-1.54), $P<0.001$], foreign nationality [1.33 (1.18-1.49), $P<0.001$], having a college degree [0.90 (0.83-0.97), $P=0.01$], multiparity [1.91 (1.73-2.12), $P<0.001$], twin pregnancy [1.39 (1.08-1.78), $P=0.009$], pharmacological treatment [0.68 (0.63-0.73), $P<0.001$], previous GD [1.16 (1.04-1.29), $P=0.01$], previous abortion [1.21 (1.12-1.32), $P<0.001$], diagnosis in the 1st trimester [0.86 (0.79-0.92), $P<0.001$] and neonatal hypoglycemia [1.21 (1.01-1.45), $P=0.04$] were associated with missing postpartum OGTT. Women with higher BMI, multiparity, foreigners, with twin pregnancies, previous history of GD, abortion, preterm delivery and neonatal hypoglycemia have an increased risk of missing OGTT. On the other hand, older women and those who needed pharmacological treatment, who have a college degree and who are diagnosed in the 1st trimester have lesser risk of missing OGTT.

Glucose alterations, insulin resistance, hypertension, and activation of the renin-aldosterone system are strictly associated in pediatric obesity

Valentina Antoniotti[1], Martina Amore[1], Simonetta Bellone[1], Roberta Ricotti[1], Roberta De Grandi[1], Marina Caputo[2], Daniele Spadaccini[2], Valentina Mancioppi[1], Gianluca Aimaretti[2] & Flavia Prodam[2]

[1]University Of Piemonte Orientale, SCDU of Pediatrics, Department of Health Sciences, Novara, Italy; [2]University of Piemonte Orientale, Department of Health Science, Novara, Italy

Background
The increase of global childhood obesity has led to an increase of associated co-morbidities also at a young age. The pro-inflammatory state and insulin resistance are two master regulators of several complications, including hypertension and pre-diabetes frequently connected in a complex cross-talk.
Aim
To evaluate the relationship between glucose alterations and blood pressure and the pathogenetic involvement of the renin-aldosterone system (RAAS) in pediatric obesity.
Methods
We retrospectively evaluated 800 paediatric subjects (11.4 $\pm$ 3.1 years) with overweight or obesity at the first visit with a complete clinical and metabolic screening (BMI, BMI-SDS, blood pressure, glucose, and insulin levels during an OGTT). Aldosterone and renin were measured with chemiluminescence, and their ratio (ARR) was calculated.
Results
774 patients had all the parameters. 11.5% of patients were with overweight and 88.5% with obesity. Blood pressure has been characterized following the last American Academy of Pediatrics guidelines: 679 patients (87,6% 88.0%) had hypertension (HTN). Of them, 38 (5%) had elevated blood pressure, 226 (29.2%) were classified as HTN stage 1, and 414 (53.4%) stage 2. Regarding glucose levels, 41 subjects had impaired glucose levels, (IFG), 52 impaired glucose tolerance (IGT), 3 type 2 diabetes (T2DM), and a totally 80 subjects had one or more glucose alterations (IFG/IGT/T2DM). Patients with IFG ($P<0.01$), IGT ($P<0.02$), or T2DM/glucose alterations ($P<0.02$) were more frequently with HTN. Blood pressure levels were higher in subjects with glucose alterations ($P<0.04$) than those with normal glucose levels (NGT). OGTT glucose levels and HOMA-IR ($P<0.002$) were higher in subjects with the three HTN stages than those with normal levels. Subjects with glucose levels $>$ 155 mg/dl after 60' at OGTT had more frequent HTN ($P<0.001$) and higher diastolic blood pressure levels ($P<0.002$) than NGT. We also found increased activation of the renin-angiotensin-aldosterone system (RAAS), positively correlated with BMI and female gender, that mainly characterized subjects in HTN stage 2. Aldosterone levels were higher in subjects with glucose levels $>$ 155 mg/dl after 60' at OGTT than those without it ($P<0.003$).
Conclusions
Already in childhood obesity, there is a close relationship between insulin resistance, glucose alterations, hypertension, and RAAS. The identification of specific risk categories, such as the presence of altered blood glucose or hypertension, could provide risk indicators to close clinical surveillance for the prevention and identification of complications and follow-up of organ damage.

Background
Polycystic ovary syndrome (PCOS) is a heterogenous endocrinopathy commonly diagnosed in reproductive age women, predisposing to the development of metabolic disturbances. However, the mechanisms underlying the connection between PCOS and metabolic disorders are still not well understood. The aim of the study was to investigate amino acid (AA) profile in women with PCOS and to assess its relation with metabolic disturbances.
Methods
326 women: 209 diagnosed with PCOS and 117 healthy controls participated in the study. Anthropometrical, biochemical and hormonal parameters were assessed. A subgroup of patients with abdominal obesity (defined as the waist circumference $\geq$ 80 cm) was separated and included 143 PCOS patients and 74 controls. The gas–liquid chromatography combined with tandem mass spectrometry was used to assess amino acids levels – branched chain amino acids (BCAAs): leucine, isoleucine, and valine, and the aromatic amino acids (AAAs): phenylalanine, tryptophan and tyrosine.
Results
Statistical analysis showed significantly higher plasma levels of the BCAAs (540.4 ± 97.0 nmol/ml vs 501.0 ± 85.7 nmol/ml; $P<0.001$) and AAAs (162.8 ± 22.6 nmol/ml vs 153.1 ± 20.5 nmol/ml, $P<0.001$) in women with PCOS. Significant correlations ($P<0.05$) were also found in PCOS patients between both BMI and HOMA-IR and BCAAs ($rs=0.34$ for BMI and $rs=0.39$ for HOMA-IR) and AAAs ($rs=0.15$ for BMI and $rs=0.23$ for HOMA-IR). In the analysis of women with abdominal obesity, there were significant differences between PCOS subjects and controls in BCAAs (560.2 ± 99.2 nmol/ml vs 513.5 ± 78.1 nmol/ml; $P<0.001$) and AAAs (163.1 ± 21.4 nmol/ml vs 156.7 ± 20.1 nmol/ml, $P=0.01$).
Conclusions
Plasma amino acid profile is altered in women with PCOS and it is correlated with BMI and HOMA-IR. Additionally, in women with abdominal obesity BCAAs

and AAAs concentrations are more severe altered in PCOS group. Derangement in the plasma amino acid profile might be an important connection between PCOS and metabolic disturbances, however, further studies are needed.

Exploring the role of skeletal muscle Mineralocorticoid Receptor in glucose metabolism and insulin signaling

Alessandra Feraco[1,2], Stefania Gorini[1,2], Vincenzo Marzolla[1], Caterina Mammi[1], Andrea Armani[1,2] & Massimiliano Caprio[1,2]
[1]IRCCS San Raffaele Rome, Laboratory of Cardiovascular Endocrinology, Roma, Italy; [2]Università Telematica San Raffaele, Department of Human Sciences and Promotion of the Quality of Life, Roma, Italy

Mineralocorticoid Receptor (MR) is able to regulate the transcription of a number of genes in the myotube, nevertheless the role of this steroid hormone receptor in skeletal muscle (SM) metabolism needs to be clarified. SM represents a major site for glucose uptake and local metabolic derangements play a pivotal role in the development of insulin resistance (IR). The aim of this study was to investigate the contribution of MR in mediating SM metabolic alterations in a mouse model of diet-induced obesity. We observed that mice fed a high fat diet (HFD mice), showed impaired glucose tolerance compared to mice fed a normal diet (ND mice). Mice fed a HFD treated with the MRA spironolactone (HFD + spiro mice) revealed an improvement in glucose tolerance, compared with HFD mice. In addition, MRA-treated obese mice showed brown adipose tissue activation, which was expected to contribute to the improved glucose metabolism. To investigate if MR blockade in SM could contribute to the observed MRA-mediated metabolic effects, we analyzed MR expression in gastrocnemius, observing that MR protein abundance was downregulated by HFD compared to ND mice, whereas administration of spiro was able to partially revert this effect in HFD + spiro mice. Interestingly, SM MR expression profile was opposite to that observed in adipose tissue (AT), showing increased protein abundance in HFD group, thus suggesting a different metabolic function of MR in AT and SM. Upregulated levels of mineralocorticoids, as well as up-regulated MR activation, are associated with impaired glucose metabolism. In our experimental model, downregulated expression and function of MR in SM of HFD mice with altered glucose tolerance, suggests that SM MR has a completely different role in regulation of glucose metabolism. To confirm this hypothesis, we investigated the effect of MR blockade on insulin signalling in a cellular model of myocytes (C2C12) with IR, which was obtained by treatment with palmitate, in the presence or absence of spiro. We confirmed MR protein downregulation in insulin resistant myotubes. We also analysed Akt phosphorylation, upon insulin stimulation, and we did not observe any difference between palmitate- and palmitate + spiro-treated cells. These results were confirmed by in vitro glucose uptake analysis. Taken together our data indicate that MR does not regulate insulin signaling in mouse myocytes, excluding any protective effect of SM MR pharmacological blockade upon local and systemic insulin sensitivity.

Sex steroids regulate liver fat content and body fat distribution in both men and women: a study in transgender persons

Marieke Tebbens[1], Moya Schutte[1], Marian Troelstra[2], Eveline Bruinstroop[3], Renée de Mutsert[4], Aart Nederveen[2], Martin den Heijer[1] & Peter H. Bisschop[3]
[1]Amsterdam UMC, Vrije Universiteit Amsterdam, Endocrinology, Amsterdam, Netherlands; [2]Amsterdam UMC, University of Amsterdam, Radiology, Amsterdam, Netherlands; [3]Amsterdam UMC, University of Amsterdam, Endocrinology, Amsterdam, Netherlands; [4]Leiden University Medical Center (LUMC), Clinical Epidemiology, Leiden, Netherlands

Objective
Visceral adipose tissue (VAT) and liver fat content are associated with insulin resistance and cardiovascular disease and show clear sex differences. Our objective is to determine the effect of estradiol and testosterone on VAT and liver fat content in trans women (assigned male at birth, identify as female) and trans men (assigned female at birth, identify as male).
Design
Open-label partly randomized intervention study in 8 trans women and 18 trans men, receiving hormone treatment.
Methods
Trans women were treated with triptorelin for 6 weeks, followed by triptorelin and estradiol for 52 weeks. VAT, abdominal subcutaneous adipose tissue (SAT) and liver fat content were quantified by magnetic resonance imaging (MRI) and magnetic resonance spectroscopy (MRS) at baseline, 6, 8, 18 and 58 weeks. Trans men were randomized to receive triptorelin and testosterone with or without anastrozole for 12 weeks, followed by only testosterone until week 52. VAT, SAT and liver fat content were determined at baseline, 6, 12 and 52 weeks.
Results
In trans women, after 58 weeks, VAT did not change (+1% (95% CI -14 to 17), SAT increased by 33% (21 to 44), the VAT/SAT ratio decreased by 0.19 (-0.28 to -0.10) and liver fat content decreased by 37% (-65 to -10), compared to week 6 (start of estradiol). In trans men with anastrozole, SAT increased by 9% (2 to 17) after 12 weeks, while VAT, VAT/SAT ratio and liver fat content did not change. In trans men without anastrozole, after 52 weeks, VAT increased by 34% (16 to 51), SAT by 15% (8 to 21), VAT/SAT ratio by 0.06 (0.03 to 0.10) and liver fat by 1% (0 to 2).
Conclusions
Sex steroids regulate liver fat content and body fat distribution in both men and women.

Evidence for three superimposed components, via which metformin affects blood glucose in obese mice

Mairam Kaplanian[1], Cecile Philippe[2], Marianna Beghini[1], Matthaeus Metz[1], Sameer Abu Eid[1], Alexandra Kautzky-Willer[1], Thomas Scherer[1] & Clemens Fürnsinn[1]
[1]Medical University of Vienna, Department of Medicine III, Division of Endocrinology & Metabolism, Vienna, Austria; [2]Medical University of Vienna, Department of Biomedical Imaging and Image-Guided Therapy, Division of Nuclear Medicine, Vienna, Austria

Introduction
Despite a plethora of suggested targets and pathways, the mechanism of anti-hyperglycaemic metformin action is still unknown. The present study critically re-analysed protocols broadly applied in preclinical rodent studies.
Methods
Obese male C57BL/6J mice on high fat diet were treated with metformin in the form of a single dose, daily intraperitoneal injections, admixture to drinking water, or continuous infusion via intraperitoneal minipumps. Glucose tolerance tests (GTT) were performed to evaluate effects on blood glucose homeostasis.
Results
Thirty min after intraperitoneal injection of 50mg/kg metformin, the plasma concentration of metformin was 56 ± 22µmol/l and glucose tolerance was improved (AUC, min*g/dl: 40.4 ± 1.8 vs 34.0 ± 1.2, $P = 0.008$). The beneficial effect on glucose tolerance was gone 3 h after drug administration, when plasma metformin was down to 2.8 ± 0.7µmol/l (AUC, min*g/dl: 39.0 ± 1.4 vs 36.4 ± 1.7, n.s.). Rapid clearance of metformin accompanied by fading of its action suggests that mice under typical long-term treatment regimens (daily dosing; admixture to food or water) are not permanently exposed to effective drug concentrations. In mice under long-term treatment, we therefore found effects on glucose tolerance to depend on the time span between the preceding metformin dose and measurement of blood glucose. Under regular treatment, however, metformin also affected glucose tolerance indirectly via reduced appetite and blunted weight gain (g gained in 7 weeks on metformin 50 mg/kg/d: +6.7 ± 1.0 vs +3.1 ± 0.5, $P = 0.005$). When dosing shortly before the GTT was avoided and weight-mediated actions were eliminated by restricted feeding of the control mice, counterintuitive worsening of glucose tolerance by metformin was unmasked (after 6 weeks with 4.1g/kg metformin in drinking water: AUC, min*g/dl: 32.2 ± 0.8 vs 38.5 ± 1.2, $P = 0.0003$). In mice continuously infused with the drug (13mg/kg/d), plasma metformin was intra-individually associated with less weight gain ($r = 0.81$) and lower blood glucose ($r = 0.78$).
Conclusions
Our results suggest three superimposed components of metformin action on blood glucose in mice: (i) Glucose lowering shortly after dosing, which fades rapidly with the clearance of plasma metformin - we hypothesise that this component accounts for antidiabetic action in the clinic. (ii) Indirect action via reduced appetite and weight gain - we suspect that this component is not sufficiently considered in many rodent studies. (iii) Deterioration of glucose homeostasis by prolonged treatment - this component is unmasked by exclusion of weight-mediated effects in combination with avoidance of dosing shortly before glucose measurements. Dependent on the specific experimental protocol, the net effect of these components can be decreased, increased, or unchanged blood glucose.

The role of chemokines in type 1 diabetes-associated neuropathy

Evangelia Baldimtsi[1,2], Nektaria Papadopoulou-Marketou[3], Maria Jenmalm[4,5] & Jeanette Wahlberg[1,2,6]
[1]Linköping University, Department of Health,Medicine and Caring Sciences, Linköping, Sweden; [2]Linköping University Hospital, Department of Endocrinology, Linköping, Sweden; [3]National and Kapodistrian University of Athens, 1st Department of Propaedeutic and Internal Medicine, Medical School, Athens, Greece; [4]Linköping University, Department of Biomedical and Clinical Sciences, Linköping, Sweden; [5]Linköping University, Division of Inflammation and Infection, Linköping, Sweden; [6]Örebro University, Faculty of Medical Sciences, Örebro, Sweden

Background and aims
Diabetic neuropathy is a common complication in patients with type 1 diabetes mellitus (T1D). In this study, we explore the importance of circulating chemokines for the development of diabetic neuropathy (DN) in T1D.
Materials and methods
This study was a cross-sectional analysis of patients with childhood onset T1D followed prospectively in a long-term longitudinal cohort study. Fifty-two patients (20 women/32 men; mean age 28 ± 4 yrs.; diabetes duration 19.5 ± 5.5 yrs.), and 19 control subjects (11 women/8 men; mean age 26.5 ± 4.5 yrs.) were included. Plasma levels of Th1- (CXCL9, CXCL10, CXCL11), Th2- (CCL17, CCL22) and Th17-associated (CXCL8, CCL20) chemokines were assessed in all subjects. Clinical examination and electroneurography tests with bilateral measurements of peroneal MCV and CMAP and sural SCV and SNAP were performed in the TID patients.
Results
Patients with diabetic neuropathy had higher levels of CXCL9 (Th1) than patients without DN. Both patients with and without neuropathy had significantly higher CXCL9 levels compared to controls, $P=0.002$ and $P=0.05$, respectively. The levels of the other chemokines were similar in patients and controls. In T1D patients with peripheral DN, the CXCL8 (Th17) levels correlated negatively with cold perception threshold (rho -0.645, $P=0.032$), while the CXCL10 (Th1) levels were positively correlated with the vibration perception threshold (rho 0.639, $P=0.034$).
Conclusions
The Th1 associated chemokine CXCL9 was increased in patients with T1D, both in patients with and without neuropathy. Increased Th1 and Th17 associated chemokines showed possible associations to an impaired peripheral sensory nerve function and nerve conduction tests for the suralis nerve.

A rapid genetic diagnosis for >80% individuals with non-CAH Primary Adrenal Insufficiency is achievable by candidate gene sequencing combined with WES

Chris Smith[1], Jordan Read[1], Charlotte Hall[1], Avinaash Maharaj[1], Lucia Marroquin Ramirez[1], Younus Qamar[1], Claire Hughes[1,2], Adrian Clark[1], Rathi Prasad[1], Li Chan[1], Salwa Musa[3] & Louise Metherell[1]
[1]William Harvey Research Institute, United Kingdom; [2]Royal London Hospital, United Kingdom; [3]Gaafar Ibn Auf Children Hospital, Pediatric Endocrinology Unit, Sudan

Primary adrenal insufficiency in children can be due to mutations in >20 genes, most commonly *CYP21A2*, giving rise to 21-hydroxylase deficiency. Phenotypically these disorders overlap and present with conditions ranging from isolated (or familial) glucocorticoid deficiency (FGD) to syndromic disorders involving multiple tissues. Distinguishing between them can be problematic, especially where biochemical testing is not possible or not undertaken. Over the last 30 years 400 individuals with suspected FGD, from 31 different countries, have been referred to our centre for genetic testing. All cases had low/undetectable serum cortisol and, where measured, elevated plasma ACTH levels. Using a combined, two-step protocol we have sequenced 369 of the 400 individuals. In the first step we sequenced the small, frequently mutated, candidate genes; *MC2R, MRAP, STAR* and *CYP11A1*, by Sanger sequencing (CGS) before proceeding to whole exome sequencing (WES) if these were mutation free. For CGS, sequences were aligned to reference sequences using BioEdit software and WES variant call files were analysed using Ingenuity Variant Analysis package and/or examination of BAM files, using the Integrative Genomics Viewer, to detect exonic deletions. Rare, synonymous or predicted benign variants were subjected to an in vitro splicing assay using the pET01 vector (MoBiTec). In 308/369 individuals we found a definitive diagnosis in a causative gene for adrenal insufficiency, a success rate of 81%, and identified many novel mutations. The findings also highlighted a number of causal synonymous and predicted benign variants resulting in splice defects. The aetiologies of cases with a gene defect were as follows; *MC2R* (22%), *MRAP* (17%), *NNT* (15%), *STAR* (9%), *CYP11A1* (7%), with the remaining 30% due to a further 13 genes. Previous founder effects were reinforced e.g S74I in *MC2R* and rs6161 in *CYP11A1* in the UK population, P24Rfs*4 in *MCM4* in Ireland and R188C in *STAR* in Canada, with new associations being discovered for T731= in *NNT* in Sudan and R222Q in *SGPL1* in Saudi Arabia. In contrast, common MRAP splice mutations seen at the exon 3/intron 3 junction were present in individuals from many countries. The use of CGS/WES now permits a rapid genetic diagnosis for >80% individuals and is an invaluable, cost-effective tool to improve tailored patient management. For patients without a genetic diagnosis, it is unclear whether they have unconventional mutations in known genes or if there are further gene defects to be discovered.

FKBP5 methylation in adrenal insufficiency: looking at a new tool for assessing the quality of glucocorticoid replacement?

Irina Chifu[1], Scheuermann Carolin[1], Burger-Stritt Stephanie[2], Juliane Lippert[1], Sabine Herterich[3] & Stefanie Hahner[1]
[1]University Hospital Würzburg, Endocrinology and Diabetes, Würzburg, Germany; [2]Uppsala University Hospital, Endocrinology and Diabetes, Uppsala, Sweden; [3]University Hospital Würzburg, Clinical Chemistry and Laboratory Medicine, Würzburg, Germany

Available glucocorticoid (GC) replacement regimens in adrenal insufficiency (AI) only roughly correspond to physiological steroid profiles. Control of substitution quality is therefore difficult but significant, as even mild chronic over- or under-replacement may be clinically relevant. FKBP5 regulates GC receptor sensitivity by reducing its affinity to cortisol when bound to the receptor complex. FKBP5 methylation has been inversely correlated with cortisol levels both in healthy controls and in patients with endogenous hypercortisolism. We analyzed FKBP5 gene methylation (DNAm) within introns containing GC responsive elements as well as promoter and proximal enhancer regions by bisulfite pyrosequencing in a cohort of 86 patients with primary (PAI, $n=57$) and secondary (SAI, $n=29$) AI. Results were correlated with GC dose, salivary and 24-hour urinary cortisol, prevalence of adrenal crises (AC) per patient-year and 24-hour blood pressure (BP) levels. GC dose and DNAm were negatively correlated for the majority of the investigated regions (intron 1 $r_s=-0.45$, $P<0.01$, intron 5 $r_s=-0.35$ $P<0.01$, intron 7 $r_s=-0.23$ $P=0.034$, promoter A1 $r_s=-0.35$ $P<0.01$, proximal enhancer A2 $r_s=-0.38$ $P<0.01$). Intronic DNAm correlated negatively with 24-hour urinary cortisol (intron 2, $r_s=-0.25$, $P=0.032$) and positively with bedtime salivary cortisol (intron 7, $r_s=0.3$, $P<0.01$). We observed a positive correlation between the prevalence of AC and intronic DNAm (intron 2 and 5, $r_s=-0.29$ $P<0.01$ for each). Systolic 24-hour and day-time BP, systolic and diastolic night-time BP and noctural dipping correlated negatively with DNAm within several intronic, promoter and proximal enhancer regions. GC replacement was higher, whereas intronic DNAm was lower in PAI compared to SAI (GC: 22 (10-60) vs 20 (10-37,5) mg $P=0.032$, intron 5: 11% vs 15% $P=0.028$). FKBP5 methylation analysis may provide helpful further insight regarding the evaluation of GC replacement and might help improving assessment of GC load in AI, as it correlates with replacement doses, cortisol levels and 24-hour BP. Our observations warrant further analyses in larger cohorts.

Diagnostic accuracy of basal cortisol level to predict secondary adrenal insufficiency in patients with pituitary disease

Campbell Mathieson[1], Razan Ali Rashid[2], Christopher S Boot[2], Andy James[2] & Yaasir Mamoojee[2]
[1]Medical Student, Newcastle University, Newcastle Upon Tyne, United Kingdom; [2]The Newcastle upon Tyne Hospitals, Endocrinology and Metabolic Medicine, Newcastle upon Tyne, United Kingdom

Objective
The 250 µg short Synacthen stimulation test (SST) is the most commonly used dynamic assessment to diagnose adrenal insufficiency (AI). There are challenges to the use of the SST in routine clinical practice, including staff and resource

limitation in the current COVID-19 pandemic and Synacthen cost. We aimed to investigate the value of basal cortisol level for predicting AI in our selected cohort of patients at risk of secondary adrenal insufficiency from pituitary disease, pituitary surgery or pituitary irradiation.
Methods
A ten-year retrospective review was performed in our tertiary unit. SSTs were performed before midday. AI was defined as peak serum cortisol level of <550 nmol/l on Roche Cortisol I assay or <420 nmol/l on Roche Cortisol II assay. Conversion of baseline cortisol level from Roche I to Roche II equivalent measurement was done using validated regression equation. Diagnostic performance was evaluated by Receiver Operating Curve (ROC) analysis.
Results
595 SSTs performed from 2010 to 2020 were included. 51 (8.6%) were positive for AI. The ROC analysis showed an overall area under the curve (AUC) for basal cortisol of 0.975 (95% CI 0.959 to 0.986). If a basal cortisol level cut-off of ≤ 237 nmol/l was implemented to predict AI, no failed SST would be missed, hence the negative predictive value to rule-out AI was 100% (95% CI 93 to 100%). By using a cut-off value of 237 nmol/l, 399 out of 544 (73%) SSTs could be eliminated. With a lower basal cortisol cut-off of ≤ 165 nmol/l, 5 out of 51 failed SSTs would be missed but 503 out of 544 (92%) normal SSTs would be avoided.
Conclusion
In our cohort of patients at risk of secondary adrenal insufficiency, basal morning serum cortisol concentration can be utilised as a convenient screening test, with high diagnostic performance, to identify patients requiring confirmatory dynamic testing using SST. Further prospective studies are required to validate the cut-off values proposed.

Diagnostic value of basal cortisol level to predict adrenal insufficiency in patients treated with glucocorticoids during COVID-19: a single centre observational cohort study

Mojca Jensterle[1,2], Matej Rakusa[1,2], Gaj Vidmar[2,3,4], Andrej Janez[1,2] & Tomaž Kocjan[1,2]
[1]Department of Endocrinology, Diabetes and Metabolic Diseases, University Medical Centre Ljubljana, Ljubljana, Slovenia; [2]Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia; [3]University Rehabilitation Institute, Ljubljana, Slovenia; [4]FAMNIT, University of Primorska, Koper, Slovenia

Objective
During the current pandemic of COVID-19, many therapeutic protocols adopted high dose systemic glucocorticoids (GC) for treatment of moderate to severe respiratory insufficiency. The suppression of the hypothalamic–pituitary–adrenal axis by synthetic GC, even after a short treatment period, cannot be reliably predicted due to pathophysiological changes in cortisol dynamics in critically ill, inter-individual pharmacokinetic differences, and sensitivity variations in glucocorticoid receptors. Moreover, the revealed pathological adrenal changes in Covid-19 patients make prior estimates even less reliable.
Aim
We aimed to estimate percentage of patients with adrenal insufficiency (AI) at the end of acute phase of COVID-19 after tapering GC toward replacement dose of hydrocortisone for at least 1 week and to investigate for the first time the basal cortisol level for prediction of AI in this population.
Methods
We retrospectively analysed 287 consecutive patients (median 65 years, range 26-91 years); 113 (39.4%) female and 174 (60.6%) male) who had low-dose (1 μg) cosyntropin testing. Site-specific cut-off levels for AI were <500 nmol/l. The overall potential of cortisol at baseline to classify patients into adrenal (in) sufficiency was assessed using receiver-operating-characteristic (ROC) curve analysis.
Results
The average cortisol level at baseline was 419 nmol/l (median 429, range 36-953 nmol/l), and at 30' 617 nmol/l (median 623, range 114-1092 nmol/l); Overall, 65 (22.6%) showed an insufficient increase of cortisol and were categorized as AI. ROC showed an overall area under the curve (AUC) for basal cortisol of 0.84, with 95% confidence interval 0.79-0.89. If basal cortisol level was below 100 nmol/l, which was the case in 7 patients (2.4%), the positive predictive value (PPV) to predict AI was 100%. If basal cortisol was at least 450 nmol/l, which was the case in 125 patients (43.6%), the negative predictive value (NPV) to predict no AI was 96.0%; if it was at least 400 nmol/l (158 patients, 55.1%), NPV was 93.0%; and if it was at least 460 nmol/l (113 patients, 39.4%), NPV was 99.1%. PPV sharply declines after the threshold of 100 nmol/l. On the other hand, PPV increases approximately linearly over the threshold range from 350 to 460 nmol/l, where it practically reaches 100%.
Conclusion
Basal cortisol levels ≤ 100 and ≥ 460 nmol/l in patients tested for possible AI were found in 41.2% and had sufficient diagnostic accuracy to safely abolish the need for cosyntropin testing. The data may help guide clinicians when testing for AI can be simplified.

Treatment of adrenal insufficiency in the netherlands from a patient perspective in the recent past. Lessions learned for europe

Anton Franken[1], Roselinda van der Vlugt[2] & Johan Beun[3]
[1]Isala Hospital Zwolle, Endocrinology, Zwolle, Netherlands; [2]Ace Pharmaceuticals, Manager Quality Assurance and Regulatory Affairs, Zeewolde, Netherlands; [3]Manager AdrenalNET, Netherlands

In 2015 AdrenalNET organized a roundtable conference with patient representatives, prescribers and pharmaceutical industry. The cause of this meeting was complaints of patients about the problematic hydrocortisone market in the Netherlands, characterized by frequent availability issues (shortage) of the hydrocortison tablets/capsules and frequent changes in manufacturers (compounding companies) leading to quality issues. All parties at the roundtable meeting agreed to join forces to achieve hydrocortisone tablets with the following requirements:
1. Immediate release hydrocortisone tablets for both children and adults. Conventional IR-released hydrocortison remains the gold standard (EndoERN position paper 2021).
2. Various strengths ranging from 1 to 10 mg.
3. Colour coded tablets with no bad taste and no need for splitting anymore4. Permanent availability which will be increased by obtaining marketing authorization and by production of hydrocortison tablets in the EU from preferable European raw materials. In 2018 one of our partners, a small Dutch pharmaceutical company, started the development of new hydrocortison tablets based on the above requirements. Despite a lot of regulatory struggles, in March 2020 registration was approved in the Netherlands for the 1,5 and 10 mg tablets, followed by recent registration (2021) of the 2 and 3 mg hydrocortison. The different strengths make it possible to mimic the individual patient's cortisol pattern during the day most closely. The introduction of the new tablets was followed by a fast-uptake in the market. At the moment expansion of these hydrocortison tablets to other European countries will take place. This project is a good example of fruitfull collaboration between patients, doctors and pharmaceutical companies which deserves a rollout over the rest of Europe. AdrenalNET and Endo-ERN may serve a important role in achieving this.

Newell-Price[8], Colin Graham Perry[9], Alessandro Prete[3], Nicole Reisch[10], Monica Stikkelbroeck[11], Philippe A Touraine[12], Helen Coope[13], John Porter[13] & Richard John M Ross[8]
[1]Cardiff University, United Kingdom; [2]NIH Clinical Center, Bethesda, United States; [3]University of Birmingham, United Kingdom; [4]Louis Pradel Hospital, Bron, France; [5]Karolinska Institute, Sweden; [6]Rigshospitalet, København, Denmark; [7]AstraZeneca, Gaithersburg, United States; [8]The University of Sheffield, United Kingdom; [9]University of Glasgow, United Kingdom; [10]Endokrinologie, Nephrologie und weitere Sektionen - Medizinische Klinik und Poliklinik IV - Campus Innenstadt, München, Germany; [11]Radboud University Nijmegen, Nijmegen, Netherlands; [12]University Hospitals Pitié Salpêtrière - Charles Foix, Paris, France; [13]Diurnal Ltd, United Kingdom

Background
The therapeutic goal in CAH is androgen control on the lowest achievable glucocorticoid dose, preferably an adrenal replacement dose (15-25 mg hydrocortisone a day)[1]. However, the glucocorticoid dose required to control androgens frequently exceeds that required for adrenal replacement[2]. Modified-release hydrocortisone (MRHC) capsules, (Efmody, Diurnal Ltd, Cardiff, UK), replicate cortisol diurnal rhythm and improve CAH control compared to standard

therapy[3]. We have examined whether MRHC can improve CAH control in patients receiving high dose standard treatment.
Methods
We reviewed the data of patients in the randomised study of standard treatment versus MRHC and selected those on >25 mg/day hydrocortisone dose equivalent (HDE=prednisolone dose 5 & dexamethasone 80)[3] at study entry. Patients were assessed at 24 weeks after blinded dose titration aimed to bring 17OHP into the optimal range (<36 nmol/l) and A4 into the reference range. After 24 weeks, patients participated in an ongoing MHRC single arm extension study. Control of CAH was defined as 0900h 17OHP <36 nmol/l.
Results
At baseline 41% (n=43/105) of patients were on >25mg HDE/day standard treatment; 21/43 were female, mean baseline 0900h 17OHP was 106 nmol/l and 48% were uncontrolled. At 24 weeks 95% (n=21/22) of patients on MRHC were controlled on median 40 mg/day (mean 17OHP 10 nmol/l) and for standard treatment 81% were controlled on median 40 mg HDE/day (mean 17OHP 49 nmol/l). In the full cohort, there were no adrenal crises in the MRHC group and three in the standard treatment group (10.7/100 patient years). After 24 weeks 27 of the 43 patients entered the clinician-titrated, MRHC single-arm extension study. At the 18-month interim analysis 76% patients were in control with a median dose of 25 mg (52% ≤25 mg/day) and mean 17OHP 24 nmol/l. In the ongoing extension study of all patients on MRHC (221 patient years), there were 12 adrenal crises in 5 patients (5.4/100 patient years).
Conclusions
It is common in CAH patients for the glucocorticoid dose to exceed the recommended adrenal replacement dose and still ~50% of patients remain uncontrolled. MRHC controlled 17OHP in 95% patients who were previously on high dose standard therapy and over time it was possible to reduce the MRHC dose to an adrenal replacement dose in ~50% of patients and retain control in 75%.

Improved biochemical control with modified-release hydrocortisone overturns the impaired fludrocortisone effect in salt-wasting CAH patients

Lea Tschaidse[1], Nicole Reisch[2], Wiebke Arlt[3] , Aude Brac De La Perriere[4], Angelica Linden Hirschberg[5], Anders Juul[6], Ashwini Mallappa[7], Deborah P Merke[8], John DC Newell-Price[9], Colin Graham Perry[10], Alessandro Prete[3], Aled Rees[11], Monica Stikkelbroeck[12], Phillippe A Touraine[13], Helen Coope[14], John Porter[14], Richard John M Ross[14] & Marcus Quinkler[15]
[1]Klinikum der Universität München, Standort Großhadern, München, Germany; [2]Endokrinologie, Nephrologie und weitere Sektionen - Medizinische Klinik und Poliklinik IV - Campus Innenstadt, München, Germany; [3]University of Birmingham, United Kingdom; [4]Louis Pradel Hospital, Bron, France; [5]Karolinska Institute, Sweden; [6]Rigshospitalet, København, Denmark; [7]AstraZeneca, Gaithersburg, United States; [8]NIH Clinical Center, Bethesda, United States; [9]The University of Sheffield, United Kingdom; [10]Queen Elizabeth University Hospital, United Kingdom; [11]Cardiff University, United Kingdom; [12]Radboud University Nijmegen, Nijmegen, Netherlands; [13]University Hospitals Pitié Salpêtrière - Charles Foix, Paris, France; [14]Diurnal, United Kingdom; [15]Endocrinology in Charlottenburg, Berlin, Germany

Background
Patients with salt-wasting congenital adrenal hyperplasia (CAH) due to classic 21-hydroxylase deficiency require glucocorticoid (GC) and mineralocorticoid (MC) replacement therapy. Recently, it was shown that twice daily modified-release hydrocortisone hard capsules (MRHC, Efmody®, Diurnal Ltd) improved control of CAH with most patients showing good disease control versus standard GC therapy. However, no data has been reported on the renin-angiotensin-aldosterone (RAA) system in these patients. This is of clinical relevance because 17-hydroxyprogesterone (17-OHP) is a known MC-receptor antagonist, and poorly controlled salt-wasting CAH patients often require higher fludrocortisone doses than patients with primary adrenal insufficiency. The aim of this study was to investigate the RAA system in patients on MRHC.
Methods
Data was analyzed from the 6-month, phase 3 study1. Patients with salt-wasting CAH (5 excluded; 83 included; 34.9% male, median age 35.3 yrs) were randomized to either MRHC twice daily (n=42) or standard GC (n=41; 4.9% dexamethasone, 39% prednisolone, 56.1% HC). MC replacement therapy with fludrocortisone remained stable and unchanged throughout the study. Blood pressure, potassium, sodium, plasma-renin-activity (PRA) serum androgen precursors 17-OHP and androstenedione were analyzed at baseline, 4, 12 and 24 weeks.
Results
Both groups improved hormonal control (17-OHP and androstenedione) on intensive monitoring and with stable GC doses on MRHC (median 25.0 to 25.0 mg/d, P= 0.062) and increased doses on standard GC (25.0 to 31.3 mg/d, P= 0.001) at 24 weeks. However, the serum 17-OHP was significantly lower on MRHC compared to standard GC at 24 weeks (2,5 nmol/l vs 10,5 nmol/l, P= 0.001). PRA decreased significantly from baseline to 24 weeks in patients on MRHC (0.83 ng/l/s to 0.48 ng/l/s, P=0.012) but not in patients on standard GC therapy (0.53 ng/l/s to 0.52 ng/l/s, P=0.613). In line with these changes, serum sodium concentrations increased from baseline to 24 weeks in patients on MRHC (138.8±1.9 mmol/l to 139.3±1.8 mmol/l, P=0.047), but remained unchanged on standard GC (139.8±1.6 mmol/l to 139.3±1.9 mmol/l, P=0.135). No significant changes were seen in systolic and diastolic blood pressure and serum potassium levels.
Conclusion
Six months of MRHC therapy decreased PRA and increased sodium levels indicating a better MC effect of the unchanged fludrocortisone dose. This might be due to the significantly decreased levels of the MC-receptor antagonist 17-OHP owing to the improved control of precursor excess by MRHC, indicating lower fludrocortisone efficacy in poorly controlled salt-wasting CAH patients.

Fertility in congenital adrenal hyperplasia (CAH) patients on modified release hydrocortisone capsules (MRHC, Efmody)

Lea Tschaidse[1], Marcus Quinkler[2], Wiebke Arlt[3], Aude Brac De La Perriere[4], Angelica Linden Hirschberg[5], Anders Juul[6], Ashwini Mallappa[7], Deborah P Merke[8], John DC Newell-Price[9], Colin Graham Perry[10], Alessandro Prete[3], Aled Rees[11], Monica Stikkelbroeck[12], Philippe A Touraine[13], Helen Coope[14], John Porter[14], Richard John M Ross[14] & Nicole Reisch[1]
[1]Endokrinologie, Nephrologie und weitere Sektionen - Medizinische Klinik und Poliklinik IV - Campus Innenstadt, München, Germany; [2]Endocrinology in Charlottenburg, Berlin, Germany; [3]University of Birmingham, United Kingdom; [4]Louis Pradel Hospital, Bron, France; [5]Karolinska Institute, Sweden; [6]Rigshospitalet, København, Denmark; [7]AstraZeneca, Gaithersburg, United States; [8]NIH Clinical Center, Bethesda, United States; [9]The University of Sheffield, United Kingdom; [10]Queen Elizabeth University Hospital, United Kingdom; [11]Cardiff University, United Kingdom; [12]Radboud University Medical Center, Nijmegen, Netherlands; [13]University Hospitals Pitié Salpêtrière - Charles Foix, Paris, France; [14]Diurnal, United Kingdom

Background
Fertility in CAH women is impaired: 0.25 live births vs 1.8 in the UK population and 45% have irregular menses vs 13.6% in healthy women[1]. Male fertility is also impaired in CAH with oligospermia reported in 48%[2]. Treatment of infertility usually involves increasing the glucocorticoid dose to normalise adrenal androgens and progesterone to facilitate ovulation and implantation, respectively. Modified-release hydrocortisone (MRHC) capsules, (Efmody, Diurnal Ltd, Cardiff, UK), replicate the physiological cortisol diurnal rhythm and improve CAH control compared to standard therapy. In the phase 3 randomised study of MRHC versus standard treatment[3]; 4 women had restoration of menses on MRHC versus 1 on standard treatment but seeking fertility was an exclusion criteria. We have examined fertility in the ongoing MHRC single arm extension study.
Methods
Review of fertility in the ongoing MHRC single arm extension study. Standard therapy dose is given as hydrocortisone dose equivalent (HDE=prednisolone dose 5 & dexamethasone 80).
Results
Twenty-seven of 49 premenopausal women were not using oral or intrauterine contraception. Of these women, 10/27 (37%) reported evidence of improved fertility: 5 reported menstrual regularisation and 5 women reported 6 pregnancies (3 healthy live births, 1 ongoing, 2 miscarriages). In these women the mean(SD) HDE on standard treatment before the study and pregnancy was 29(12) mg and then on MRHC at time of interim analysis or withdrawal due to positive pregnancy test the dose was 28(8) mg. In the 29 men (contraception data not collected), 4 pregnancies occurred in 3 female partners resulting in healthy live

births; the baseline mean(SD) HDE dose was 28(3) mg before the study and at time of pregnancy 32(10) mg. Two men had a dose increase from baseline, the 3rd subject had a dose decrease at time of first partner pregnancy, and increase to baseline dose at 2nd same partner pregnancy. 1 man had spermatograms with severe oligospermia and scarce mobile sperm on standard treatment and moderate oligospermia and 45% mobile sperm on MRHC.
Conclusions
Fertility is impaired in women and men with CAH and treatment usually aims to increase glucocorticoid dose. In the MRHC single arm extension study patients reported improved fertility with no increase in glucocorticoid dose in women.

Usefulness of the EU-TIRADS score on sparing thyroid nodules cytology: a retrospective study
Francisca Puga, André Carvalho & Cláudia Freitas
Centro Hospitalar Universitário do Porto, Endocrinology, Portugal

Introduction
Incidental diagnosis of thyroid nodules has increased in recent years, leading to thyroid cancer diagnosis inflation. Nonetheless, mortality rate for thyroid malignancies remains very low, suggesting that its treatment is unlikely to affect the overall prognosis in the majority of cases. Several thyroid imaging scores have been proposed to reduce unnecessary invasive diagnostic procedures. Our aim was to verify the usefulness of the EU-TIRADS score on sparing thyroid nodules cytology.
Methods
We conducted a retrospective and observational study of thyroid nodules submitted to fine-needle aspiration biopsy (FNAB) between January 2016 and October 2021 at our center. Each nodule was classified as whether having an indication for FNAB (group A) or not (group B), according to the EU-TIRADS score. We then compared cytology results between the two groups, using Bethesda diagnostic categories.
Results
FNAB were performed in 1935 thyroid nodules from 1308 patients. Using the EU-TIRADS score, 766 (39.6%) nodules had no cytology indication (group B). Of these, 40.2% ($n=308$) were EU-TIRADS 2, 35.4% ($n=271$) EU-TIRADS 3 $\leq$20 mm, 20.2% ($n=155$) EU-TIRADS 4 $\leq$15 mm and 4.2% ($n=32$) EU-TIRADS 5 $\leq$10mm. In group B, a suspicious or malignant category was reported only in 7 (0.9%) nodules. Suspicious follicular neoplasm was reported in 13 (1.7%) nodules. Group A presented a higher prevalence of suspicious or malignant categories (2.8% vs 0.9%, $P<0.01$), a higher prevalence of suspicious follicular neoplasm category (4.1% vs 1.7%, $P<0.01$) and a higher prevalence of nondiagnostic categories (45.1% vs 36.5%, $P<0.01$). Notably, nondiagnostic categories were found in 279 (36.5%) of nodules submitted to cytology in group B, leading to repetition of cytology and consequent avoidable visit to the clinic in 63 individuals. Interestingly, when comparing avoidable cytology rate per year, we observed a lower rate in the more recent year (26.8% vs 41.3%, $P<0.01$), suggesting a greater adherence to the EU-TIRADS system for decision making.
Conclusion
In the context of a common disease, such as thyroid nodules, application of the EU-TIRADS system score can avoid unnecessary cytologies, reducing over-diagnosis and consequent overtreatment.

Background
Molecular analysis of thyroid fine-needle aspiration biopsy (FNA) was proposed to improve indeterminate nodules management. However, sensibility and specificity as well as the cost of molecular diagnostics require to be improved to increase their cost-effectiveness for medical practice setting. Raman spectroscopy (RS) demonstrated ability in separating benign from malignant thyroid lesions in surgically removed tissues, based on specific RS profile. This study aimed to investigate the diagnostic performance of RS on cytological samples obtained by thyroid FNA.
Methods
In this prospective, blinded monocentric study, we enrolled 123 patients with indeterminate or worse cytological diagnosis, candidate to surgery according to international guidelines, and submitted to RS analysis of FNA samples. Cytology specimens were evaluated in agreement to Italian Reporting System for Thyroid Cytology[1] as follows: TIR1 (non-diagnostic), TIR1C (non-diagnostic-cystic), TIR 2 non-malignant/benign, TIR3A (low-risk indeterminate lesion), TIR3B (high-risk indeterminate lesion), TIR 4 (suspicious of malignancy), or TIR 5 (malignant). As previously published[2], the two diagnostic subcategories referred to indeterminate nodules with low (TIR3A) and high risk (TIR3B) of malignancy, may be respectively compared to the class III and Class IV of The Bethesda System for Reporting Thyroid Cytopathology. We compared RS, cytology and final histology, as reference standard, using various statistical approaches.
Findings
Our study population included 37 TIR3A, 32 TIR3B, 16 TIR4 and 38 TIR5; the 30.9% of patients had benign histological diagnosis after surgery. In particular, 72.9% of patients classified TIR3A and 31.3% TIR3B had benign histological diagnosis. RS analysis of FNA samples had overall specificity of 86.8% in predicting thyroid malignancy. In indeterminate cytological categories, RS specificity was 86.5%. In patients with TI-RADS score four or five, the specificity of RS increased to 87.5% for TIR3A and reached 100% in TIR3B.; if considering RS positive test, unnecessary surgery was reduced to 7.4% in the whole sample, 33.3% in TIR3A, and 6.7% in TIR 3B.
Interpretation
We demonstrated for the first time that RS represents a valuable tool for thyroid cytology and a valid alternative to molecular analyses, able to improve management and reduce unnecessary surgery in indeterminate nodules.

Tailoring the diagnostic indication to radioactive iodine treatment in differentiated thyroid cancer- novel biomarkers
Angelika Buczyńska[1], Maria Kościuszko[2], Iwona Sidorkiewicz[1], Agnieszka Adamska[2], Katarzyna Siewko[2], Adam Krętowski[1,2] & Anna Popławska-Kita[2]
[1]Clinical Research Centre, Medical University of Bialystok, Białystok, Poland; [2]Department of Endocrinology, Diabetology and Internal Medicine, Medical University of Bialystok, Białystok, Poland

Differentiated thyroid cancer (DTC) is the most common malignant neoplasm arising from the thyroid parenchymal cells. DTC incidence is steadily increasing worldwide and there are approximately 1700 new cases/per year in Poland. The biopsy with subsequent thyroid resection plays a central role in the diagnosis and treatment of this malignancy. After surgery, radioactive iodine (RAI) treatment is recommended to eradicate potential residual disease and improve prognosis. Due to the fact that RAI application is associated with oxidative stress formation, this treatment may exert an important impact on homeostasis. From the other hand, it was proved that protein 53 (p53), nuclear factor kappa B (NF-kB), forkhead box protein 01 (FOXO) and sirtuin 1 (SIRT1) play a crucial role in oxidative stress as well as cancer progression. Therefore, the determination of their role may be useful in DTC clinical management. In our study, we evaluated the total oxidative status (TOS), total antioxidant capacity (TAC), and p53, NF-kB, FOXO, SIRT1 concentrations to assess diagnostic usefulness of these parameters as indication markers for RAI therapy. For the purpose of this study 60 patients diagnosed with different stages of DTC after total thyroidectomy with an indication to RAI therapy and 20 pT1a DTC patients after total thyroidectomy without any recommendation to RAI therapy were enrolled as study and control groups, respectively. Serum TOS status and SIRT1 concentration were significantly higher (both $P<0.001$), when TAC status and p53, NK-kB, FOXO concentrations were significantly lover (all $P<0.05$) in the study group

compared to the control group. All the parameters were tested for their diagnostic utility as indicators for RAI treatment. The diagnostic usefulness as RAI indication markers was demonstrated for TAC (AUC=0.99), FOXO (AUC=0.78), TOC (AUC=0.76), SIRT1 (AUC=0.74), p53 (AUC=0.71) and NK-kB (AUC=0.68). Furthermore, our study revealed increased oxidative stress and decreased antioxidant capacity in DTC patients qualified for RAI treatment. This may indicate a worse prognosis and advanced neoplastic process.

Introduction

Differentiated thyroid cancers (DTCs) carrying BRAF and TERT mutations are associated with high-risk clinicopathological features and poor prognosis. However, there are currently no studies comparing BRAF-TERT tumors to other double mutated DTCs.

Aim

To verify whether BRAF-TERT mutated DTCs differ from other double mutated DTCs in terms of clinicopathological characteristics and outcome.

Materials and Methods

168 DTCs consecutively operated between 2017 and 2021 were analyzed by Next Generation Sequencing. Based on the number of mutant genes, patients were first classified into single or double mutated groups. Multiple mutated DTCs were further subclassified on the basis of the presence or absence of the BRAF-TERT mutation in two groups and finally compared each other regarding clinicopathological characteristics, persistent disease one year after the initial treatment and at the end of the follow-up, respectively.

Results

In our population 25/168 DTCs (14,8%) had a double mutation, which in more than 50% (14/25 – 56%) was BRAF-TERT positive. The other double mutated tumors were subdivided as: 5/25 RAS-TERT (20%), 2/25 BRAF-P53 (8%), 2/25 BRAF-PI3KCA (8%), 1/25 RAS-PI3KCA (4%) and 1/25 TERT-PI3KCA (4%). From the comparison with single mutated DTCs, double mutated DTCs were more associated with older age, larger tumor, more advanced TNM stage (OR 8,88; 95% CI 2,68 to 29,36), greater risk of structural persistence (OR 13,39; 95% CI 5,06 to 35,41), increased progression of disease (OR 7, 00; 95% CI 2.04 to 23,93) and death. Compared to other double mutated, BRAF-TERT DTCs do not differ in age, sex, aggressive histotype, tumor size, extrathyroidal extension, lymph node involvement, distant metastases, stage (AJCC 8 ed), ATA risk, post-therapeutic I-131 whole body scan and PET uptake (*P*-value > 0.05). Although 3 of the 14 patients carrying BRAF-TERT mutated DTC died from disease progression, this data was not statically significant and no differences were observed in terms of disease persistence rates at 12 months and at the last follow-up. The two groups differ from each other only in the value of thyroglobulin at the time of ablation, which was statistically significant lower in the BRAF-TERT subgroup (median 2,2 ng/dl vs 54,10 ng/dl *P*-value 0.010).

Conclusions

Double mutated DTCs showed similar clinicopathological features, regardless the pair of gene involved. Furthermore, lower thyroglobulin at ablation in BRAF-TERT mutated DTCs should not be considered as a valid predictor of remission. Further prospective studies with longer follow-up and wider population are necessary to confirm our results.

Introduction

There is no clear indication for radioiodine treatment (RAI) in patients affected by differentiated thyroid cancer (DTC) in Stage I and ATA intermediate risk, according to American Thyroid Association (ATA) guidelines.

Purpose

Our aim is to evaluate whether integration of BRAF status and thyroglobulin TSH-stimulated at the time of RAI (A-HTg) could further improve accuracy of stratification, and therefore therapeutic management, in DTC patients with Stage I AJCC and ATA intermediate risk.

Materials and Methods

This retrospective study involved 372 patients affected by DTC with Stage I AJCC 8th ed. and ATA intermediate risk, followed at the Endocrinology and Diabetes Prevention and Treatment Department from 2000 to 2020. For each patient we analyzed persistence of the disease one year after the initial treatment and at the end of the follow up (median: 8 years), BRAF status and A-HTg levels, respectively. By ROC curve we calculated the A-HTg cutoff of 5.9 ng/ml (sensitivity 64%, specificity 75%, AUC 0.725).

Results

In our population, 265/372 (68.8%) patients had BRAFV600E mutation, 121/372 (32.5%) A-HTg levels $>$ 5.9 ng/ml, 91/372 (24.5%) persistent disease after one year and 75/372 (20.2%) at the end of the follow up. The presence of A-HTg levels $>$ 5.9 ng/ml, regardless of BRAF status, was associated with a higher risk of disease persistence after one year (BRAFwt: RR 7.615, p-value $<$ 0.001; BRAFV600E: RR 5.535, p-value $<$ 0.001) and at the end of the follow up (BRAFwt: RR 3.004, p-value 0.038; BRAFV600E: RR 4.776, p-value $<$ 0.001). Our population was further divided in 4 groups: A-HTg $<$ 5.9 ng/ml and BRAFwt, A-HTg $<$ 5.9 ng/ml and BRAFV600E, A-HTg $>$ 5.9 ng/ml and BRAFwt, A-HTg $>$ 5.9 ng/ml and BRAFV600E. In these subpopulations we observed a progressive increase of persistent disease after one year, respectively of 8.3%, 15.6%, 40.9% and 50.6% (*P*-value $<$ 0.001), and at the end of the follow up, respectively of 9.7%, 15.1%, 24.4% and 46.2% (*P*-value $<$ 0.001).

Conclusions

Among patients with Stage I and ATA intermediate risk DTC, those with high A-HTg and BRAFV600E had the maximum rate of persistent disease. Therefore, radioiodine treatment could be proposed only to this subpopulation, rather to the entire cohort of Stage I and ATA intermediate risk. Prospective studies with longer follow-up and wider population are necessary to confirm our results.

The mRNA of fibronectin 1 and of the integrin subunit alpha V are powerful prognostic indicators in papillary thyroid carcinoma

Mario Vitale[1], Vincenzo Marotta[2], Anna Tortora[2], Giulia Izzo[2] & Domenico Rocco[1]

[1]University of Salerno, Department of Medicine, Surgery and Dentistry, Italy; [2]UOC Clinica Endocrinologica e Diabetologica, AOU S. Giovanni e Ruggi D'Aragona, Italy

Integrins are cell-extracellular matrix adhesion molecules considered functionally related to the development of cancer metastasis. Starting from the dataset of

mRNA-seq of papillary thyroid carcinoma (PTC) from the TCGA, we determined the expression of fibronectin 1 (FN1) and fibronectin-binding integrins in PTC. We then analyzed the association of the expression of these two genes with the driver genes, the stage of the disease and its outcome. 355 PTCs and 58 normal thyroid (NT) tissues with the corresponding mutations of the driver genes, the pathological characteristics and the outcome of the disease entered the analysis. FN1 mRNA was increased 60-fold in PTC compared to NT. The integrin heterodimers that bind FN are 41, 51, V1, V3 and V6. The mRNA of V, 1 and 6 were all overexpressed. Flow cytometric analysis with specific antibodies confirmed in two PTC cell lines (BCPAP and TPC1) that the integrins V1, V3 and V6 were highly expressed. BRAFV600E positive PTCs showed the greatest expression of FN1 and integrin subunits, while the RAS positive PTC expression profile was much lower and similar to that of NT. FN1 expression was positively correlated with lymph node metastases, advanced stage and extrathyroidal extension ($P < 0.0001$) and with poor disease outcome (odds ratio 8.2: $P < 0.001$). The expression of V mRNA also correlated positively with an advanced disease and a worse outcome (odds ratio 4.05; $P < 0.002$). In conclusion, PTCs with BRAFV600E have a higher expression of FN1 and V mRNA. The expression of these genes correlates positively with an advanced disease and an unfavorable outcome, representing a powerful prognostic indicator.

Immune-related thyroid dysfunctions during PD-1/PD-L1 inhibitors and their association to the oncological outcome: new evidence

Matteo Ferrari[1], Alice Anna Nervo[1], Sara Basile[1], Enrica Migliore[2], Valentina D'Angelo[1], Giovanni Gruosso[1], Daniela Rosso[1], Francesca Retta[1], Alessandro Piovesan[1] & Emanuela Arvat[1]
[1]Azienda Ospedaliero-Universitaria Città della Salute e della Scienza di Torino, Oncological Endocrinology Unit, Torino, Italy; [2]Azienda Ospedaliero-Universitaria Città della Salute e della Scienza di Torino, Cancer Epidemiology Unit, Torino, Italy

Background
Immune checkpoint inhibitors (ICIs) showed impressive results in several malignancies; however, a large spectrum of immune-related adverse events (IRAEs) may occur, including thyroid dysfunction (DYSTHYR). IRAEs seem to be associated with better cancer outcome; limited data suggested that thyroid toxicity could be a predictor of response to ICIs.
Patients and methods
We retrospectively evaluated all patients who started treatment with the programmed cell death protein-1 (PD-1) and its ligand (PD-L1) inhibitors between 2017 and 2020 at the Città della Salute e della Scienza Hospital (Department of Oncology). Patients with central hypothyroidism were excluded from the analysis. Both the new onset and the worsening of pre-existing DYSTHYR were recorded; hypothyroidism was categorized as grade (G) 1 or 2 according to TSH levels ($< \text{or} \geq 10$ mU/l) similarly to thyrotoxicosis (G1 or 2 in case of TSH $>$ or ≤ 0.1 mU/l). Radiological tumor response was defined according to RECIST criteria. Progression free survival (PFS) and overall survival (OS) were assessed and compared among different groups.
Results
Among 324 patients (median age 67 years, 70.7% males, 95.4% treated with anti-PD-1, 49.4% affected by lung cancer), DYSTHYR was observed in the 24.7% of the population, after a median time of 3.3 (1.8-6.2) months. The most recorded event was hypothyroidism (85%); DHYSTHYR was G2 in 70% of cases. No statistically significant benefit in terms of PFS was observed in patients with DYSTHYR. However, the development of DISTHYR was associated with a significantly longer OS (87.3% vs 73.5% at 12 months, $P = 0.03$) and lower mortality (HR 0.61; 95% CI 0.39-0.95). Considering only patients without pre-existing thyroid dysfunction at baseline (277, 85.5% of the sample), a better OS was observed in case of DYSTHYR G2 in comparison to cases with DYSTHYR G1 or without DYSTHYR ($P = 0.03$), with a decreased risk of death (HR 0.47; 95% CI 0.24-0.91).
Conclusions
DYSTHYR is a common IRAE during anti PD-1/PD-L1 treatment. We detected a better clinical outcome in patients with DISTHYR during ICIs, in terms of improved OS and reduced mortality. In subjects without pre-existing thyroid alteration, the benefit was observed especially in case of detection of higher TSH levels during ICIs.

Introduction
Metastatic pituitary neuroendocrine tumors (PitNETs) or pituitary carcinomas are rare and challenging conditions. We present a recent and encouraging observation of a temozolomide (TMZ)-resistant clinically non-functioning metastatic PitNET showing a remarkable response to the anti-PDL1 drug Pembrolizumab.
Case presentation
A 57-years-old man had transsphenoidal surgery in November 2012 for a large non-functioning intra/suprasellar mass revealed by visual defects, and invasive into the left cavernous sinus. A diagnosis of "null cell" PitNET (Ki-67 10%, p53 5%) was made and in June 2013 the surgical resection was completed transcranially. One year later he received stereotactic radiotherapy on the left cavernous remnant with a good response. However, delayed infrasellar regrowth was observed, first presenting as nasal pseudopolyps and leading to re-operation in March 2018. The pathological diagnosis was consistent with the aggressive clinical behavior (Ki67 20%, p53 10%) and two small pre-pontine nodules revealed metastatic progression. Further immunohistochemical characterization of the tumor indicated a PIT1 lineage. The patient started TMZ with a standard schedule for 5 cycles, followed by a metronomic schedule in association with stereotactic radiotherapy on pre-pontine nodules and additional small multiple asymptomatic brain and spinal metastases indicative of disease progression. The primary tumor also progressed with nasal obstruction and visual loss. Searching for alternative therapeutic options, a high expression of PDL-1 was found and suggested immunotherapy. TMZ was withdrawn and in March 2021 the patient started Pembrolizumab. Encouraging results were noticed after 4 cycles of treatment. After 8 cycles of treatment, a remarkable clinical, radiological and metabolic response was documented, with a significant shrinkage of the primary lesion, a regression of metastatic nodules, and a decrease of SUV values at 18-FDG PET-CT. Moderate cutaneous and renal toxicities (G1-G2) and mild eosinophilia were observed and successfully managed by systemic steroid therapy and transient drug withdrawal. Pembrolizumab is currently continued as a maintenance therapy.
Discussion
To the best of our knowledge, no such remarkable response to anti-PDL1 monotherapy in a Pit1-positive metastatic PitNET has been reported so far. Interestingly, in few reports of other aggressive or metastatic PitNET treated by immunotherapy, PDL-1 expression – if available - was low ($<1\%$) or negative. This case supports recent data suggesting that PIT1-positive PitNETs may express more PDL-1 than other phenotypes.
Conclusion
This observation suggests a promising role of immunotherapy for metastatic PitNETs, refractory to standard therapy. In addition to the potential role of PDL-1 expression, further predictors of response should be searched for.

Macro-GH – a novel clinical entity causing a diagnostic challenge – a case report

Maria Stelmachowska-Banas[1], Magdalena Ostrowska[1], Tomasz Goszczyński[2], Konrad Kowalski[3], Marta Korbonits[4], Renata Kapuścińska[1], Wojciech Zgliczyński[1] & Piotr Glinicki[1]
[1]Centre of Postgraduate Medical Education, Department of Endocrinology, Warsaw, Poland; [2]Hirszszfeld Institute of Immunology and Experimental Therapy, Polish Academy of Science, Wrocław, Poland; [3]Masdiag Laboratory, Warsaw, Poland; [4]William Harvey Research Institute, Barts and the London School of Medicine, Queen Mary University of London, Department of Endocrinology, London, United Kingdom

Introduction
Hormone macromolecules are complexes of hormones with other compounds, most often with IgG immunoglobulin. They show variable immunoreactivity in immunochemical tests (IRMA, ELISA, CLIA, ECLIA) and usually have a weak biological effect. They can interfere with immunological assays of various hormones. Some known hormone macrocomplexes are: BB-PRL (24% - 34%), macro-TSH (0.6% - 1.2%) and very rare macromolecules of various hormones: calcitonin, PTH, insulin (single reports). Presentation of a new hormone macromolecule – macro-GH (GH- growth hormone), that may interfere with different GH assays leading to false-high results in serum samples.
Case presentation
A 61-year-old female was admitted to our department with suspected acromegaly. Laboratory test showed increased fasting GH level without suppression on oral glucose tolerance test and normal IGF-1. A trial 3-month treatment with the long-acting somatostatin analogue was initiated. Despite the treatment, elevated GH with normal IGF-1 levels persisted. No visible decrease in pituitary adenoma size on MRI was detected. Finally, the patient underwent a transsphenoidal resection of a pituitary tumor. After the surgery, laboratory tests remained unchanged with elevated GH level and normal IGF-1. Interference in the determination of GH level was suspected.
Methods and results
We found a different immunoreactivity (different results) in the determination of GH by routine immunochemical methods: ECLIA, CLIA and IRMA. A serial dilution test showed non-linearity. Rheumatoid factor (RF) was absent. The test for the presence of heterophile antibodies was performed. GH recovery after incubation was 95%, indicating no interference from heterophile antibodies. In the penultimate stage, a sample of the patient's serum was incubated with the serum of an acromegalic patient with a high concentration of GH. The GH recovery after incubation was 98%. Next the sample was precipitated with 25% PEG. The GH recovery was 12%, which means that 88% of growth hormone was in the form of macrocomplex (macro-GH). The last step in confirming the presence of the macrocomplex GH (macro-GH) was the use of the reference method - size-exclusion chromatography (SEC).
Conclusions
In the analyzed case, we confirmed a very rare type of interference - a presence of macro-GH. In each case of suspected inconsistency of laboratory test results with the clinical picture and/or other tests, it is advisable to start the procedure of excluding/looking for various types of interference that may impede the diagnosis and/or treatment of patients with various endocrine diseases.

RC4.3

Pre-treatment GH levels and number of therapeutic interventions for acromegaly management are predictive of altered MRI bone shape and severity of arthropathy in acromegaly

Nikolaos Kyriakakis[1,2], Michael Bowes[3], Julie Lynch[1], Sarah R Kingsbury[4], Steve M Orme[1], Robert D Murray[1,2] & Philip G Conaghan[4]
[1]Leeds Teaching Hospitals NHS Trust, Department of Endocrinology, Leeds, United Kingdom; [2]University of Leeds, Leeds Institute of Cardiovascular and Metabolic Medicine (LICAMM), Leeds, United Kingdom; [3]Imorphics Ltd, Manchester, United Kingdom; [4]University of Leeds, Leeds Institute of Rheumatic and Musculoskeletal Medicine, Leeds, United Kingdom

Introduction
Emerging research in 3D-bone shape has provided new insights into the pathogenesis of osteoarthritis (OA). OA patients have increased subchondral bone area, associated with higher prevalence of cartilage loss. Higher B-score, a novel, machine learning-derived OA bone biomarker, is associated with increased OA symptom severity and structural progression. Arthropathy, despite being the commonest cause of morbidity amongst acromegaly patients, remains one of the under-investigated areas in acromegaly and currently, data based on modern imaging modalities are limited.
Design/Methods
Cross-sectional study, in which bilateral knee MRI scans were obtained from 60 patients with acromegaly. Knee bone shape, 3D-joint space width (3DJSW), cartilage thickness, B-score and bone area were measured based on automated segmentation of MR images using active appearance models.
Results
Thirty-nine acromegaly patients (65%) had B-score <2 (Group 1), indicating absence of significant arthropathy on knee MRI, with the remaining 21 patients (Group 2) having B-score ≥ 2. There was no difference in age, male:female ratio, height and weight between the two groups. Following adjustment for these variables, Group 2 patients had increased mean femoral, tibia and patella bone areas compared with Group 1. Both mean medial and lateral femorotibial cartilage thickness were increased in Group 2 [Medial cartilage thickness, Group 1: 5.35mm (95% CI 5.0-5.7) vs Group 2: 6.12 mm (95% CI 5.66-6.59), $P=0.01$; Lateral cartilage thickness, Group 1: 6.48 mm (95% CI 6.17-6.79) vs Group 2: 7.78 mm (95% CI 7.36-8.2), $P<0.001$], leading to increased 3DJSW medially. Patients with B-score ≥ 2 had higher median pre-treatment GH levels [Group 1: 6.6 (4.1-17) mg/l vs Group 2: 39 (5.4-57.8) mg/l, $P=0.015$] and required significantly higher number of pituitary surgeries than patients with B-score <2. Multiple linear regression analysis showed that higher number of pituitary surgeries, radiotherapy and use of GH-lowering medications were independently correlated with higher B-scores. 3DJSW was positively associated with higher pre-treatment GH levels, height, weight and male gender. Regarding clinical outcomes, Group 2 patients had significantly longer median duration of knee pain [4 years (1.75-10)] than Group 1 [1.5 years (0-5)], $P=0.01$. Additionally, 47.6% of Group 2 patients had undergone previous joint replacement surgery compared with 12.8% in Group 1 ($P=0.009$).
Conclusions
Patients with B-score ≥ 2 had higher pre-treatment GH values and required higher number of therapeutic interventions for the management of acromegaly, suggesting that the risks of more profound changes to the bone shape and increased severity of arthropathy are dependent on the degree of overall GH excess.

RC4.4

KLB gene mutations - a rare cause of hypogonadotropic hypogonadism

Catarina Cidade-Rodrigues, Catarina Chaves, Filipe Cunha, Mariana Martinho & Margarida Almeida
Centro Hospitalar do Tamega e Sousa, Endocrinology, Penafiel, Portugal

Introduction
Congenital hypogonadotropic hypogonadism (CHH) is a rare disease. Mutations in various genes have been implicated in its pathophysiology, the most frequent being *ANOS1*, *FGFR1* and *GNRHR* genes. FGFR1 is essential for cell proliferation, differentiation and migration during embryonic development and is involved in GnRH neuron development and maintenance. Klotho-*beta* protein (KLB) is expressed in the postnatal hypothalamus and is the co-receptor for FGF21 binding to his receptor FGFR1. Recent evidence suggests that FGF21/KLB/FGFR1 pathway is implicated in approximately 17% of CHH cases.
Case report
Male, 19 years old, diagnosed with hypogonadism at the age of 16 because of pubertal delay and anosmia. He had no history of testicular/head trauma. No family history of hypogonadism or congenital malformations. He was treated with testosterone with complete pubertal development and stopped for no apparent reason. He had normal libido and no erectile dysfunction. Physical examination: no congenital abnormalities, weight 69.9 Kg, height 180.5 cm, BMI 21.45 kg/m^2, arm-span 178 cm, waist-circumference 98 cm. Testicular volume: 12 ml(left) and 10 ml(right). He had secondary sexual characteristics and gynecomastia. No synkinesis. His total testosterone without treatment was <0.1 ng/ml, FSH 1.5 mUI/ml, LH 0.6 mUI/ml, TSH 1.33 uUI/ml, free T4 0.84 ng/dl, 8h 00 cortisol 10.01 ug/dl, prolactin 10.2ng/ml, IGF-1 357ng/ml, total cholesterol 201mg/dl, HDL-cholesterol 47 mg/dl, LDL-cholesterol 123mg/dl, triglycerides 150 mg/dl, insulin 23.4 µUI/ml, glucose 87 mg/dl, HbA1c 5.0%. Pituitary MRI: normal-sized gland, no sellar/parasellar masses and olfactory bulbs and tracts were present. Normal renal ultrasound. Karyotype: 46,X,inv (Y) (p11.2 q11.2). Genetic next-generation sequencing identified the variant NM_175737,3:c,2443A$>$G p.(Lys815Glu) in *KLB* gene and the variant NM_000406.2:c,937_947del p.(Phe313Metfs*3) in *GNRHR* gene, both in heterozygosity. He was diagnosed with congenital hypogonadotropic hypogonadism due to heterozygous mutations in *KLB* and *GNHRHR* genes and started on testosterone treatment.
Discussion
The mechanism involved in CHH caused by loss-of-function *KLB* mutations is not well understood, however it appears to be related to the inability of GnRH neurons to release GnRH in response to FGF21. The phenotypic spectrum is wide. Most patients have metabolic defects consistent with the metabolic role of the FGF21/KLB/FGFR1 pathway. This was present in our patient, who had hypercholesterolemia, insulin resistance and increased waist circumference. The *KLB* gene variant presented was described only once in literature, however, this is the first case ever associated with a *GNRHR* gene mutation. The *GNRHR* gene normally cause autosomal recessive CHH but the presence of a heterozygous *GNRHR* mutations in a patient with a *KLB* mutations might have act synergically in the pathogenesis and phenotype of this disease.

Validation of the ICD-codes for acromegaly – strategies to reduce false positive cases and improve estimation of the incidence in Sweden

Erika Tsatsaris[1], Jonas Robèrt[2], Katarina Berinder[3], Lorenza Bonelli[4], Pia Burman[4], Per Dahlqvist[3], Charlotte Höybye[3], Oskar Ragnarsson[6], Konstantina Vouzouneraki[5] , Anna-Karin Åkerman[7], Bertil Ekman[2] & Britt Eden Engstrom[1]

[1]Department of Medical Sciences, Endocrinology and Mineral Metabolism, Uppsala University, Department of Endocrinology and Diabetes, Uppsala University Hospital, Uppsala, Sweden; [2]Department of Health, Medicine and Caring Sciences, Linköping University, Linköping, Sweden; [3]Department of Molecular Medicine and Surgery, Karolinska Institutet, Department of Endocrinology, Karolinska University Hospital, Stockholm, Sweden; [4]Department of Endocrinology, Skåne University Hospital Malmö, University of Lund, Malmö, Sweden; [5]Department of Public Health and Clinical Medicine, Umeå University, Umeå, Sweden; [6]Institute of Medicine at Sahlgrenska Academy, University of Gothenburg, Department of Internal Medicine and Clinical Nutrition, Gothenburg, Sweden; [7]Department of Internal Medicine, Örebro University Hospital, Örebro, Sweden; *Erika Tsataris and Jonas Robèrt are joint first authors

Purpose
We aimed to validate the diagnosis and estimated national incidence of acromegaly reported in the Swedish National Patient Register (NPR), based on clinically reported International Classification of Diseases (ICD-codes), in comparison with the Swedish Pituitary Register (SPR).
Methods
All patients in NPR or SPR between 1991-2018 with the ICD-9 or ICD-10 diagnosis of acromegaly and age >18 years at diagnosis were included. The diagnosis was assumed correct if found in both registers. Medical records were reviewed in two of Sweden's six healthcare regions in patients only found in one of the registers. An algorithm aiming to correctly identify most patients with acromegaly in the NPR was constructed from validated data and applied to the remaining four health care regions. The algorithm was based on at least two registrations in the NPR of diagnostic codes E220 or 253A or the diagnostic code alone in combinations with codes for pituitary tumour and/or pituitary surgery, giving the highest functional diagnosis sensitivity and high positive predictive value (PPV).
Results
A total of 1868 patients were found, 938 reported in both registers and 930 patients only in one register (908 only in the NPR and 22 only in the SPR). Internal validation of the algorithm was performed in the SPR and captured 98.9% (928 of 938) of the patients. All 22 patients only reported in the SPR were validated, and 14 patients were confirmed with acromegaly. Applying the diagnostic algorithm to the NPR-search reduced the number of patients only found in NPR to 347, of which 85 have confirmed acromegaly after review of medical records. Thus, 1023 of the total 1846 patients with acromegaly codes in the NPR were confirmed to have acromegaly (PPV 55.4%). The most common reasons for misclassification were acromegaly initially suspected but later ruled out, hyperprolactinemia/prolactinoma, non-functioning pituitary adenoma, other/unknown pituitary tumours or cysts. Among the 1037 confirmed cases, 952 patients were already in the SPR, which gave a coverage rate of 91.8%. Based on this validation, the annual incidence of acromegaly in Sweden during 1991-2018 was calculated to 5.1 per million.
Conclusion
By using the diagnostic code for acromegaly alone to identify patients with the disease in NPR is not sufficiently specific for epidemiological research. However, the usage of an algorithm including combinations of diagnostic, tumour and surgical codes increased the probability of correct diagnosis and provided an improved estimate of the incidence of acromegaly in Sweden.

DOI: 10.1530/endoabs.81.RC4.5

Impact of diabetes on morbidity and mortality in patients with acromegaly

Daniela Esposito[1], Daniel S Olsson[1], Stefan Franzén[2], Soffia Gudbjörnsdottir[3], Mervete Miftaraj[3], Jonatan Nåtman[3] , Ann-Marie Svensson[3] & Gudmundur Johannsson[1]

[1]Institute of Medicine, Sahlgrenska Academy, University of Gothenburg and Sahlgrenska University Hospital, Department of Internal Medicine and Clinical Nutrition and Department of Endocrinology, Gothenburg, Sweden; [2]Sahlgrenska Academy, University of Gothenburg, Health Metrics Group, Gothenburg, Sweden; [3]National Diabetes Register, Centre of Registers, Gothenburg, Sweden

Background
Diabetes is an important risk factor for cardiovascular morbidity and mortality but its impact on outcome in acromegaly is unknown.
Methods
This was a nationwide, observational, matched-cohort study. Adult patients with acromegaly due to a pituitary adenoma were identified in the Swedish National Patient Registry between 1987 and 2020 and those with coexistent type 2 diabetes in the National Diabetes Registry and Drug Registry. Overall mortality, and cardiovascular mortality and morbidity were estimated in acromegalic patients with diabetes (ACRO-DM group) in comparison with those without diabetes (ACRO group) using Cox regression adjusted for multiple confounders with propensity score.
Results
The study included 786 patients with acromegaly, 254 in the ACRO-DM group and 532 in the ACRO group. Mean follow-up was 9.2 years. At baseline, mean age (SD) was 62.6 (11.4) and 60.0 (12.1) years ($P=0.004$) and mean duration of acromegaly was 6.8 (8.1) and 6.0 (6.2) years ($P=0.098$) in the ACRO-DM and ACRO group, respectively. Mean income and level of education were lower in patients with coexistent diabetes while the frequency of pre-existing cardiovascular diseases was higher (61% vs 37%, $P<0.001$). The use of pituitary surgery (71% vs 68%, $P=0.62$) and radiotherapy (16% vs 16%, $P=1.00$) was similar among the two groups. Overall, 466 (59%) patients received pharmacotherapy in the entire study cohort. The use of somatostatin analogues (37% vs 30%, $P=0.055$) and GH receptor antagonists (10% vs 6%, $P=0.063$) was somewhat more frequent in the ACRO-DM group. The unadjusted overall mortality rate per 1000 person-years was 35.1 (95% CI 27.2–44.7) for the ACRO-DM group and 20.1 (16.5–24.3) for the ACRO group, with a hazard ratio (HR) of 1.58 (1.12–2.23) after adjustment for multiple confounders. The ACRO-DM group had increased cardiovascular mortality (HR 2.11, 1.09–4.10) and increased risk of cardiovascular diseases (HR 1.49, 1.21–1.82). Risk factor for cardiovascular diseases were age [HR 1.03 (95% CI 1.02–1.04)], diabetes duration [HR 1.09 (1.05–1.13)], diastolic blood pressure [HR 1.02 (1.00–1.04)], body mass index [HR 1.05 (1.01–1.09)], and treatment with antihypertensive drugs [HR 2.1 (1.21–3.64)] or lipid-lowering medication [HR 1.60 (1.08–2.36)].
Conclusions
Diabetes in patients with acromegaly was associated with excess overall and cardiovascular mortality and increased risk of cardiovascular diseases. These findings are novel and emphasize the need of optimizing management of acromegaly to prevent the development of diabetes since it might improve survival.

The burden of pain in patients with acromegaly

Ilonka Kreitschmann-Andermahr[1], Annalena Kahl[1], Timo Deutschbein[2], Jürgen Honegger[3], Nicole Unger[4], Mario Detomas[5,6], Sabrina Giese[3], Bernadette Schroeder[1], Witold Chmielewski[1] & Sonja Siegel[1]

[1]University Hospital Essen, Neurosurgery and Spine Surgery, Essen, Germany; [2]MEDICOVER Oldenburg MVZ, Oldenburg, Germany; [3]University of Tübingen, Neurosurgery, Tübingen, Germany; [4]University Hospital Essen, Endocrinology, Diabetes and Metabolism, Essen, Germany; [5]Würzburg, Würzburg, Germany; [6]University Hospital Würzburg, Endocrinology and Metabolism, Würzburg, Germany

Introduction
The aim of the present study was to explore pain prevalence, pain locations and its impact on everyday activities and health-related quality of life (QoL) in a large cohort of patients with acromegaly.
Methods
We conducted a survey at three major centers specialized on the treatment of pituitary diseases. 124 patients with acromegaly (mean age 56.6y ± 13.5) filled in a self-constructed questionnaire on acromegaly symptoms, pain including a pain location diagram and interference with daily life. Additionally, joint pain, physical functioning and stiffness were queried with the Western Ontario and McMaster Universities Arthritis Index (WOMAC), and health-related QoL was assessed with the Short Form (SF)-36. Prevalences (in valid %), comparison of means by *t*-tests and Pearson correlation coefficients (r) are reported.
Results
62% of the patients reported pain they attributed to acromegaly. Of these 78% reported pain located in the joints, predominantly in knees and hips. 59% of them had headache and 47% had back pain. Of those patients with pain 84% reported daily pain, 81% had pain during work, 80% while sitting or lying down and 62% in stressful situations. 60% of them avoided certain activities to reduce pain. Pain prevalences did not differ between men and women (n.s) and were unrelated to age (n.s). Patients with pain had significantly lower physical (34.6±11.0 vs

48.7±10.3, $P=0.000$) and mental QoL (48.9±10.5 vs 42.0±11.5, $P=0.002$). Physical QoL was negatively correlated to the WOMAC subscales pain ($r=$-0.723), stiffness ($r=$-0.499) and functional limitation ($r=$-0.777) as well as to the number of different pain locations ($r=$-0.599, all $P=0.000$). The impact on psychological QoL was less pronounced (r ranging from -.279 to -.360), but still highly significant (all $P<0.005$).

Discussion

The results indicate that the majority of acromegaly patients suffers from pain with a detrimental effect on their daily living and QoL. This underlines the importance of addressing joint pain and other painful conditions in the diagnostic and therapeutic management of acromegaly.

RC4.8

Impaired insulin secretion without changes in insulin sensitivity explains hyperglycemia in patients with acromegaly treated by pasireotide LAR

Peter Wolf[1], Alexandre Dormoy[2], Luigi Maione[2], Sylvie Salenave[2], Jacques Young[2], Peter Kamenicky[2] & Philippe Chanson[2]
[1]Medical University of Vienna, Internal Medicine III, Division of Endocrinology and Metabolism; [2]Université Paris-Saclay, Hôpital Bicêtre, Service d'Endocrinologie et des Maladies de la Reproduction, Le Kremlin Bicetre, France

Background

Pasireotide is a second line treatment for acromegaly. Besides the growth hormone (GH) lowering efficacy, clinical use is limited by side effects on glycemic control. The aim of this study was to evaluate longitudinal changes in beta-cell function and insulin sensitivity induced by pasireotide therapy in patients with acromegaly.

Methods

We performed a retrospective study in 33 patients. Efficacy (GH and IGF-I concentrations; tumor size) and effects on glycemic control were analyzed in all patients. In 14 patients longitudinal data on oral glucose tolerance tests were available before, shortly (mean±SD: 6.1±3.8 months) and on long term (mean±SD: 24.4±11.1 months) after initiation of pasireotide therapy. Insulin secretion (Insulinogenic index; Disposition index) and insulin sensitivity were calculated by validated indices.

Results

Hyperglycemia induced by pasireotide was mediated by impaired insulin secretion, which occurred shortly after initiation of treatment and then remained stable on long term (median (min; max): Insulinogenic index: 80 (12; 542) vs 16 (6.4; 101) vs 25 (3.7; 396) pmol/mmol, respectively; $P=0.028$; Disposition index 1.45 (0.42; 4.88) vs 0.53 0.17; 2.63) vs 0.60 (0.22; 1.71), respectively; $P=0.024$). No significant changes in insulin sensitivity were observed, despite a marked reduction of GH/IGF-I concentrations. Older age and a worse glycemic control at baseline were the strongest predictors for hyperglycemia and the need for an antidiabetic treatment.

Discussion

Worsening of glycemic control during pasireotide therapy is caused by an impaired insulin secretion, whereas insulin sensitivity is not affected. These findings might be important for the choice of the anti-diabetic treatment for pasireotide induced hyperglycemia.

Vascular cellular adhesion molecules are high during one year after acute COVID-19 infection in patients with type 2 diabetes

Anna Alieva, Feruza Khaydarova, Khurshida Sultonova, Khurshida Kamalova, Vasila Talenova & Iroda Tajieva

Background

Molecules of adhesion is a group of glycoproteins which expressed in cell surface and play pivotal role in inflammatory and oncological processes, and new studies show increasing of adhesion molecules within 6-12 hours after COVID-19 contamination, peaking in 24 hours. High level of adhesion molecules is a predictor of disease severity and mortality rate.

Aim

Of our study was to evaluate the level of VCAM-1 in patients with type 2 diabetes mellitus in one year after COVID-19 infection.

Materials and methods

We studied 166 type 2 diabetes patients who had COVID-19 in 2020 in 3-15 months (average, one year) after the acute infection. VCAM-1 was tested using Human ELISA Kit assay (Elabscience) in the laboratory of the Republican centre of Endocrinology. Statistic analysis was performed using STATA v.16.0.

Results

The level of VCAM-1 stayed increased up to 15 months after the COVID-19 onset. It was significantly lower in patients regularly taking rivaroxaban (174.65, 95%CI 134.2-215.1 vs 618.12, 95%CI 542.04-694.19), beta-blockers (466.39, 95% CI 373.91-558.87 vs 676.35, 95% CI 578.15-774.56), ACE inhibitors (417.76, 95% CI 314.72-520.81 vs 674.82, 95% CI 586.86-762.77), statins (318.65, 95% CI 238.54-398.75 vs 717.02, 95% CI 630.12-803.91), and fibrates (235.35, 95% CI 133.96-336.75 vs 902.53, 95% CI 812.43-992.63) and had no difference depending on glucose lowering therapy, aspirin or clopidogrel, or coagulogram. Interestingly, VCAM-1 level was significantly lower in those patients who received dexamethasone (423.76, 95% CI 332.37-515.14 vs 664.26, 95% CI 572.79-755.72) and remdesivir (244.29, 95% CI 160.25-328.32 vs 666.07, 95% CI 586.89-745.25), but not favipiravir during the acute COVID-19. Patients who had arterial hypertension and did not take regular antyhypertensive therapy had significantly higher levels of VCAM-1 (851.09, 95% CI 597.77-1104.42 vs 527.93, 95% CI 461.99-593.86).

Conclusion

Endothelial dysfunction may be preserved up to one year after COVID-19, and patients with type 2 diabetes should be monitored closely for post-COVID vascular complications.

Key words: Diabetes, COVID-19, vascular adhesion molecules, endothelial dysfunction

Aims

Lipoprotein(a) [Lp(a)] is an independent risk factor for atherosclerotic cardiovascular disease (ASCVD) in the general population. However, such a role in patients with familial hypercholesterolemia (FH) is less documented. The purpose of this study was to evaluate the association between Lp(a) concentrations and ASCVD prevalence in adult patients with FH.

Methods
This was a cross-sectional study from the Hellenic Familial Hypercholesterolemia Registry (HELLAS-FH). Patients were categorized into 3 tertiles according to Lp(a) levels.
Results
A total of 541 adult patients (249 males) with possible/probable/definite FH heterozygous FH (HeFH) were included (mean age 48.5 ± 15.0 years at registration, 40.8 ± 15.9 years at diagnosis). Median (interquartile range) Lp(a) concentrations in the 1st, 2nd and 3rd Lp(a) tertile were 6.4 (3.0-9.7), 22.4 (16.0-29.1) and 77.0 (55.0-102.0) mg/dl, respectively. There was no difference in lipid profile across Lp(a) tertiles. The overall prevalence of ASCVD was 9.4% in the first, 16.1% in the second and 20.6% in the third tertile ($P = 0.012$ among tertiles). This was also the case for premature ASCVD, with prevalence rates of 8.5%, 13.4% and 19.8%, respectively ($P = 0.010$ among tertiles). A trend for increasing prevalence of coronary artery disease (8.3%, 12.2% and 16.1%, respectively; $P = 0.076$ among tertiles) was also observed. No difference in the prevalence of stroke and peripheral artery disease was found across tertiles.
Conclusions
Elevated Lp(a) concentrations are significantly associated with increased prevalence of ASCVD in patients with possible/probable/definite HeFH.

Microvascular assessment of diabetes mellitus patients by nailfold capillaroscopy

Genessis Maldonado[1], Zineb Aouhab[2], Madalina Ionescu[3], Amala Chacko[1], Diana Franco[1], Lydia Robles[1] & Deyger Navarrete[1]
[1]Loyola MacNeal Hospital, Internal Medicine, Berwyn, United States; [2]Loyola University Medical Center, Rheumatology, Maywood, United States; [3]Loyola Macneal Hospital, Endocrinology, Berwyn, United States

Introduction
Diabetes mellitus (DM) is frequently associated with vascular complications including diabetic microangiopathy. Nailfold capillaroscopy is a useful non-invasive diagnostic tool to identify changes in the microvascular architecture. Published literature hints at the presence of nailfold circulatory morphologic changes in diabetic patients.
Objective
The purpose of the study was to identify by nailfold capillaroscopy microvascular changes in patients with type II diabetes mellitus.
Materials and methods
Observational, descriptive and prospective study which included patients with diabetes type II. Capillaroscopy was performed in the fourth and fifth digit of the non-dominant hand, by a 200x magnification capillaroscope (Dino-Lite). Data was analized using SPSS v.23.
Results
We included 36 diabetic patients, 58% [21] male and 42% [15] female, with a mean age of 36 ± 18, race included hispanic 56% [20], white 39% [14], African American and asian in 3% respectively. The mean of years of diagnosis was 16 ± 10 [1-40] years. The mean of hemoglobin A1c was 7.96 ± 1.6 [5.3-12.3] and mean of latest glucose level was 159 ± 65 [83-427]. The majority had an uncontrolled disease 64% [23] and 36% [13] controlled diabetes mellitus. Capillaroscopy was performed in the fourth and fifth digit of the non-dominant hand. The visibility of the patients studied was good in 58% [21], poor 39% [14] and none in 3% [1]. The architecture was altered in 70% [25] and normal in 31% [11]. Capillary density was reduced 29% [14], very reduced in 6% [2], good in 42% [15] and very good in 14% [5]. The presence of giant capillaries was seen in 44% [16], avascular areas in 36% [13], ramified capillaries 25% [9], ectasia 67% [24], microhemorrhages 6% [2], tortuous capillaries 83% [30] and cross linked capillaries 83% [30]. SD pattern was seen in 11% [4]. The mean of apical capillary diameter was 41.59 ± 8.7μm [32-71]. It was seen a significance correlation between the presence of decrease density and increased HgbA1c. Between groups of controlled and uncontrolled diabetes, it was seen that the architecture was more altered in the uncontrolled group than the controlled, density was reduced in 23% and 42% in the uncontrolled group.
Conclusion
The overall architecture was altered in 70%, the characteristic pattern was the presence of ectasias, tortuous and cross linked with increased presence of ramified capillaries and reduced density. It was evident that patients with uncontrolled diabetes had more capillaroscopic changes than the controlled disease group. Further studies will need to be performed to correlate these findings.

Introduction
Nonalcoholic fatty liver disease (NAFLD) is the leading cause of chronic liver disorders. Endocan is a novel molecule of endothelial dysfuction which is expressed in liver. SGLT2i have been reported to improve NAFLD through amelioration of inflammation. While there are contradictory results regarding the serum endocan levels in NAFLD patients, data regarding endocan expression in liver tissue are limited.
Aim
Herein, we aimed to investigate the effect of SGLT2i empagliflozin on the expression of endocan in liver tissues as well as in hepatocyte cells and to delineate the underlying mechanism.
Material and methods
ApoE(-/-) mice fed a western high-fat diet were used as NAFLD model. At the age of 5 weeks, ApoE(-/-) male mice were switched from normal diet to HFD. After 5 weeks, mice were divided into two groups: Control-groups (HFD + vehicle), Empa-group (HFD + empagiflozin 10 mg/kg/day) for 5 further weeks. At the end of intervention, mice were sacrificed, whole blood was drawn by cardiac puncture and liver tissues were harvested. H&E staining was performed in all liver sections for histomorphometric analysis and IHC was performed to evaluate endocan levels. The mRNA levels of endocan, ICAM-1,VCAM-1,LFA-1,SGLT2, and IL-6 were measured by qRT-PCR and the protein levels of p65 and phospho-p65, were evaluated by immunoblotting. HepG2 cells were cultured in media supplemented with low(1 g/l), intermediate(2.25 g/l) and high(4.5 g/l) glucose concentrations. The expression of the abovementioned genes were evaluated after 24 and 48 h of treatment with empagliflozin (10^{-6}, 2×10^{-6},10^{-7}, 5×10^{-7} M).
Results
Biochemical tests revealed reduction in blood glucose, total cholesterol, LDL-cholesterol, and triglycerides after empagliflozin intervention for 5 weeks as compared to the Control-group. Additionally, empagliflozin administration resulted in reduced hepatic lipid accumulation and NA score (NAS). Empagliflozin significantly increased the endocan mRNA and protein levels while reduced IL-6 mRNA levels. Western blot analysis revealed that empagliflozin also regulates NF-κB pathway through phosphorylation of p65 subunit. Moreover, our in vitro data confirmed the in vivo results since 48 hours incubation of HepG2 cells with empagliflozin (10^{-6}M,2×10^{-6}M) at the presence of low and intermediate glucose levels, but not high glucose levels, increased endocan expression ($P < 0.01$ and $P < 0.05$,respectively). Interestingly, SGLT2 mRNA expression was detected in liver and HepG2 cells.
Conclusions
Our in vitro and animal study results indicate that empagliflozin ameliorates NAFLD through –among others- induction of endocan expression. Regulation of NF-κB pathway and IL-6 expression may mediate these effects.

Very Low Calorie Ketogenic Diet combined with interval training for preserving muscle mass during weight loss in sarcopenic obesity: a pilot study

Elisabetta Camajani[1,2], Alessandra Feraco[2,3], Sabrina Basciani[1] & Massimiliano Caprio[2,3]
[1]Sapienza University of Rome, Department of Experimental Medicine, Rome, Italy; [2]San Raffaele Roma Open University, Department of Human

Sciences and Promotion of the Quality of Life, Rome, Italy; [3]IRCCS San Raffaele Pisana, Laboratory of Cardiovascular Endocrinology, Rome, Italy

The prevalence of sarcopenic obesity (SO) is increasing worldwide, posing important challenges to public health and national health care system, especially during the COVID pandemic. In subjects with SO, it is essential to reduce body weight preserving lean mass, in order to avoid a worsening of muscle function. Lifestyle modification with adequate nutrition and proper physical activity is essential to counteract SO progression. In accordance with the Position Statement of the Italian Society of Endocrinology, Very Low Calorie Ketogenic Diet (VLCKD), a well established nutritional intervention in the context of obesity, has been promoted also for the treatment of SO. To date, the effects of physical training during VLCKD have not been studied.

Aim

This pilot study aims to determine the efficacy of VLCKD combined with interval training, compared to a VLCKD alone, on weight-loss, body composition and physical performance in patient with SO.

Materials and methods

Twenty-six patients with SO, aged between 50 and 70 years, who met the inclusion criteria, accepted to adhere to a VLCKD nutritional program ($<$ 800 Kcal/die) and gave informed consent, were enrolled in the study. Thirteen patients followed a structured VLCKD protocol (VLCKD group) and thirteen patients followed a structured VLCKD protocol combined with interval training (IT), two times a week (VLCKD+IT group). Data were collected at baseline and after 45 days. Anthropometric indexes, body composition by Bioelectrical Impedance Analysis, muscle strength measurement by Chair Stand Test and physical performance analysis by Short Physical Performance Battery were assessed at baseline and at the end of treatment.

Results

At the end of the study, Body Mass Index, body weight and waist circumference were significantly reduced both in the VLCKD group and in the VLCKD+IT group. Moreover, significant improvement of muscle strength and physical performance was found in all groups. A significant reduction in hip circumference was observed only in the VLCKD+IT group. A multiple comparisons of delta variations in the measured parameters between groups was performed. No differences were observed for the majority of parameters, with the exception of FFM and FM: the individuals fed with VLCKD combined with IT preserved their FFM ($P<0.0001$) and reduced their FM ($P=0.0006$) to a greater extent than in the VLCKD group.

Conclusions

Our pilot study showed that a VLCKD was effective in terms of body weight reduction, particularly of FM; moreover, we conclude that the combination of VLCKD and interval training determines a better preservation of FFM.

Effects of bariatric surgery and dietary intervention on changes in insulin resistance and appetite hormones over the period of 3 years

Malgorzata Brzozowska[1,2,3], Michelle Isaacs[2,4], Dana Bliuc[2,3], Paul Baldock[2,3,5], John Eisman[2,3,4,5], Chris White[2,6,7], Jerry Greenfield[2,3,4] & Jacqueline Center[2,3,4,5]

[1]The Sutherland Hospital, Endocrinology, Caringbah, Australia; [2]UNSW Sydney, Faculty of Medicine, Sydney, Australia; [3]Garvan Institute of Medical Research, Healthy Ageing Theme, Darlinghurst, Australia; [4]St Vincent's Hospital Sydney, Endocrinology, Darlinghurst, Australia; [5]The University of Notre Dame Australia, School of Medicine, Darlinghurst, Australia; [6]Prince Of Wales Hospital, NSW Health Pathology, Randwick, Australia; [7]Prince Of Wales Hospital, Endocrinology, Randwick, Australia

Objectives

Little is known about the mechanisms responsible for improvement in insulin resistance after bariatric surgery. We examined the impact of three types of bariatric surgery, in comparison with dietary intervention (DIET) on concurrent changes in Homeostatic Model Assessment for Insulin Resistance (HOMA-IR) and appetite hormones over the period of 3 years. We also investigated the weight loss independent hormonal effects on insulin resistance.

Methods

Fifty-five adults undergoing weight-loss interventions, Roux-en-Y gastric bypass RYGB ($n=$ 7), gastric sleeve GS ($n=$ 21), laparoscopic adjustable gastric banding surgery LAGB ($n=$ 11) and DIET ($n=$ 16) were studied at baseline and at 1, 3, 6, 12, 24 and 36-months post intervention. Measurements of glucose (BSL), HbA1c, insulin levels, fasting and postprandial PYY and GLP1, adiponectin, C-reactive protein (CRP), retinol-binding protein 4 (RBP4), fibroblast growth factor-21 (FGF21) and dual-Xray absorptiometry were performed throughout the study. Two separate, random, intercept mixed-effects models examined the HOMA-IR changes within individual groups and in comparison with DIET during the initial phase of rapid weight loss (0-12 months) and during the stage of weight stability (12-36 months).

Results

During the first 12 months, RYGB, GS and DIET, but not LAGB, led to significant reductions in HOMA-IR. However, after controlling for the lost weight, postoperative HOMA-IR values were no longer different to the DIET group. During the phase of weight stability, all three bariatric procedures, achieved significant reductions in HOMA-IR, with the greatest difference in the RYGB group (-3.7; 95% CI: -5.4, -2.1; $P=0.001$). After controlling for the weight loss procedure, weight and body composition changes, HOMA-IR level decreased by 1.1 (95% CI: -2.1, -0.06; $P=0.045$) for every 2-fold increase from baseline in postprandial PYY. Fasting insulin declined by 3.4 mU/l (95% CI: -7.2, 0.09; $P=0.06$) for every 2-fold increase in adiponectin level. Initial, non-sustained changes in RBP4 and FGF21 had no significant association with HOMA-IR values.

Conclusions

An initial rapid weight loss after bariatric surgery is a major contributing factor to the decline in HOMA-IR score. The exaggerated secretions of the PYY hormone and adiponectin are associated with weight-independent improvements in HOMA-IR during weight stability. The metabolic roles of RBP4 and FGF21 may be related to rapid fluctuations in weight or changes in nutritional intake. Further mechanistic studies involving larger numbers of subjects are needed to fully understand the complex neuroendocrine regulation of weight, appetite, and glucose homeostasis in bariatric patients.

How do people with type 2 diabetes compare with type 1 diabetes in their outcomes of diabetes-related ketoacidosis?

Amy Birchenough[1], Senthil Krishnasamy[2], Sanjay Saraf[3], Megan Owen[2], Dineshwaran Rajendran[3], Gobeka Ponniah[4] , Wai Nga Alice Yip[4], Emily Warmington[4], Meghnaa Hebbar[4] & Haaziq Sheikh[5]

[1]Sandwell and West Birmingham Hospitals NHS Trust, United Kingdom; [2]Walsall Manor Hospital, United Kingdom; [3]Good Hope Hospital, Birmingham, United Kingdom; [4]University of Birmingham, United Kingdom; [5]Haberdashers' Adams' Grammar School, United Kingdom

Introduction

Diabetes-related ketoacidosis (DKA) is an acute endocrine emergency requiring immediate diagnosis and management. Common misconception is that DKA is associated with type 1 diabetes only. We explored the proportion of people with type 2 diabetes, and compared the management, complications and outcome of DKA between people with type 1 and type 2 diabetes.

Methods

We conducted a retrospective study on people admitted with DKA across six hospitals in the United Kingdom from January to November 2021. DKA was diagnosed as serum glucose $\geq$ 11 mmol/l or known history of diabetes, ketones $\geq$ 3 mmol/l and pH $\leq$7.3 or bicarbonate $\leq$ 15 mmol/l. Data on demographics, use of fixed-rate insulin infusion (FRIII) and intravenous fluid infusion (IVI), blood glucose and ketone monitoring, DKA duration and length of stay were collected. We also collected data on hypoglycaemia and potassium derangement during DKA treatment.

Results

A total of 418 people admitted during this period with biochemically-proven DKA were included. 287 (68.7%) of people had type 1 diabetes; 131 (31.3%) had type 2 diabetes. There was no significant difference in duration of DKA between people with type 1 vs type 2 diabetes (13.2 hours vs 15 hours, $P=$ 0.137), however, those with type 2 diabetes had a significantly longer length of stay (3 days vs 8 days, $P=0.000$). There was no significant difference in the proportion of hourly glucose (99.9% vs 98.6%, $P=0.633$) and ketone measurement (71.5% vs 68.6%, $P=0.731$), or use of FRIII (100% vs 100%, $P=0.376$) and IVI (100% vs 93.3%, $P=0.681$) There was no significant difference in the prevalence of hypoglycaemia (12.2% vs 12.2%, $P=0.959$), hypokalaemia (31.7% vs 36.6%, $P=0.36$) or hyperkalaemia (33.4% vs 36.6%, $P=0.345$).

Conclusions

Nearly a third of DKA cases are in people with type 2 diabetes, debunking the myth DKA is synonymous with type 1 diabetes. There was no significant difference in the complications or outcomes associated with DKA between people with type 1 vs type 2 diabetes mellitus, suggesting the current guidelines are appropriate for either type of diabetes. However, further research is needed to study if revised guidelines may result in better outcomes in DKA in type 2 diabetes. People with type 2 diabetes had significantly longer hospital stays; this

finding may support earlier discharge planning and allocation of resources in those with type 2 diabetes who present with DKA.

Attitude of Italian endocrinologists towards obesity management. Results of a survey with 534 respondents

Marco Chianelli[1], Olga Eugenia Disoteo[2], Borretta Giorgio[3], Roberto Attanasio[4], Agnese Persichetti[5], FRANCO GRIMALDI[6], Agostino Paoletta[7], Irene Samperi[8], Enrico Papini[1], Rinaldo Guglielmi[1] & Alessandro Scoppola[9]
[1]Regina Apostolorum Hospital, Endocrinology Department, Italy; [2]ASST Grande Ospedale Metropolitano Niguarda, SC Diabetologia, Milan, Italy; [3]Santa Croce & Carle Hospital, Department of Endocrinology, Diabetes and Metabolism, Cuneo, Italy; [4]AME, Scientific Committee, Milan, Italy; [5]IRCCS-Regina Elena National Cancer Institute, Service of Pharmacovigilance, Rome, Italy; [6]University Hospital S. Maria della Misericordia, Endocrinology, Metabolic Disease and Clinical Nutrition Unit, Udine, Italy; [7]ULSS 6 Euganea, Padova, Italy; [8]Azienda Sanitaria Locale Novara, SSD of Diabetology, Novara, Italy; [9]Santo Spirito Hospital, Endocrinology Unit, Rome, Italy

Background
Obesity represents a threatening worldwide epidemic but, beyond the guidelines recommendations, its modalities of treatment in the medical community appear as variable and not clearly defined. Aim of our survey was to assess the present real-world approach to obesity management in Italy.
Methods
Online anonymous survey among the 2248 members of the Italian Association of Clinical Endocrinologists (AME). The survey included 8 questions about demographics and 26 questions about obesity management.
Results
Response rate was 23.7% (534/2248 endocrinologists). The survey sample was representative of the Italian endocrinologist population, because sex, age, regional distribution, and professional experience of respondents were not different from the overall figures of the AME members. 38.0% of respondents worked in a hospital setting and 31.0% in private practice only. Obesity was managed by dedicated professionals in half of professional settings. 76.0% of patients seeking an endocrine consultation resulted affected by obesity as the main reason for referral or as a coexisting clinical condition. 47.0% of endocrinologists referred their obese patients to specialists with specific experience, while 39.0% of respondents directly managed their patients. Pharmacologic treatments were directly employed in addition to lifestyle modifications by 58.0%, 33.0% and 10.0% of respondents in patients with first-, second-, and third-degree obesity, respectively. Metformin, orlistat, naltrexone/bupropion, and liraglutide were employed by 36.0%, 6.5%, 4.8%, and 20.0% of respondents, respectively. Over half of respondents claimed that the drugs cost was the main factor that limited the use of anti-obesity drugs and that this factor impacted unfavorably on the adherence to long-term treatment. Metabolic surgery was considered for obese patients resistant to medical treatment in 9.0%, 20.0%, and 37.0% of first-, second-, and third-degree cases, respectively. According to 34% of respondents, psychological support should be offered to all obese patients. Finally, 44% of respondents stated that the availability of new drugs with greater efficacy, lower cost and less side-effects would increase the number of obese patients eligible for anti-obesity medical treatment and would improve their adherence to therapy.
Conclusions
The results of this large-scale, obese-centered, survey demonstrate that obesity is widely impacting on the clinical activity of Italian endocrinologists. The use of pharmacologic treatment is considered as an appropriate therapeutic support in 10.0–58.0% of cases, and metformin and liraglutide appear as the most used drugs. The availability of drugs with greater efficacy and lower side-effects could markedly improve the clinical approach to these patients and their long-term management.

Clinical relevance of body composition measurement at L3 level in gastroenteropancreatic neuroendocrine tumors

Fernando Sebastián Valles[1], Nuria Sánchez de la Blanca Carrero[1], Víctor Rodríguez Laval[2], Carolina Knott Torcal[1], Ana Serrano-Somavilla[3], Rebeca Martínez-Hernández[1], Elena Martín-Pérez[4], Jose Luis Muñozde Nova[4], Mónica Marazuela[3] & Miguel Sampedro-Nuñez[3]
[1]Hospital de La Princesa, Endocrinología, Madrid, Spain; [2]Hospital de La Princesa, Radiología, Madrid, Spain; [3]Hospital de La Princesa, Endocrinología y Nutrición, Madrid, Spain; [4]Hospital De La Princesa, Cirugía General y del Aparato Digestivo, Madrid, Spain

Introduction
Nutritional status in patients with neuroendocrine tumors (NETs), especially with gastroenteropancreatic origin, may be affected and have an impact on prognosis and survival. Different techniques are currently available to assess nutritional status, but not all of them are accessible in routine clinical practice. In this context, Body composition of NET patients was calculated by computed tomography (CT) at L3 level to evaluate its importance on clinical prognosis.
Materials and Methods
We collected gastroenteropancreatic NET patients with L3 level CT images at diagnosis since 2004 at Hospital Universitario La Princesa (Madrid). L3 CT images were analyzed using NIH ImageJ protocol and R version 4.0. The following measures were obtained: body area, visceral fat tissue, subcutaneous fat, total fat, intermuscular fat, very low density muscle, low density muscle, normal density muscle (NDM), high density muscle and total muscle. All of them were normalized by the squared height of each patient. We used normality Shapiro-Wilk test and Mann-Whitney-U or Kruskal-Wallis tests and one-way t test or ANOVA/ANCOVA for group differences in those with non-normal and normal distribution respectively. We applied Spearman correlation to establish possible relationships between age and biochemical parameters and body composition measures. All the statistical analysis was performed using R 4.0 version.
Results
The sample is composed of 61 gastroenteropancreatic NET patients classified according to: 1) their NET primary location in small intestine (44.26%), pancreatic (37.70%) and large intestine (24.59%); and 2) tumor type: nonfunctioning (70.49%), functioning carcinoid (24.59%), gastrinoma (4.92%) and insulinoma (6.56%). Patients' mean age was 63.19 +/-10.97 years, and 53.73% were females. NDM was positively correlated with albumin ($r=0.3655$, $P=0.0084$) and lymphocyte number ($r=0.3749$, $P=0.0100$). On the other hand, NDM was inversely correlated with age ($r=$-0.5185, $P=0.0012$), myosteatosis ($r=$-0.7065, $P<0.0001$) and inflammation parameters such as ferritin ($r=$-0.3038, $P=0.0349$) and fibrinogen ($r=$-0.3119, $P=0.0481$). Low levels of NDM and total muscle were associated with any type ($P-=0.0007$, $P=0.0029$) and tumor-specific mortality ($P=0.0149$, $P=0.0113$), regardless of sex and age in multivariable analysis. Patients with metastasis have less total fat (pvalue=0.0187) and myosteatosis was more frequent in insulinoma ($P<0.05$) than in non-functioning tumors, carcinoids and gastrinomas. There were no differences according to tumor location.
Conclusion
Body composition analysis is feasible using CT data acquired in routine clinical practice in patients with NETs. Low levels of NDM seem to be independently associated with a worse analytical profile and with mortality.

Reciprocal interactions between fibroblast and pancreatic neuroendocrine tumor cells: putative impact of the tumor microenvironment

Thomas Cuny[1], Gregoire Mondielli[1], Peter van Koetsveld[2], Wouter de Herder[2], Anne Barlier[1] & Leo Hofland[2]
[1]Aix Marseille University, INSERM, U1251, Marseille Medical Genetics, Marseille, France; [2]Division Endocrinology, Erasmus Medical Center, Department of Internal Medicine,, Rotterdam, Netherlands

Introduction
Pancreatic neuroendocrine neoplasms (PNEN) present with a fibrotic stroma which constitutes the tumor microenvironment (TME). The role played by stromal fibroblasts over the growth of PNEN and their sensitivity to the mTOR inhibitor, RAD001, are as yet unestablished.
Methods
We investigated reciprocal interactions between 1) human PNEN cell lines (BON-1/QGP-1) or primary cultures of human ileal neuroendocrine neoplasm (iNEN) or PNEN, and 2) human fibroblast cell lines (HPF/HFL-1). Proliferation was assessed in transwell co-culture (HFL-1tw, HPFtw, BON-1tw, QGPtw) or in the presence of serum-free conditioned media (BON-1cm, QGP-1cm, HFL-1cm, HPFcm), with and without RAD001. Migration of BON-1/QGP-1 was evaluated when incubated with HPFcm.
Results
Proliferation of BON-1 and QGP-1 increased in the presence of HFL-1cm, HPFcm, HFL-1tw and HPFtw (BON-1: +46 to +70% and QGP-1: +42 to

+55% $P < 0.001$ vs controls for both), whereas this stimulatory effect was reversed in presence of RAD001. Likewise, proliferation of human iNEN and PNEN primary cultures increased in presence of HFL-1 or HPF. Reciprocally, BON-1cm and BONtw stimulated the proliferation of HPF (+90 +/- 61% and +55 +/- 47% respectively, $P < 0.001$ vs controls), an effect less pronounced with either QGP-1cm or QGPtw (+19 to + 27%, $P < 0.05$ vs controls) and unmodified by RAD001. RAD001 resulted in a decrease of colony number of BON-1 and QGP-1, while colony size remained the same in presence of the drug. Finally, a higher migration potential of BON-1 and QGP-1 occurred in presence of HPFcm ($P < 0.001$ vs basal).

Conclusions

Fibroblasts, in the TME of PNEN, represent a target of interest to control escape from mTOR inhibitors tumor growth and dissemination.

New epigenetic and functional features in pheochromocytoma

Jacopo Manso[1], Loris Bertazza[1], Susi Barollo[2], Simona Censi[2], Sofia Carducci[2] & Caterina Mian[2]
[1]Padua University, Department of Medicine (DIMED), Padova, Italy; [2]Padua University, Department of Medicine (DIMED), Padua, Italy

Background

Pheochromocytoma (Pheo) is a tumor deriving from chromaffin cells. It can be studied using ^{18}F-dihydroxyphenylalanine (DOPA) - positron emission tomography (PET) due to its overexpression of L-type amino acid transporters (LAT1 and LAT2). The oncogenic pathways involved are still poorly understood. This study examined the relationship between ^{18}F-DOPA-PET uptake and LAT1 expression, and explored the role of miR-375 and putative target genes.

Methods

A consecutive series of 58 Pheo were retrospectively analyzed, performing ^{18}F-DOPA-PET in 32/58 patients. qRT-PCR was used to assess the expression of LAT1, LAT2, phenylethanolamine N-methyltransferase (PNMT), miR-375, and the major components of the Hippo and Wnt pathways. 24 h-urinary metanephrine, normetanephrine, epinephrine and norepinephrine were analyzed for diagnostic purposes prior to surgery. Principal germline mutations associated with hereditary Pheo were also studied.

Results

Pheo tissues had significantly higher LAT1, LAT2 and PNMT mRNA levels than normal adrenal tissues. MiR-375 was strongly overexpressed. YAP1 and TNKS1 were upregulated, while beta-catenin, axin2 and MCT8 were downregulated. A positive relationship was found between ^{18}F-DOPA-PET SUVmean and LAT1 gene expression, as was for 24 h-urinary norepinephrine and LAT1.

Conclusion

The present study confirms in a larger population that LAT1 and LAT2 are upregulated in Pheo. It provides the first experimental proof of a quantitative correlation between ^{18}F-DOPA uptake and LAT1 expression levels, and the first evidence of miR-375 overexpression in Pheo, with a consensual downregulation of the Wnt signaling. The present report also pave the way to studies on the Hippo pathway as a possible new oncogenic driver in Pheo

Glucose-coated superparamagnetic iron oxide nanoparticles prepared by metal vapor synthesis can target GLUT1 overexpressing tumors: in vitro tests and in vivo preliminary assessment

Daniele Barbaro[1,2], Lorenzo Dibari[3,3], Valentina Gandin[4], Cristina Marzano[4] & Claudio Evangelisti[5]
[1]U.O. Endocrinology, ASL Nord Ovest Toscana, Livorno, Italy; [2]USL Tuscany Northwest, Pisa, Italy; [3]University of Pisa, Pisa, Italy; [4]University of Padua, Padova, Italy; [5]CNR PISA, Pisa, Italy

Background

It is well known that one of the basic characteristics of tumor cells is that they are greedy for glucose. Delivering Glucose Coated Superparamagnetic iron oxide nanoparticles (Glc-SPIONs) to tumor cells by i.v. administration could represent "the magic bullet" for detecting and treating cancer,

Materials, methods and results

Glc-SPIONs were prepared by a new approach called Metal Vapor Synthesis (MVS) and their structural features were investigated by transmission electron microscopy and dynamic light scattering. Our Glc-SPIONs are homogeneous, with a mean diameter of 2.7 nm, and surrounded by a thick layer of glucose, reaching an apparent hydrodynamic diameter of 13 nm (30). From 4 mg/ml onwards, there was a constant level of positive contrast in a T1-weighted sequence at MRI. In vitro experiments were performed in three cell lines: pancreatic cancer (PSN-1), human papillary thyroid cancer (BCPAP), and human embryonic kidney non-tumor cells (HEK293). Concentration of the Glc-SPIONs we used did not affect cell viability. Glc-SPIONs were internalized in all the cancer cells in a time-dependent manner. PSN-1 cells were the most effective at internalizing Glc-SPIONs. Although significantly higher than the control cells, a lower Fe content was detected in human BCPAP cells treated with Glc-SPIONs. We evaluated GLUT1 expression in each cell line and demonstrated that the exposure time Glc-SPION uptake in the two different cancer cells correlated well with the detected GLUT1 levels, thus suggesting the involvement of GLUT1 in the cellular internalization of Glc-SPIONs. To confirm the involvement of GLUT1 in Glc-SPIONs internalization, cellular uptake experiments were also conducted by pre-treating cancer cells for 1 h with specific GLUT1 inhibitors, namely a polyclonal anti-GLUT1, WZB117, Fasentin, BAY-876, and STF-31. *In vivo* tests were performed on mice inoculated with Lewis lung carcinoma. Our results showed a great bioavailability to the malignant tissue by the i.v. administration of Glc-SPION while a substantial number of Glc-SPIONs were excreted in the urine 6 h after injection, thus supporting the hypothesis that Glc-SPIONs can be efficiently eliminated by the kidney. Regarding nefrotoxicity treatment with Glc-SPIONs led to a 24 h excretion of uTP, which was three times lower than the one recorded with cisplatin.

Conclusion

To the best of our knowledge, our study demonstrates for the first time that Glc-SPIONs prepared with MVS can be electively internalized by tumor cells both *in vitro* and *in vivo* by exploiting one of the most universal metabolic anomalies of cancer.

Granin family peptides and INSM-1 (Insulinoma-associated protein 1) in the biochemical diagnosis of pheochromocytoma

Piotr Glinicki[1], Magdalena Ostrowska[1], Maria Stelmachowska-Banas[1], Lucyna Papierska[1], Alicja Szatko[1], Konrad Kowalski[2] & Wojciech Zgliczyński[1]
[1]Centre of Postgraduate Medical Education, Department of Endocrinology, Warsaw, Poland; [2]Masdiag Laboratory, Warsaw, Poland

Introduction

Pheochromocytoma is a rare, usually benign tumor composed of neuroendocrine (chromaffin) cells of the adrenal medulla. It is the cause of secondary arterial hypertension. The biochemical diagnosis of a pheochromocytoma is based on the determination of concentration/excretion of catecholamine metabolites in blood or urine. The most sensitive biomarkers in the biochemical diagnosis of pheochromocytoma are plasma free methanephrines (metanephrine, normetanephrine and 3-methoxytyramine) assayed with chromatography tandem mass spectrometry (LC-MS/MS). Neuroendocrine cells have the ability to produce various proteins and neuropeptides, which, together with catecholamines, are released into the blood and can be designated as so-called circulating tumor markers.

Purpose

The aim of the study was to assess the usefulness of the determination of levels of selected Granin family proteins and INSM-1 (Insulinoma-associated protein 1) in the diagnosis of patients with pheochromocytoma.

Material and methods

Patients were divided into 4 groups:
1. Patients with pheochromocytoma ($n = 39$),
2. Patients with incidentaloma ($n = 20$),
3. Patients with primary arterial hypertension ($n = 20$),
4. Control group – healthy volunteers ($n = 40$).

The following biochemical determinations were performed in all patients: plasma levels of metanephrine, normetanephrine and 3-methoxytyramine, concentration of chromogranin B (CgB), proSAAS, INSM-1, chromogranin A (CgA) and derivates peptides: Pancreastatin/chromogranin A (250-301), Serpinin/prepro-chromogranin A (429-454), WE-14/prepro-chromogranin A (342-355) and Catestatin. Biochemical determinations were made using the LC-MS/MS technique with various immunochemical techniques (RIA, IRMA, ELISA).

Results

In patients with adrenal pheochromocytoma levels of: CgA, WE-14 and Catestanin were significantly different ($P < 0.001$) compared to control groups (adenoma, hypertension and healthy subjects). The concentration of INSM-1 was significantly higher ($P < 0.001$) in patients with pheochromocytoma compared to

the group of healthy people. In the group of patients with pheochromocytoma, the following indicators of the diagnostic value of the analyzed biomarkers were obtained: CgA: 82% sensitivity and 100% specificity (AUC 0,930); CgB: 87% sensitivity and 77% specificity (AUC 0,885); WE-14: 90% sensitivity and 95% specificity (AUC 0,959); Catestatin: 80% sensitivity and 92% specificity (AUC 0,903); Pancreastatin: 80% sensitivity and 95 specificity (AUC 0,913); proSAAS: 82% sensitivity and 67% specificity (AUC 0,760); INSM-1: 97% sensitivity and 100% specificity (AUC 0,976).
Conclusion
Determination of biomarkers: CgA, WE-14, Catestatin and INSM-1 had the highest diagnostic value in patients with pheochromocytoma.

The clinical and molecular evaluation of the GIP/GIPR axis in Medullary Thyroid Cancer (MTC)

Gianluca Occhi[1], Loris Bertazza[2], Susi Barollo[2], Eva Galletta[1], Alberto Mondin[2], Stefania Zovato[3], Maurizio Iacobone[4], Eleonora Zilio[1], Serena Avallone[2], Konstantions Lefkimmiatis[5,6], Giulietta Di Benedetto[6,7], Caterina Mian[2], Carla Scaroni[2] & Daniela Regazzo[2]

The glucose-dependent insulinotropic polypeptide receptor (GIPR) is a 7-transmembrane class B G-protein coupled receptor that mediates the incretin response after nutrient stimulation. Although mostly involved in metabolic disorders, in the last years an improper activation of the GIP/GIPR axis has been increasingly recognized in endocrine tumors, with a potential diagnostic and prognostic value. In Medullary Thyroid Cancer (MTC), a neuroendocrine tumor of the parafollicular C cells, a high tumor-to-normal tissue ratio (T/N ratio) of GIPR was reported both in human and in rat. In this latter, a direct link between the neoplastic transformation and the mechanism of receptor overexpression has been proposed. In this work, we aimed at evaluating the potential diagnostic and prognostic significance of GIPR expression in a large cohort of MTC by correlating GIPR mRNA steady-state level with patients' clinical features. Moreover, given the paucity of data on the GIP/GIPR axis in this tumor type, an additional aim of this study was to molecularly dissect the signaling pathways associated with GIPR stimulation in MTC-derived cells with particular attention to cell proliferation and calcitonin secretion. By Droplet Digital PCR (ddPCR) technology, we observed a GIPR positive expression (GIPR+) of nearly 80% (38/49) of MTC tumoral specimens and more frequently in larger, advanced-stage cancer with higher Ki-67 values and sporadic rather than familial manifestation. In MTC-derived cells (i.e., MZ-CRC-1, and a primary culture originating from a regional metastatic lymph node of a GIPR+ MTC patient), GIPR stimulation induced cAMP elevation – with the consequent activation of the PKA cascade – and a small but significant fluctuation in Ca^{2+}, both likely associated with increased calcitonin secretion. GIP has instead no effects on cell viability nor on PI3K-Akt and MAPK-ERK1/2 signalling pathways. The data emerging from this study confirmed the high T/N GIPR ratio in MTC tumors and demonstrate for the first time that it may represent an index of the degree of advancement of the malignant process. The observation that GIP stimulated the adenylyl cyclase and activate the downstream cAMP pathway in MTC-derived cellular models confirms the correct coupling of GIPR to Gas which was ultimately related to an increased CT secretion. Further studies with specific provocative tests, however, will be mandatory to establish the real involvement of GIP/GIPR axis in regulating calcitonin secretion in MTC.

Oncological patients with endocrine complications after immunotherapy with checkpoint inhibitors present longer progression free and overall survival

Stavroula A Paschou[1], Michael Liontos[2], Evangelos Eleftherakis-Papaiakovou[2], Katerina Stefanaki[1], Christos Markellos[2], Konstantinos Koutsoukos[2], Flora Zagouri[2], Theodora Psaltopoulou[2] & Meletios-Athanasios Dimopoulos[2]
[1]Endocrine Unit and Diabetes Center, Department of Clinical Therapeutics, Alexandra Hospital, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece; [2]Hematology and Oncology Unit, Department of Clinical Therapeutics, Alexandra Hospital, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece

Aim
To investigate the association of endocrine complications after ICIs immunotherapy with progression free survival (PFS) and overall survival (OS) in a large single-center oncological cohort.
Patients and methods
In total, 351 patients were included in the analysis, 248 men (70.7%) and 103 women (29.3%). The median age was 66 years. Patients had a variety of cancer types, namely bladder cancer (131, 37.3%), renal cancer (89, 25.4%), lung cancer (74, 21.1%), ovarian cancer (22, 6.3%) and other types of cancer (35, 10%). The majority (314, 89.4%) were classified as stage IV, while 10.6% (37) were classified as stage III. Most of the patients received immunotherapy with anti-PD1 agents (262, 74.6%) and the rest with anti-PD-L1 agents (89, 25.4%). Kaplan-Meier estimates were used to describe and visualize the effect of categorical variables on OS and PFS. Survival analysis was performed by Kaplan-Meier curves and survival differences between groups were estimated using the log-rank test. The estimation of the prognostic value of several variables with patients' survival was made by Cox regression models.
Results
In total, 68 (19.4%) of patients presented an endocrine complication after immunotherapy with ICIs. Specifically, 66 (18.8%) had thyroid dysfunction, 1 patient presented hypophysitis (0.3%) and 1 patient had combination of thyroid dysfunction and hypophysitis (0.3%). Patients with an endocrine complication had mPFS of 15 months (95% CI 11.0-18.9 months), while in those without endocrine complication mPFS was 7 months (95% CI 6.1-7.9 months, $P<0.001$). Similarly, median OS (mOS) was statistically significant lower in the patients' group without endocrine complication. In fact, mOS was 51 months (95% CI 39.3-62.7 months) for these patients. These results retained significance in terms of longer PFS (1.812, 95% CI 1.270-2.586) and OS (1.805, 95%CI 1.088-2.994) after multivariate analysis.
Conclusions
ICIs endocrinopathies may be a positive predictor of immunotherapy response.

Pancreatic neuroendocrine tumors (PanNETs) are heterogeneous neoplasms with a relatively low but increasing incidence, mainly due to the difficulty in diagnosing this disease in its early stages. This notably complicates the treatment of this pathology and leads to a poor prognosis. One of the main reasons for this problem is the lack of adequate diagnostic biomarkers as well as effective therapeutic targets. In this sense, there is still a limited knowledge about alternative splicing, a key process emerging as a transversal hallmark of cancer, as its frequent dysregulation influences most tumor cell features. In a pilot study, we discovered that *CELF4*, — a member of the CELF/BRUNOL family, which is involved in the regulation of RNA splicing, editing, and translation in the central nervous system —, may be altered in PanNETs. Therefore, we aimed at evaluating the role of *CELF4* as a biomarker and/or therapeutic target in PanNETs. To this end, *CELF4* expression levels were determined using a microfluidic based technology, comparing tumor and adjacent non-tumor tissue,

in a cohort of 20 PanNETs patients. This revealed a clear overexpression of *CELF4* in tumor tissue compared to adjacent non-tumoral tissue. Then, an RNA-seq dataset was used to investigate the associations between *CELF4* expression, patient clinical parameters, and splicing event patterns. We observed that *CELF4* is linked to critical features of malignancy, the expression of key genes in tumors (*TP53* or *CDKN2B*) and different splicing events profiles. Likewise, the functional relevance of this factor was determined *in vitro* with several functional assays (cell proliferation and drug response) in two PanNETs cell models (BON-1 and QGP-1), including an mTOR phospho-antibody array to determine the mechanism of action of *CELF4*. Remarkably, the modulation of *CELF4* expression levels in the cell lines resulted in a significant change in proliferation as well as in the response of these cells to the mTOR inhibitor everolimus. In particular, *CELF4* silencing resulted in a disruption of several crucial intermediaries in the mTOR signaling pathway. Finally, we carried out *in vivo* studies using BON-1-xenografted mice, observing a significant reduction of tumor growth by silencing *CELF4*. These results demonstrate that the splicing factor *CELF4* is dysregulated in PanNETs, and its alteration can contribute to tumor development and a more aggressive phenotype, impacting the mTOR signaling pathway. Altogether, these findings provide original evidence that encourage further study of this factor as a novel potential target in PanNETs.

Does the postoperative dose of hydrocortisone influence the health-related quality of life in patients with cured Cushing syndrome?

Ivana Kraljevic[1,2], Anja Barac[3], Mirsala Solak[1], Tanja Skoric Polovina[1], Annemarie Balasko[1], Karin Zibar Tomsic[1], Tina Dusek[1,2] & Darko Kastelan[1,2]
[1]University Hospital Center Zagreb, Dpt of Endocrinology, Zagreb, Croatia; [2]Zagreb University School of Medicine, Zagreb, Croatia; [3]General Hospital Dubrovnik, Division of Internal Diseases, Dubrovnik, Croatia

Objective
Patients with Cushing syndrome (CS) have impaired health-related quality of life (HRQoL) before and after surgery. The data on the optimal hydrocortisone dose after surgical cure of CS is scarce. Therefore, we investigated the influence of hydrocortisone dose on HRQoL after surgical treatment of CS. We hypothesized that patients who receive higher hydrocortisone doses after surgery would have better HRQoL and fewer cortisol withdrawal symptoms.
Methods
The study population comprised 38 patients with CS, 18 with adrenal, and 20 with pituitary origin. After surgical remission of CS, patients were randomized to 15 mg or 30 mg of hydrocortisone. All patients completed the EQ-5D questionnaire at baseline, one month, and three months after surgery. In addition, data on symptoms related to cortisol withdrawal and the consequent need for hydrocortisone dose escalation were collected.
Results
The HRQoL did not differ between patients receiving 15 mg (22 patients) or 30 mg (16 patients) of hydrocortisone, at baseline, after one month, or three months after curative surgery. Total EQ-5D scores in patients on 15 mg and 30 mg of hydrocortisone were 60(1-90) vs 60(0-100), 70(3-85) vs 45(2-95), and 80(20-100) vs 52.5(20-100), respectively ($P=0.934$, $P=0.308$, and $P=0.544$). Three patients needed a temporary increase of hydrocortisone dose during follow-up due to acute illness or worsening of symptoms.
Conclusions
This prospective randomized study showed no difference in HRQoL between patients receiving 15 or 30 mg of hydrocortisone replacement therapy in the first three months after the surgical remission of CS.

Development and internal validation of a predictive score for the diagnosis of central adrenal insufficiency when morning cortisol is in the grey zone

Fabio Bioletto, Alessandro Maria Berton, Emanuele Varaldo, Daniela Cuboni, Chiara Bona, Mirko Parasiliti Caprino, Nunzia Prencipe, Ezio Ghigo, Silvia Grottoli, Mauro Maccario & Valentina Gasco
University of Turin, Department of Medical Sciences, Turin, Italy

Background
When evaluating a patient for central adrenal insufficiency (CAI), there is a wide range of morning cortisol values for which no final conclusion on hypothalamus-pituitary-adrenal (HPA) axis function can be drawn; in these cases, a stimulation test is required. Aim of this study was to develop an integrated model for the prediction of CAI when morning cortisol is in the grey zone, here defined as 40.0-160.0 μg/l.
Methods
Overall, 119 patients with history of sellar tumour which underwent insulin tolerance test (ITT) for the evaluation of HPA axis were enrolled; a peak cortisol value $\geq$ 180.0 μg/l at ITT was adopted for the definition of CAI. Supervised regression techniques were used for model development. Model calibration was evaluated by the Hosmer-Lemeshow test. A ten-fold cross-validation algorithm was adopted for internal validation.
Results
After a stepwise backward selection, the variables retaining a statistically significant association with the outcome were morning cortisol values, the presence of $\geq$ 3 other pituitary deficits, and male sex. Based on these predictors, a multivariable predictive model was developed, and showed a significantly better diagnostic performance in the prediction of CAI than morning cortisol alone (AUC 0.811 vs 0.699, $P=0.003$). The Hosmer-Lemeshow test did not reveal any significant miscalibration ($P=0.54$). At ten-fold cross-validation, the final estimation of the model performance on unseen data was equal to 0.769, thus reassuring about a small overfitting effect. In order to simplify the use of the model in clinical practice, a novel predictive score (CAI-score) is proposed, on a 5.5-point scale, by considering morning cortisol (0 points if 130.1-160.0 μg/l, 1 point if 100.1-130.0 μg/l, 1.5 points if 70.1-100.0 μg/l, 2.5 points if 40.0-70.0 μg/l), other pituitary deficits (2 points if $\geq$3 deficits), and sex (1 point if male). A diagnostic algorithm integrating CAI-score and ITT is finally presented, with an overall accuracy of 99.2%, and the possibility to avoid the execution of a stimulation test in 25.2% of patients.
Conclusion
This was the first study that formally proposed and internally validated a multivariable predictive score for the diagnosis of CAI when morning cortisol is in the grey zone. This score might be helpful to reduce the number of patients who need a stimulation test for the assessment of HPA axis function.

Pituitary microadenoma vs macroadenomas in cushing's disease: does size matter?

Amit Akirov[1,2], Ilan Shimon[1,2], Manisterski Yosi[3], Nirit Aviran-Barak[3], Varda Nadler[3], Sandra Alboim[3], Vered Kopel[3], Gloria Tsvetov[3] & Dania Hirsch[1,2,3]
[1]Tel Aviv University, Sackler School of Medicine, Tel Aviv-Yafo, Israel; [2]Beilinson Medical Center, Petah Tikva, Israel; [3]Maccabi Healthcare Services, Tel Aviv-Yafo, Israel

Background
The majority of adrenocorticotropic hormone (ACTH)-secreting pituitary adenomas are less than 10 mm in diameter and are described as microadenomas, while corticotroph macroadenomas ($\geq$10 mm) are a less common cause of Cushing's disease. Prior reports on the differences of clinical and biochemical behavior of corticotroph microadenomas and macroadenomas were inconsistent.
Objective
Describe the clinical and biochemical characteristics of patients with corticotroph macroadenomas and microadenomas.
Methods
Retrospective charts review of patients with Cushing's disease treated at Rabin Medical Center between 2000 and 2017, or at Maccabi Healthcare Services in Israel between 2005 and 2017. Tumors in which the largest diameter was $\geq$10 mm were considered to be macroadenomas. When no visible tumor was seen on MRI, the tumor was considered to be a microadenoma. Epidemiologic, clinical and biochemical factors were compared between patients with corticotroph macroadenomas and microadenomas.
Results
The cohort included 105 patients (82 women, 78%; mean age $\pm$ SD, 41.5 $\pm$ 14.5 years), including 68 patients (64.8%) with a pituitary microadenoma (mean size, 5.2$\pm$2.2 mm), 25 patients (23.8%) with a macroadenoma (mean size, 18.0$\pm$7.7 mm), and 12 patients with no visible adenoma. Baseline characteristics were similar between the groups, including age, gender, body mass index, and comorbidities. Most common reasons for completing an investigation for Cushing's syndrome among patients with microadenomas and macroadenomas were weight gain (46.3% vs 52.0%, $P=$NS) and Cushingoid features (27.5% vs 20.0%, $P=$NS). While mean urinary free cortisol levels (5.2 $\pm$ 5.4 ULN vs 7.8

± 8.7 ULN) and mean serum cortisol levels following low-dose dexamethasone suppression test (487.6 ± 329.8 vs 372.0 ± 324.5 nmol/l, respectively), were higher among patients with macroadenomas, the differences were not statistically significant and there was considerable overlap between the two groups. Concentrations of ACTH were greater in patients with macroadenoma than in those with microadenoma (1.9 ± 1.2 ULN vs 1.3 ± 0.8 ULN, respectively, $P = 0.01$). Most patients in both groups underwent transsphenoidal surgery, and rates of recurrent or persistent disease were similar in patients with microadenomas and macroadenomas (35.2% vs 28.6%, respectively; P=NS). The rate (83.9% vs 83.3%, respectively) and duration (9.4 ± 8.3 vs 9.7 ± 11.9 months, respectively) of post-operative glucocorticoid treatment were similar in both groups.
Conclusions
While ACTH-secreting macroadenomas exhibit higher plasma ACTH levels than microadenomas, there was no correlation between tumor size with cortisol secretion values or clinical characteristics in patients with Cushing's disease.

Evaluation of the impact of covid-19 on the hypothalamic-pituitary-adrenal axis and the hypothalamic-pituitary-thyroid axis

Juliette Andre[1], Abdallah Al-Salameh[1], Noemie Scherman[1], Claire Andrejak[2] & Rachel Desailloud[1]
[1]CHU Amiens Picardie, Department of Endocrinology, Diabetes Mellitus and Nutrition, Amiens, France; [2]CHU Amiens Picardie, Department of Pulmonary Diseases, Amiens, France

Context
The long-term consequences of Covid-19 are unknown. Most patients experience persistent symptoms more than a month after the acute illness, including fatigue, dyspnea, memory loss, concentration disorder. The pituitary, the thyroid and the adrenal gland express the ACE-2 receptor, which is the cellular receptor for SARS-CoV-2, and could therefore be affected by the virus. However, the effect of Covid-19 on the hypothalamic-pituitary-adrenal-axis and hypothalamic-pituitary-thyroid-axis are unclear.
Objective
Our objective was to evaluate the impact of the SARS-CoV-2 infection on the hypothalamic- pituitary-adrenal-axis and hypothalamic-pituitary-thyroid-axis in the medium term.
Methods
A prospective, observational study conducted from May 2020 to March 2021 at Amiens University Hospital, including 318 adult patients hospitalized for Covid-19. Participants attended a medical consultation 3 month after hospital admission. They had serum cortisol, TSH and FT4 analyzed, and the persistence of symptoms after hospitalization was evaluated. Adrenal insufficiency was defined by a morning cortisol <5 g/dl. Possible central hypothyroidism was defined by FT4 below the laboratory range and low or normal TSH levels.
Results
The post-COVID-19 consultation took place 112 [97-144] days after hospital admission. Basal morning serum cortisol was available for 232 patients. 2 patients had secondary adrenal insufficiency, with basal cortisol levels respectively of 1.4 and 2.1 g/dl, and adrenocorticotropin levels of 3.3 et 7.6 pg/ml. No patient had primary adrenal insufficiency. The median of basal cortisol level was 13.1 g/dl [10.1-16.9] in the group of patients who received Dexamethasone during hospitalization, and 14.7 g/dl [11.5-18.3] in the group of patients who didn't receive Dexamethasone, there was no statistical difference between the two groups. TSH and FT4 were available for 219 patients. 8 patients had results compatible with central hypothyroidism. One patient had both central adrenal insufficiency and central hypothyroidism, due to a pituitary apoplexy following Covid-19 infection. 113 patients presented with persistent symptoms. There was no difference in basal cortisol level between patients who experienced persisting symptoms and those who didn't, the median of cortisol levels were respectively 14.1 and 13.9 g/dl. The FT4 levels were not different between patients with persisting symptoms and those without.
Conclusion
The pituitary- adrenal axis function was preserved 3 months after hospitalization in patients who survived the infection. 3% of the patients had results in favour of central hypothyroidism and <1% had secondary adrenal insufficiency. 35% of the participants had persistent symptoms after the infection but these symptoms were not related to either hypothalamic-thyroid-axis or hypothalamic-adrenal-axis dysfunction.

Osilodrostat therapy improves physical manifestations of hypercortisolism in patients with cushing's disease: findings from the phase III LINC 3 study

Rosario Pivonello[1], Maria Fleseriu[2], Shimatsu Akira[3], John Newell-Price[4], Richard Auchus[5], Richard Feelders[6], Alberto Pedroncelli[7], Andrea Piacentini[8] & Beverly MK Biller[9]
[1]Universitá Federico II di Napoli, Dipartimento di Medicina Clinica e Chirurgia, Sezione di Endocrinologia, Naples, Italy; [2]Oregon Health & Science University, Pituitary Center, Departments of Medicine and Neurological Surgery, Portland, OR, United States; [3]Omi Medical Center, Kusatsu, Japan; [4]The Medical School, University of Sheffield, Department of Oncology and Metabolism, Sheffield, United Kingdom; [5]University of Michigan, Ann Arbor, Division of Metabolism, Endocrinology and Diabetes, Departments of Internal Medicine and Pharmacology, Ann Arbor, MI, United States; [6]Erasmus Medical Center, Department of Internal Medicine, Endocrine Section, Rotterdam, Netherlands; [7]Recordati AG, Basel, Switzerland; [8]Recordati SpA, Milan, Italy; [9]Massachusetts General Hospital, Neuroendocrine and Pituitary Tumor Clinical Center, Boston, MA, United States

Background
Improving physical manifestations of hypercortisolism is an important treatment goal for patients with Cushing's disease (CD). In the Phase III LINC 3 study (NCT02180217), osilodrostat therapy, a potent oral 11β-hydroxylase inhibitor, rapidly normalised mean urinary free cortisol (mUFC) in most patients with CD and sustained control of mUFC over a median treatment period of 130 weeks (W). Here we describe concomitant improvements in physical manifestations of hypercortisolism.
Methods
137 adults with CD and mUFC >1.5 times the upper limit of normal were enrolled in the published 48W core phase. 106 patients opted to enter the extension phase, which ended when all patients had received ≥72W of treatment. Photographs from the shoulders up (frontal and lateral) and of the trunk with the patient standing (frontal and dorsal) were taken by investigators at baseline, every 12W during the core phase, and at W72; manifestations were rated subjectively on a semi-quantitative scale: 0=absent; 1=mild; 2=moderate; 3=severe. Body weight and waist circumference were also measured. Data are presented descriptively for all patients with an assessment at baseline and the given visit.
Results
At baseline, most patients had mild, moderate or severe physical features of hypercortisolism: dorsal fat pad (73.7%), supraclavicular fat pad (68.6%), central obesity (71.5%), facial rubor (63.5%), hirsutism (58.5% [females only; n=62/106]), proximal muscle atrophy (51.8%), striae (48.9%) and ecchymosis (38.7%). At W48 (n=97) and W72 (n=86), respectively, improvements in physical features scores from baseline were noted in 52.6% and 57.0% of patients for dorsal fat pad, 51.5% and 53.5% for supraclavicular fat pad, 42.3% and 39.5% for central obesity, 46.4% and 52.3% for facial rubor, 34.2% (n=26/76) and 34.4% (n=22/64) for hirsutism, 38.1% and 34.9% for proximal muscle atrophy, 32.0% and 30.2% for striae, and 35.1% and 31.4% for ecchymosis. Mean weight improved from 80.8 kg at baseline to 75.5 kg (–4.6%) at W48 and 74.1 kg (–5.8%) at W72. Mean waist circumference decreased from 103.5 cm at baseline to 97.4 cm (–4.2%) at W48 and 95.6 cm (–5.8%) at W72. Mean body mass index improved from 30.3 kg/m^2 at baseline to 28.4 kg/m^2 (–4.6%) at W48 and 27.9 kg/m2 (–5.8%) at W72.
Conclusions
Most patients in LINC 3 had physical manifestations of hypercortisolism at baseline. Osilodrostat therapy provided long-term mUFC control and clinical improvements, with reductions in patient weight and the severity of physical manifestations, including hirsutism, that were sustained through to W72.

Background
Osilodrostat (potent oral 11β-hydroxylase inhibitor) provided rapid normalisation of mean urinary free cortisol (mUFC) in Cushing's disease (CD) patients during the 48-week (W) core period of LINC 4 (NCT02697734) and was well tolerated. We report long-term efficacy and safety results from the LINC 4 core and extension phases.
Methods
73 adults with CD and mUFC >1.3 upper limit of normal (ULN) were enrolled. LINC 4 comprised a 12W, randomised, double-blind, placebo-controlled period followed by 36W of open-label osilodrostat. At W48, patients could continue receiving open-label osilodrostat during an optional extension. Dose adjustments were permitted based on efficacy/tolerability (open-label range, 1–30 mg bid). Efficacy/safety are reported for all patients unless otherwise stated (excludes W1–12 data for placebo recipients).
Results
65/73 patients completed the core phase; 60 entered the extension. Median (range) osilodrostat exposure from core baseline to study end was 87.1 (2–127) W; median (IQR) average dose was 4.6 (3.7–9.2) mg/day. 15 patients discontinued osilodrostat, 7 after W48 (6 because of adverse events [AEs]). The proportion of patients with normal mUFC ($\leq$138 nmol/24 h) was 68.5% ($n=50/73$) at W48, 61.5% ($n=40/65$) at W72 and 72.4% ($n=42/58$) at extension end-of-treatment (EOT). Median mUFC decreased from 2.5ULN (core baseline) to 0.5ULN (W48 and W72) and 0.4ULN (EOT). Median late-night salivary cortisol decreased from 2.8ULN (core baseline) to 1.2ULN (W48 and W72) and 1.1ULN (EOT). Most common AEs overall were decreased appetite (46.6%), arthralgia (45.2%), fatigue (39.7%), nausea (37.0%), headache (34.2%) and dizziness (30.1%). AEs related to hypocortisolism and accumulation of adrenal hormone precursor occurred in 28.8% (21/73) and 61.6% (45/73) of patients overall, less frequently in the extension than the core. Most were grade 1/2 and resolved with dose reduction/interruption and/or concomitant medication. After W48, one patient experienced an AE of hirsutism. Median adrenocorticotropic hormone increased from 1.1ULN (core baseline) to 3.0ULN (W48), 3.6ULN (W72) and 3.5ULN (EOT). Median change (95%CI) in pituitary tumour volume (by MRI) from core baseline to last assessment was 4.0 (-24.1, 169.8) mm^3; AEs related to pituitary tumour enlargement led to discontinuation in 2 and 0 patients during the core and extension. No trend was observed between tumour volume change and osilodrostat dose.
Conclusion
Osilodrostat provided long-term control of cortisol production during LINC 4. Fewer AEs related to hypocortisolism and accumulation of adrenal hormone precursors occurred during the extension than the core. Osilodrostat is an effective and well-tolerated long-term treatment option for CD patients.

Outcome in repeat transsphenoidal surgery in patients with persistent and recurrent Cushing's disease

Isabella Nasi-Kordhishti & Jürgen Honegger
Eberhard Karls Univerity Tübingen, Department of Neurosurgery, Tübingen, Germany

Objective
Transsphenoidal surgery is the treatment of choice for Cushing's disease (CD). Surgery is challenging due to the often very small adenomas. In experienced pituitary centers a high remission rate is reported. Nevertheless, endocrinologists and neurosurgeons face cases with persistent or recurrent CD .These patients must be referred to an experienced pituitary center. In addition to medical treatment, radiation therapy and bilateral adrenalectomy, repeat TSS must also be evaluated. The aim of this study is to analyse the outcome of repeat surgery and to compare persistent and recurrent CD.
Methods
We retrospectively analysed 52 patients with confirmed CD, who underwent repeat TSS in our department. Both persistence of CD after unsuccessful first surgery ($n=24$) and recurrence of CD ($n=28$) were the indications for repeat TSS. Thirty-two patients underwent their first surgery externally, 20 patients had both TSS in our pituitary center. All surgeries were performed by a single experienced pituitary surgeon through a microscopic transsphenoidal approach.
Results
The time range between the first and the repeat TSS was between 0 – 93 months (median 7.5 months) in the case of persistent CD, and between 3 – 219 months (median 64.5 months) in the cases of recurrent CD ($P<.0001$). A high-quality MRI was performed preoperatively in all cases. A clear adenoma was found in 65.4% of cases (66.7% persistent CD, 64.3% recurrent CD). A remission rate of 71% ($n=17/24$) was achieved in the group with persistent CD, and of 82% ($n=23/28$) with recurrent CD. The complication rate was 5.7% (8.3% in persistent CD, 3.6% in recurrent CD). There was no mortality rate in either group.
Conclusion
Persistent and recurrent CD pose a greater challenge for further treatment. If repeat surgery is an option, it should be offered to the patient at an experienced pituitary center. A higher remission rate is achieved in recurrent CD compare to persistent CD. With high surgical experience, there is still a low complication rate of repeat TSS with a satisfactory probability of remission.

Growth hormone excess in fibrous dysplasia and mccune albright syndrome (FDMAS)

Oana O Dănilă[1,2], Raya ES Geels[1], Kim Claessen[3], Maartje E Meier[1,4], Elizabeth M Winter[1], Nienke Biermasz[3] & Natasha M Appelman-Dijkstra[1]
[1]Leiden University Medical Center, Department of Medicine, Division of Endocrinology & Center for Bone Quality, Leiden, Netherlands; [2]National Institute of Endocrinology C.I. Parhon, Bucharest, Romania; [3]Leiden University Medical Center, Department of Medicine, Division of Endocrinology & Center for Endocrine Tumors, Leiden, Netherlands; [4]Leiden University Medical Center, Department of Orthopedic Surgery, Leiden, Netherlands

Introduction
Fibrous dysplasia (FD)/McCune Albright Syndrome (MAS) is a rare disorder affecting bone and hormonal glands. In FDMAS patients, autonomous GH hypersecretion (GH+) is the most common endocrinopathy after Precocious Puberty and has a great impact on the morbidity and complication rate in patients with craniofacial fibrous dysplasia. However clinical and biochemical features of GH over secretion can be subtle and awareness is warranted. We aimed to explore the GH/IGF-I axis in FDMAS.
Methods
We included 163 patients with measurements of GH/IGF-1. Patients with MAS and GH+ were compared with MAS-patients without GH-. Growth hormone excess was diagnosed by Growth Hormone suppression Test (GST) with 75 grams of glucose, cut off value of 1.45 mU/l. GST is performed in our center in case of progressive Craniofacial FD (CFD), phenotypic changes or IGF-1 levels >1.0SD as typical complaints of acromegaly are often lacking in FDMAS.
Results
38 (68.4% females) MAS patients were included,10 had GH excess. In the GH+ group, 7 had prolactin co-secretion. All 10 subjects had precocious puberty and CFD, 7 had skull base involvement. Patients with GH+ were diagnosed with FDMAS at a younger age, 3.5 (0-14 yrs) vs 12 years (1-51 yrs) than GH- patients, $P<0.01$. Median age of GH+ diagnosis was 36 years (7-43 yrs). GH+ was more frequent in males, 7 vs 3. A pituitary microadenoma could be detected in 3

patients (30%). GH+ correlated with visual impairment ($P<0.001$, $r=0.267$), $n=7$ subjects (70%) resulting in blindness in 4. IGF1 levels at time of GH+ diagnosis were within the normal range in 60% of FDMAS GH+ subjects, 48 nmol/l (24.3-88.3) SD 1.95, albeit significantly higher than FDMAS GH- patients, $P=0.007$. Alkaline phosphatase-(ALP) at first presentation was higher in FDMAS GH+ ($P<0.01$), also after correction for disease severity. All GH+ patients were started on medical treatment as surgery was not feasible. After 12 months IGF-1 levels dropped to 37.3 nmol/l (17.30-50.60), SD 0.5 ($P=0.04$). In addition, ALP decreased as well from 1131.5 U/l to 598.5 U/l, $P=0.034$.
Conclusion
In this cohort of FDMAS patients, GH excess was observed in 26% of patients. 60% had IGF-1 levels < 2.5 SD and could only be diagnosed with GST. GH excess was associated with more visual impairment and higher bone turnover. Early diagnosis using GST should be performed as in 60% of subjects IGF-1 levels were within the normal range as treatment is of upmost importance to prevent complications in the future.

Temporal effects of encaleret (CLTX-305) on mineral physiology in autosomal dominant hypocalcemia type 1 (ADH1): results from a phase 2B, open-label, dose-ranging study [NCT04581629]

Rachel Gafni[1], Iris Hartley[1], Kelly Roszko[1], Karen Pozo[1], Edward Nemeth[2], Ramei Sani-Grosso[3], Arun Mathew[3], Ananth Sridhar[3], Mary Scott Roberts[3], Jonathan Fox[3] & Michael Collins[1]
[1]National Institutes of Health, Skeletal Diseases and Mineral Homeostasis Section, Bethesda, United States; [2]MetisMedica, Toronto, Canada; [3]Calcilytix Therapeutics, Inc, San Francisco, United States

Autosomal dominant hypocalcemia type 1 (ADH1), caused by gain-of-function variants in the calcium-sensing receptor (CaSR, gene: *CASR*) and is characterized by hypocalcemia, hyperphosphatemia, low parathyroid hormone (PTH), and hypercalciuria. Calcilytics (negative allosteric modulators of the CaSR) decrease the sensitivity of activated receptors to extracellular calcium and normalize blood and urine abnormalities in ADH1 rodent models. Encaleret is an oral calcilytic under investigation as a treatment for ADH1. Data on the encouraging effects of encaleret on PTH and blood and urine calcium (Ca) were previously reported. Here we expand on those data and describe the temporal and relative changes in PTH, nephrogenous cAMP (NcAMP), tubular reabsorption of phosphate (TRP), blood phosphate (Pi) and Ca, fractional excretion of Ca (FECa), 1,25-dihydroxyvitamin D ($1,25(OH)_2$ D), and intact FGF23 (fibroblast growth factor 23) after encaleret administration. Six adults (22-60 years) with ADH1 due to 4 *CASR* variants were studied in Period 1 of a Phase 2b, open-label, dose-ranging study. Subjects received sequential, increasing daily doses of encaleret for 3d (30 mg, 90 mg, 180 mg) followed by 180mg bid on day 4 and 120 mg or 180 mg bid on day 5, while undergoing frequent blood and urine sampling. The temporal changes in the mean$\pm$SD values over 24 hr on day 4 are compared to baseline (blood volume limitations only allowed for collection of the mineral panel parameters through day 4). PTH was low at baseline (3.4 ± 4.5 pg/ml, normal 10-65), rose rapidly, peaked at 2 hr (65.0 ± 49.2), and remained normal through the 24 hrs measured. NcAMP rose by 4hr and was significantly increased through the 24 hrs measured. TRP and Pi decreased rapidly and remained significantly decreased through 24 hrs. FECa was 0.03 ± 0.02 at baseline, was significantly decreased by 4hr, which was maintained through 24 hrs. Blood albumin-corrected Ca was below normal prior to 0hr dosing (7.6 ± 0.6 mg/dl, normal 8.4-10.2), was normal by 4hr and remained significantly increased from 8-24 hrs. $1,25(OH)_2$ D was below normal at 0hr, increased and remained in the normal range from 4-24 hrs. Intact FGF23 was above normal at time 0hr and surprisingly remained unchanged over the 13hrs monitored, despite the reported changes in Pi, PTH and $1,25(OH)_2$ D. Bone turnover markers CTX and P1NP were unchanged compared with day 1. Encaleret was well-tolerated, with no serious adverse events reported. The observed temporal changes of key mineral homeostasis factors and normalization of blood Ca and FECa in encaleret-treated subjects with ADH1 shed light on mineral physiology and potential utility of encaleret in ADH1.

What is the most efficient way to fortify food items with vitamin D? A randomised, multiple crossover study

Rasmus Espersen[1,2], Lene Ring Madsen[3,4,5], Caroline Nebel[6,7], Marianne Danielsen[6,7], Trine Dalsgaard[6,7] & Lars Rejnmark[1,2]
[1]Aarhus University, Department of Clinical Medicine, Denmark; [2]Aarhus University Hospital, Department of Endocrinology and Internal Medicine, Aarhus, Denmark; [3]Regional Hospital West Jutland, Department of Internal Medicine, Herning, Denmark; [4]Steno Diabetes Center Aarhus, Aarhus, Denmark; [5]Danish Diabetes Academy, Odense, Denmark; [6]Aarhus University, Department of Food Science, Aarhus, Denmark; [7]Aarhus University, iFood, Centre for Innovative Food Research, Aarhus, Denmark

Introduction
Vitamin D insufficiency (25-hydroxy vitamin D <50 nmol/l) is a global health problem. Vitamin D food fortification might be the solution, but knowledge is sparse on whether fortification of various food items affects the bioavailability differently. It is generally assumed that ingesting vitamin D with a fatty meal improves the bioavailability of vitamin D. Furthermore, complex formation with whey protein isolate (WPI) may enhance the stability of vitamin D and thereby improve bioavailability. We studied the efficiency of fortifying different food items with vitamin D_3.
Materials and methods
In a randomised, multiple (5-periods), crossover trial, we enrolled 30 postmenopausal women with vitamin D insufficiency aged 60-80 years. We measured immediate changes in plasma concentrations of cholecalciferol (D_3) in response to intake of different food matrices with 200 µg D_3 added i.e., 1) 500 mL of water, 2) 500 mL of milk, 3) 500 mL of juice, 4) 500 mL of juice with D3 complex-bound to WPI, and 5) 500 mL of water without D_3 (placebo). The different food matrices were provided in a randomised order with at least ten days washout period in-between study days. On each study day, blood samples were collected at 0 h, 2 h, 4 h, 6 h, 8 h, 10 h, 12 h and 24 h.
Results
Complexation D_3 -WPI in apple juice did not enhance maximum concentration (Cmax) of serum D_3 compared to juice without WPI (25 nmol/l vs 24 nmol/l; $P=0.61$), nor the area under the time-D_3 curve (AUC) (370 nmol/l *24 h vs 357 nmol/l *24 h; $P=0.93$). However, compared to juice, Cmax and AUC of serum D_3 were significantly higher in response to intake of milk (30 nmol/l and 452 nmol/l *24 h) and water with D_3 added (32 nmol/l and 479 nmol/l *24 h) ($P<0.05$, all). No difference in serum D_3 was observed between milk and water ($P=0.29$, Cmax; $P=0.33$, AUC).
Conclusion
The bioavailability of D_3 assessed by Cmax and AUC was superior in water and milk compared to juice, independent of whether complexation D_3 -WPI was added to juice.

Accuracy, costs and radiation exposure of current preoperative localization procedures in patients with primary hyperparathyroidism, a retrospective cohort study in a Swiss tertiary referral center

Martin Siegenthaler[1], Ole Christopher Maas[2], Frida Renström[1], Thomas Clerici[3], Flavio Forrer[2], Walter Kolb[3], Stefanie Sinz[3] & Stefan Bilz[1]
[1]Cantonal Hospital of St. Gallen, Clinic for Endocrinology, Diabetology, Osteology and Metabolic Diseases, St. Gallen, Switzerland; [2]Cantonal Hospital of St. Gallen, Clinic for Radiology and Nuclear Medicine, St. Gallen, Switzerland; [3]Cantonal Hospital of St. Gallen, Clinic for Endocrine Surgery, St. Gallen, Switzerland

Background
Focused parathyroidectomy has become the standard procedure for patients with sporadic primary hyperparathyroidism (pHPT) fulfilling the criteria for surgical therapy and requires preoperative localization procedures. Ultrasound imaging (US) and ^{99m}Tc-sestamibi-scintigraphy with/without SPECT/CT (SC) are established first line procedures. ^{18}F-choline PET/CT (PET) has emerged as a novel sensitive and specific method. However, current reimbursement policy in Switzerland limits its use to patients with negative or equivocal first line imaging.

The aim of this study was to compare the accuracy, costs and radiation exposure of SC and PET in patients with negative or equivocal US imaging.
Methods
We retrospectively evaluated all US, SC and PET images performed in patients with sporadic pHPT referred for surgery at our institution between March 2017 and June 2021. US imaging was reported diagnostic, equivocal or negative, SC and PET were reported as positive or negative. Parathyroidectomy was considered successful if normal serum calcium levels were observed six months postoperative.
Results
The study included 239 patients of which all underwent US imaging, 164 (68.6%) received SC and 70 (29.3%) PET imaging. The final diagnostic accuracy of a diagnostic preoperative US ($n=66$) was high with a sensitivity of 100% and a PPV of 95.5%. In patients with equivocal ($n=130$) or negative ($n=42$) US, the accuracy of PET was increased when compared to SC (negative US: sensitivity 38.9% vs 87.5%, PPV 77.8% and 91.3%; equivocal US: sensitivity 70.7% vs 95.0%, PPV 92.1% and 90.5%). The estimated total costs per patient with PET as immediate second line imaging following equivocal US would have been 32% higher compared to a stepwise approach, but comparable in patients with initially negative US. Immediate PET imaging would have reduced radiation exposure by approximately 3.6 mSv (41.8%) and 2.4 mSv (32.4%) in patients with negative and equivocal US results, respectively.
Conclusions
The results confirm the superior accuracy of PET vs SC for the localization of parathyroid adenomas in patients with sporadic pHPT and negative or equivocal US imaging. In patients with negative US immediate PET imaging reduces radiation exposure at comparable costs and should be recommended without previous SC.

Estradiol is the major sex steroid regulating bone marrow fat in both men and women: a study in transgender persons

Marieke Tebbens[1], Moya Schutte[1], Marian Troelstra[2], Aart Nederveen[2], Martin den Heijer[1] & Peter H den Heijer[3]
[1]Amsterdam UMC, Vrije Universiteit Amsterdam, Endocrinology, Amsterdam, Netherlands; [2]Amsterdam UMC, University of Amsterdam, Radiology, Amsterdam, Netherlands; [3]Amsterdam UMC, University of Amsterdam, Endocrinology, Amsterdam, Netherlands

Background
Bone marrow fat is a unique fat depot that is regulated independently of other fat depots. Estradiol is an important regulator of bone marrow fat. This is illustrated by an increase in marrow fat fraction after menopause and a decrease following estradiol replacement. We hypothesize that estradiol is the major sex steroid that regulates bone marrow fat not only in women, but also in men.
Methods
This is an open-label partly randomized intervention study in trans women (assigned male at birth, identify as female) and trans men (assigned female at birth, identify as male) receiving hormone treatment. Trans women were treated with triptorelin for 6 weeks, followed by triptorelin and estradiol for 52 weeks. Measurements were performed at baseline, 6, 8, 18 and 58 weeks. Trans men were randomized to receive triptorelin and testosterone with or without anastrozole for 12 weeks, followed by only testosterone until week 52. Measurements were performed at baseline, 6, 12 and 52 weeks. The marrow fat fraction was quantified by magnetic resonance imaging (MRI). The bone mineral density (BMD) was estimated by dual-energy X-ray absorptiometry (DXA) at baseline and after 12 months.
Results
In trans women, the marrow fat fraction increased by 0.09 (95% CI 0.05 to 0.12) after 6 weeks, compared to baseline. Compared to week 6, the marrow fat fraction decreased by 0.06 (0.01 to 0.11), 0.09 (0.04 to 0.14), 0.08 (0.03 to 0.13) at 8, 18, and 58 weeks, respectively. In trans men without anastrozole, the marrow fat fraction did not change at week 6 and 52, but was slightly higher at week 12 (0.05 (0.01 to 0.08)), compared to baseline. In trans men with anastrozole, compared to baseline, the marrow fat fraction increased by 0.06 (0.03 to 0.09) and 0.06 (0.03 to 0.09) at week 6 and 12, respectively. BMD did not change in response to hormone treatment in any of the groups.
Conclusion
The results of this study indicate that estradiol and not testosterone is the major sex steroid regulating bone marrow fat in both men and women.

Background
Patients with hypoparathyroidism experience significant physical and cognitive symptoms and reduced health-related quality of life (HRQoL). Conventional therapy for hypoparathyroidism does not fully alleviate diminished HRQoL. The Hypoparathyroidism Patient Experience Scales (HPES) were developed to assess disease-specific physical and cognitive symptoms as well as the impact of hypoparathyroidsm on HRQol. TransCon PTH, an investigational long-acting prodrug of parathyroid hormone (PTH[1-34]), is in development as a potential hormone replacement therapy for adults with hypoparathyroidism.
Methods
The phase 2, randomized, double blind placebo controlled 4-week PaTH Forward trial was followed by an open label extension period and enrolled 59 participants. HRQoL was assessed at Week 4 and Week 26 in an exploratory ad-hoc analysis using HPES and the 36-Item Short Form Survey (SF-36) to assess the role of HPES in measuring the impact of TransCon PTH on HRQoL
Results
Improvements in HPES scores were significantly greater for participants treated with TransCon PTH ($n=44$) compared with placebo ($n=15$) from baseline to Week 4 of the trial for both HPES-Total Symptom score (Mean difference [standard error] in scores -20.0 [4.6], $P < 0.01$; 84% of treated patients had improved scores versus 47% of placebo, $P=0.013$) and HPES-Total Impact Score (Mean difference [standard error] in scores -15.7 [5.0], $P< 0.01$; 75% of treated patients had improved scores versus 40% of placebo, $P =0.025$). All HRQoL assessments demonstrated continued score improvements in patients treated with TransCon PTH at Week 26 of the trial compared with baseline. Participants treated with TransCon PTH who had higher (worse) HPES (Impact & Symptom) scores at baseline demonstrated a greater magnitude of improvement at Week 26 as did participants with lower (worse) SF-36 scores at baseline. The Pearson correlation analysis showed that HPES results diverged from SF-36 results over time, with a greater number of domain scores having a correlation of -0.40 or larger at Week 4 compared with Week 26.
Conclusions
This exploratory ad-hoc analysis of the PaTH Forward trial demonstrated improved HRQoL and symptom scores in participants treated with TransCon PTH compared with placebo. In addition, correlation analyses identified the distinct value and dynamic range of HPES as disease-specific assessment tools in hypoparathyroidism. The decreased correlation between HPES and SF-36 over time in the trial indicates that HPES and SF-36 are not redundant.

The resorption status of magnesium screws for surgical treatment of ankle fractures assessed by HRpQCT – 2.5 years follow-up data of a first-in-human study

Ines Föß[1], Victor Labmayr[2], Ulrike Wittig[2], Annelie Martina Weinberg[2], Patrick Holweg[2] & Barbara Obermayer-Pietsch[1]
[1]Medical University of Graz, Division of Endocrinology, Department of Internal Medicine, Graz, Austria; [2]Medical University of Graz, Department of Orthopedics and Traumatology, Graz, Austria; I.F. and V.L. equally contributed as first authors; P.H. and B.O-P. equally contributed as last authors

Background
Bioresorbable screws for surgical fracture treatment are of great interest for the orthopaedic community. Such implants are designed to provide stability and compression of the fracture and should dissolve after healing, thereby making removal of surgical material obsolete. Magnesium implants are a new material option. So far, long-term follow-up of fracture healing and material decay has not been studied in human. Here, we present the results of the 2.5 year follow-up of 6 patients with medial malleolus fractures after surgical stabilization with magnesium screws.
Design and Methods
6 patients with isolated, bimalleolar or trimalleolar ankle fractures were surgically treated using bioresorbable screws (magnesium 99.1%, calcium 0.45%, zinc 0.45%) with an initial volume of 243,3 mm3 (+/- 5). Fracture healing was assessed clinically after one year. Implant resorption was studied after 2.5 years with HR-pQCT (high resolution peripheral quantitative computed tomography). Screw residues were carefully evaluated in a binary approach for every slice (residual present vs not present). Zones of degradation without visible bone were contoured manually and the volume was evaluated.
Results
All patients showed clinical evidence of fracture healing confirmed by plain radiographs, with full weight bearing and absence of pain in the fractured ankle after 1 year. After 2.5 years, resorption of the implant material was almost complete. Of the 11 implants in 6 patients, 3 were dissolved without visible residuals whereas at 8 implantation sites minimal residuals were observed, as assessed by HR-pQCT. In 10% of slices (min. 0%; max. 33%) residuals were observed at implant sites. The degradation zones lacked visible ingrowth of new bone for the most part. Mean volume of degradation zones was 504.8 mm^3 (min. 239.2 mm^3; max. 1109.1 mm^3).

	male, 32 years	female, 51 years	female, 58 years	male, 59 years	male, 33 years	male, 23 years
Slices with residuals (ventral implant)	175/532 (33%)	102/610 (17%)	41/541 (8%)	68/557 (12%)	27/525 (5%)	0/596 (0%)
Slices with residuals (dorsal implant)	133/495 (27%)	13/541 (2%)	35/555 (6%)	0/531 (0%)	N/A	0/558 (0%)

Conclusion
Considering the successful fracture healing and excellent clinical outcome after one year, bioresorbable magnesium screws are a viable option for fracture fixation. Implant removal is not necessary and the 2.5 year follow-up showed the screw material largely resolved. However, enlarged degradation zones and the lack of new bone in these zones were observed.

Insulin resistance as indexed by the estimated glucose disposal rate and liver fat content are correlated in type 1 diabetes

Jonathan Mertens[1,2,3], Maarten Spinhoven[4], Eveline Dirinck[1,2], Luisa Vonghia[3], Sven Francque[1,3] & Christophe De Block[1,2]
[1]University of Antwerp, Laboratory of Experimental Medicine and Paediatrics, Antwerpen, Belgium; [2]Antwerp University Hospital, Endocrinology, Diabetology and Metabolism, Edegem, Belgium; [3]Antwerp University Hospital, Gastroenterology and Hepatology, Edegem, Belgium; [4]Antwerp University Hospital, Radiology, Edegem, Belgium

Introduction
The prevalence of metabolic syndrome is increasing in individuals with T1D, which could potentiate the development of NAFLD. The pathophysiology of NAFLD in T1D is still unclear, due to the co-existence of predisposing and protective factors. Insulin resistance (IR) is theorized as a key driver of NAFLD.
Aim
We investigated the association between liver fat content (LFC), NAFLD, and IR in individuals with T1D. Subjects underwent magnetic resonance spectroscopy (MRS) to determine LFC. The estimated glucose disposal rate (eGDR) was calculated in two ways based on: (1) the presence of hypertension, waist circumference (cm), and HbA1c (%), and (2) the presence of hypertension, body mass index (BMI, kg/m^2) and HbA1c (%). An eGDR <8 mg/kg/min is considered insulin resistant. A mean LFC $\geq$ 6.0 % on MRS was considered diagnostic for NAFLD.
Results
Seventy-eight subjects were included. Age was 59 $\pm$ 17 years, BMI was 27.6 $\pm$ 5.0 kg/m2, waist circumference was 87 $\pm$ 13 cm in females and 99 $\pm$ 12 cm in males, and hypertension was present in 63%. LFC based on MRS was 4.3 $\pm$ 4.0 %, NAFLD was present in 11 (14%) subjects. HbA1c was 7.4 $\pm$ 1.2 % indicating good glycaemic control. The eGDRwaist measured 6.4 $\pm$ 2.5 mg/kg/min, and $eGDR^{BMI}$ was 6.4 $\pm$ 2.2 mg/kg/min. Correlation between eGDR methods was excellent ($r = 0.96$, $P < 0.001$). Kappa between eGDR methods was 0.87, $P < 0.001$. Prevalence of IR was 27% ($eGDR^{BMI}$) and 30 % ($eGDR^{waist}$). All 11 cases of NAFLD were in the IR group, regardless of eGDR method. Linear regression showed a weak correlation between $eGDR^{waist}$ and LFC (r: -0.277, B: -0.442, 95% CI: -(0.792 - 0.091), $P=0.014$), and between $eGDR^{BMI}$ and LFC (r: -0.270, B: -0.480, 95% CI: -(0.872 – 0.089, $P=0.017$). NAFLD was associated with the $eGDR^{waist}$ as a continuous variable (OR: 0.62, 95% CI: 0.39 - 0.99, $P=0.049$) in a logistic model including BMI, age, and gender. $eGDR^{BMI}$ was not significantly associated in a model including waist, age and gender.
Conclusions
These data show that IR, as indexed by the eGDR based on waist circumference, is associated with LFC and the presence of NAFLD in individuals with T1D. More studies are needed to elucidate the role of IR in the etiology of NAFLD in individuals with T1D.

Weight changes and all-cause mortality in patients with prediabetes and diabetes

Jia Li[1], Gyorgy Simon[2], M. Regina Castro[3] & Pedro Caraballo[4]
[1]University of Minnesota, Department of Computer Science and Engineering, Minneapolis, United States; [2]University of Minnesota, Department of Medicine and Institute of Health Informatics, Minneapolis, United States; [3]Mayo Clinic, Department of Medicine, Rochester, United States; [4]Mayo Clinic, Department of Medicine and Department of Quantitative Health Sciences, Rochester, United States

Introduction
Weight loss is a cornerstone in the management of prediabetes and diabetes mellitus. The association between weight and all-cause mortality is controversial and even paradoxical. Studies usually assess baseline weight. Studies assessing weight changes over time are limited. We present preliminary results of our attempt to model weight changes in patients with prediabetes and diabetes assessing the relationship with all-cause mortality.
Methods
We evaluated a retrospective cohort of Olmsted county residents with prediabetes ($n=15868$) and diabetes ($n=10744$) seen at Mayo Clinic. They had vital signs before and after 01-01-2005 and were alive by 01-01-2011. Body mass index (BMI) was calculated to assess weight changes and classified as Low or High using 32 as cutoff. The study period, 01-01-2000 to 01-01-2011 was divided in 3 stages: Baseline from 01-01-2000 to 12-31-2004 (5 years), Follow-up 1 from 01-01-2005 to 12-31-2007 (3 years) and Follow-up 2 from 01-01-2008 to 01-01-2011 (3 years). For each patient we defined six 3-step BMI trajectories by using BMI Low (L), High (H) or any value (X): 1) L-L-L: always low BMI. 2) H-H-H: always high BMI. 3) L-H-L: start and end with Low but had a High BMI at some point. 4) H-L-H: start and end with High but had a Low BMI at some point. 5) H-X-L: start with High but end with Low BMI. 6) L-X-H: start with Low but end with High BMI.

Results
As expected, diabetes mortality rates were higher than prediabetes, but their overall distribution by BMI trajectories was similar (Table). Subjects with high BMI (H-H-H) had lower mortality rate compared with low BMI (L-L-L). Subjects that ended with Low BMI, regardless of initial BMI level (L-H-L and H-X-L), had higher mortality than subjects ending with high BMI (H-L-H and L-X-H).
Conclusion
Our preliminary results evaluating BMI trajectories suggest elevated mortality in subjects with BMI below 32 when compared with BMI above 32, and subjects that lost weight when compared with those that gained weight. These results are contrary to our expectation and against our conceived pathophysiological interaction between obesity, diabetes and its complications. The fact that similar findings have been described for other clinical conditions, impose the need for additional research to find a suitable explanation related to methodology or clinical cause.

Table. Mortality rates by BMI Trajectory

	L-L-L	H-H-H	L-H-L	H-L-H	H-X-L	L-X-H
Diabetes	19.79%	12.65%	15.87%	13.59%	21.78%	13.15%
PreDiabetes	11.98%	5.87%	10.53%	5.60%	11.91%	6.34%

Primary bile acids differentially regulate differentiation of human abdominal and gluteal pre-adipocytes

Rugivan Sabaratnam[1], Ismael da Conceição[1], Nellie Loh[1], Constantinos Christodoulides[1], Fredrik Karpe[1], Jeremy Tomlinson[1] & Nikolaos Nikolaou[1,2]
[1]University of Oxford, Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, United Kingdom; [2]University of Cambridge, Department of Pathology, Cambridge, United Kingdom

Bile acids (BAs) are synthesised from cholesterol in the liver and promote lipid digestion. An emerging body of evidence, however, suggests that BAs are also key signaling molecules with potent metabolic and endocrine functions, exerting their effects through activation of BA receptors, including the farnesoid-X- (FXR) and the G-protein-coupled- (TGR5) receptors. Disturbed BA synthesis has been associated with type 2 diabetes mellitus and insulin resistance, and recent studies have revealed expression of BA receptors in adipose tissue. However, the potential role of BAs to regulate human adiposity is poorly described. We have hypothesised that BAs play an important role in human adipose tissue differentiation and function. Human abdominal and gluteal pre-adipocytes were differentiated into mature-like adipocytes in the presence of vehicle (DMSO), cholic acid (CA) or chenodeoxycholic acid (CDCA) (primary BAs, 50uM) for 12 days. Adipocyte differentiation was determined by qPCR and AdipoRed staining. Intracellular triglyceride accumulation, glucose concentration, and adipokine secretion were determined by ILab biochemistry analyser and ELISA. CDCA treatment of human abdominal and gluteal pre-adipocytes significantly impaired adipogenic differentiation, as demonstrated by AdipoRed staining. However, CA had no impact. Endorsing these data, intracellular triglyceride levels were significantly lower in CDCA-, but not CA-treated, mature-like adipocytes compared to vehicle-treated cells [vehicle: 2388 ± 448.3 vs 126.1 ± 25.41 nmol/mg protein, $P = 0.04$]. In addition, intracellular glucose concentrations were elevated in CDCA-, but not CA-treated, cells compared to vehicle-treated ones (vehicle: 0.11 ± 0.03 vs CDCA: 0.34 ± 0.08 nmol/mg protein ($n = 3$)]. Supporting these findings, expression of the key adipogenesis gene markers *PPARG2*, *CEBPA*, *PLIN1* and *ADIPOQ* were significantly reduced in mature-like abdominal and gluteal cells following CDCA treatment, but were unchanged following CA treatment. Consistent with decreased *ADIPOQ* expression, cell media adiponectin levels were significantly lower in CDCA-treated cells. The effect of CA on adiponectin formation was not significant. In conclusion, we have demonstrated the differential effect of primary BAs on human adipocyte differentiation. Whilst CA had no effect, CDCA treatment resulted in marked repression of adipogenesis in human abdominal and gluteal adipocytes. Our data suggest that alterations in BA levels and/or composition of the BA pool can have a detrimental effect on adipogenesis, potentially contributing to abnormal lipid storage in non-adipose tissues, downstream leading to insulin resistance and hypertriglyceridemia. Additional studies are now required to elucidate the exact mechanisms through which BAs underpin their effects on adipose tissue function.

Adequate metabolic control at early stages of childhood onset type 1 diabetes prevent diabetic neuropathy: a 30 year follow up study

Evangelia Baldimtsi[1,2], Salvador Amezcua[3], Håkan Olausson[3], Johnny Ludvigsson[4,5], Lars Hyllienmark[6] & Jeanette Wahlberg[1,2,7]
[1]Linköping University, Department of Health,Medical and Caring Sciences, Linköping, Sweden; [2]Linköping University Hospital, Department of Endocrinology, Linköping, Sweden; [3]Linköping University, Center for Social and Affective Neuroscience, Linköping, Sweden; [4]Linköping University, Department of Biomedical and Clinical Sciences, Linköping, Sweden; [5]Crown Princess Victoria Children's Hospital, Division of Pediatrics, Linköping, Sweden; [6]Karolinska University Hospital, Clinical Neurophysiology, Stockholm, Sweden; [7]Örebro University, Faculty of Medical Sciences, Örebro, Sweden

Background and aims
Diabetic neuropathy is a common complication of type 1 diabetes. In this study we investigated the importance of long-term metabolic control for the development of diabetic neuropathy in patients with type 1 diabetes diagnosed in childhood.
Materials and methods
Longitudinal cohort study. Twenty-five patients (9 women 16 men) were studied three times with neurophysiological measurements and clinical examinations. At baseline the patients were 15.7 ± 3.7 yrs. (range 7-22) and had diabetes duration of 7.7 ± 3.3 yrs. (range 4-15). At the first follow up 2007-2009 the patients were 29 ± 3.9 yrs. (range 20-35), and had a diabetes duration of 21.6 ± 4.3 yrs. (range 10-31). At the second follow up 2017-2018, the patients were 38.6 ± 3.7 yrs. (range 31-4) and had a diabetes duration of 31.2 ± 4.7 yrs. (range 20-39). The assessment of neurological symptoms followed a standardized process. A neuropathy impairment assessment (NIA) was used to evaluate the signs of diabetic neuropathy. Nerve conduction tests were carried out according to standard techniques. The presence of clinical diabetic neuropathy was determined by a staged approach according to established criteria. Subclinical neuropathy is defined as an electrophysiological abnormality of nerve function without clinical symptoms or signs.
Results
At the initial examination, all patients were free of clinical or subclinical neuropathy. At the first follow up, ten patients 10/25 (40%) had developed clinical ($n = 5$) or subclinical neuropathy ($n = 5$) and they had significantly higher HbA1c, 77.4 ± 16.2 mmol/mol, than the 15 patients without neuropathy, 60.3 ± 8.6 mmol/mol, $P = 0.022$. At the second follow up fifteen patients15/25 (56%) fulfilled the criteria of clinical ($n = 9$) or subclinical neuropathy ($n = 6$). At the second follow up, HbA1c in the ten patients with diabetic neuropathy decreased from 77.4 ± 16.2 mmol/mol at the first follow up to 64.2 ± 16.5 mmol/mol at the second follow up, $P = 0.013$. The additional group of five patients who developed neuropathy between the first and second follow up reduced their HbA1c from 72.0 ± 10.8 mmol/mol to 57.8 ± 14.1 mmol/mol, $P = 0.006$. Taken together, at the second follow up, the difference in HbA1c levels between the 15 patients with neuropathy, 61.4 ± 10.5 mmol/mol, and the 10 patients without neuropathy, 59.6 ± 13.6 mmol/mol, was no longer significant.
Conclusion
The prevalence of diabetic neuropathy in the patient cohort increased with longer diabetes duration and progressed to clinical neuropathy in several cases despite a better metabolic control at the last follow up. The study indicates that an inadequate glycaemic control at early stages of the disease is a risk factor for developing diabetic neuropathy.

GLP-1RAs and glucagon can reshape adipose differentiation in vitro by activating the "browning process"

Giulia Cantini[1], Martina Trabucco[1], Laura Fei[1], Arianna Propato[1], Daniele Guasti[2], Giovanni Quartararo[3], Mario Maggi[1], Edoardo Mannucci[1] & Michaela Luconi[1]
[1]University of Florence, Experimental and Clinical Biomedical Sciences - Endocrinology Unit, Florence, Italy; [2]University of Florence, Experimental

and Clinical Medicine, Florence, Italy; [3]Santa Maria Nuova Hospital, General, Bariatric and Metabolic Surgery Unit, Florence, Italy

Obesity is associated with increased and dysfunctional white adipose tissue (WAT). Pharmacological approaches of obesity are still far from obtaining a stable weight loss. Glucagon-like peptide-1 receptor agonists (GLP-1RAs) have been proposed as anti-obesity drugs due to their effects on weight loss. Furthermore, dual agonists engaging both GLP-1 and glucagon are currently under investigation for their marked effects on weight loss, although their mechanisms of action is still unclear. Compared to WAT, brown adipose tissue (BAT) is specialized in energy dissipation by heat production resulting from the specific expression of the mitochondrial enzyme uncoupling protein-1 (UCP-1). There is growing interest for new therapeutic strategies aimed at stimulating BAT to increase energy expenditure and counteract the dysfunctional expansion of WAT in obesity. Our group has previously demonstrated that liraglutide, GLP-1 and glucagon impair the proliferative and differentiation ability of an *in vitro*-model of primary human adipose-derived stem cells (ASCs), supporting a peripheral action of GLP-1RAs on weight loss. In this study, we compared the effect of these three molecules in reshaping adipogenesis toward brown adipogenesis by stimulating the "browning process" in ASCs. Glucagon, liraglutide and GLP-1 (10nM) added during in vitro-stimulated adipogenesis significantly reduced intracellular triglyceride accumulation evaluated by Adipored staining (-24%,-40%,-23%, $P<0.001$) associated with a decreased expression in the white-adipocyte marker FABP4 (-48%,-94%,-78%, $P<0.05$), while the functional marker adiponectin was upregulated (+34%,65%,72%, $P<0.05$). These findings suggest a differentiation reshape towards a more functional adipocyte phenotype. Moreover, adipogenesis in the presence of the three molecules resulted in a significant upregulation of the brown phenotype marker UCP-1 (fold-increase 2.13, 2.48, 2.14-fold versus adipogenesis alone, $P<0.05$). Mitochondrial functional analysis through Seahorse technology of the adipocytes differentiated in the presence glucagon, liraglutide and GLP-1 revealed a significant increase in the maximal respiration (+15%,25%,29%, $P<0.05$) and a similar reduction (-17%,-14%,-18%, $P<0.001$) in ATP production, supporting a stimulation of the browning process. Finally, morphological analysis of the differentiated adipocytes revealed that liraglutide, GLP-1 and glucagon addition to the adipogenic media associated with an increase in the number and surface of mitochondria and an increase in the number of lipid droplets with decreased diameter, coherently with the typical feature of brown adipocytes. In conclusion, we demonstrated a direct effect of glucagon and GLP1RAs in inducing a significant improvement of the in vitro-derived adipocytes, determining a metabolic shift towards the brown phenotype, coherently with a peripherical action exerted by these molecules directly on the adipose tissue.

Differences in prevalence of, and precipitating factors for, diabetes related ketoacidosis in type 1 and type 2 diabetes mellitus

Dengyi Zhou[1], Haaziq Sheikh[2], Dineshwaran Rajendran[3], Shamanth Soghal[4] , Wai Nga Alice Yip[1], Anjitha Anilkumar[1], Meghnaa Hebbar[1], Lakshmi Rengarajan[5], Senthil Krishnasamy[6] & Parth Narendran[4]

[1]University of Birmingham, College of Medical and Dental Sciences, Birmingham, United Kingdom; [2]Haberdashers' Adams' Grammar School, Birmingham, United Kingdom; [3]Good Hope Hospital, Sutton Coldfield, United Kingdom; [4]Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom; [5]Birmingham Heartlands Hospital, Birmingham, United Kingdom; [6]Walsall Manor Hospital, Walsall, United Kingdom

Introduction

Diabetes related ketoacidosis (DKA) is usually associated with type 1 diabetes mellitus (T1DM). However, DKA is increasingly being recognised in type 2 diabetes mellitus (T2DM). We studied the differences in prevalence and precipitating factors of DKA between T1DM and T2DM.

Methods

This retrospective study included all DKA episodes from January to November 2021 in six hospitals in the West Midlands, UK. DKA was diagnosed as serum glucose $\geq$ 11 mmol/l or known history of diabetes, ketones $\geq$ 3 mmol/l and pH $\leq$7.3 or bicarbonate $\leq$ 15 mmol/l as per Joint British Diabetes Societies guidelines. People admitted with DKA were classified as having T1DM or T2DM based on established diagnosis, autoantibody status, and/or phenotypic features. We compared the differences in prevalence and precipitating factors between these two groups.

Results

465 episodes of DKA were identified. 47 were excluded from analysis due to unclear diabetes type. 68.7% ($n=287/418$) had T1DM and 31.3% ($n=131/418$) had T2DM. The differences in precipitating factors for DKA in T1DM vs T2DM were significant ($P=0.006$). The most common precipitating factor in both groups was intercurrent illness (T1DM: $n=107/287$, 37.3%; T2DM: $n=57/131$, 43.5%). More DKA episodes were precipitated by suboptimal compliance to treatment in T1DM compared to T2DM (T1DM: $n=99/287$, 34.5%; T2DM: $n=20/131$, 15.3%). 9 (6.9%) episodes of DKA were related to SGLT2 in T2DM compared to none in T1DM. 19 (6.6%) episodes of DKA were new diagnoses of T1DM. Other precipitating factors included COVID-19 (T1DM: $n=14/287$, 4.0%; T2DM: $n=16/131$, 12.2%), sepsis (T1DM: $n=10/287$, 3.5%; T2DM: $n=11/131$, 8.4%), alcohol (T1DM: $n=12/287$, 4.2%; T2DM: $n=3/131$, 2.3%), drug induced (T1DM: $n=2/287$, 0.7%; T2DM: $n=3/131$, 2.3%) and trauma (T1DM: $n=2/287$, 0.7%; T2DM: $n=0/131$, 0.0%).

Conclusion

DKA is no longer synonymous with T1DM and we are now seeing significant DKA case numbers in T2DM. The precipitating factors differed between the two types of diabetes and these results can help allocate resources for improved education and individualised clinical care appropriately to minimise morbidity and mortality associated with an eminently preventable condition.

Background/Introduction

Diabetic ketoacidosis (DKA) is a severe complication of diabetes mellitus type 1 (T1DM) with potentially life-threatening course. Data on patient knowledge about DKA in German-speaking countries is rare. Thus, we aimed to gather data about T1DM patients' knowledge in terms of DKA.

Methods

Together with two T1DM patients and an experienced diabetes counselor, we developed an anonymous questionnaire covering general knowledge about DKA, as well as baseline health and social characteristics. First, health care professionals rated patient's knowledge about their management of diabetes and DKA from 0 (no idea) to 10 (best knowledge) and patients were then asked to fill out the questionnaire at the end of their outpatient clinic appointment. Filling out the questionnaire was fully voluntary.

Results

5 Swiss and 1 German endocrine outpatient clinics participated in the study. In total, 333 questionnaires were collected. Patients had a mean diabetes duration of 22 years (SD 15), and 109 (33.5%) patients used insulin pumps and the remainder basal/bolus insulin therapy. 176 patients (54%) stated that they were male and 148 (45%) female. Mean age was 47 years (SD 16). 78 patients (24%) were not familiar with the term "diabetic ketoacidosis" and 25 (7.7%) were unsure about it. The patients' personal knowledge on DKA was rated significantly lower by themselves (mean 4.33, SD 3.11 vs 5.60, SD 2.34; $P<0.0001$) compared to their physicians' assessment but correlated significantly ($r=0.268$, 95% CI [0.1253; 0.3992]; $P=0.0002$). 46% of patients were not able to name any symptom and 44% could not spontaneously think of possible causes of DKA. When presented with multiple answers to choose from, thirst (74%), polyuria (66%), sleepiness (66%) and nausea/vomiting (51%) were among the most frequently picked. As causes of DKA, 61% stated "missed insulin injection" and 54% "illness". 185 (64%) patients do not test for ketone bodies at all. About 40% of all patients felt secure in treating DKA with 206 patients (67%) wanting more information about the condition.

Conclusion
Patient knowledge about DKA is insufficient, especially symptoms and causes are not well understood. However, most patients would like to have more information about DKA, making it a good point to start from in the attempt to reduce DKA prevalence.

Long-term treatment with glucagon-like peptide-1 (GLP-1) receptor agonists: a real-life study

Sara Piccini[1,2], Giuseppe Favacchio[2], Gherardo Mazziotti[1,2], Andrea Lania[1,2] & Marco Mirani[2]
[1]Humanitas University, Biomedical Sciences, Pieve Emanuele (MI), Italy; [2]IRCCS Humanitas Research Hospital, Endocrinology, Diabetology and Andrology Unit, Rozzano, Italy

RCTs and real-life studies have shown the efficacy of GLP-1 RAs on weight loss, glycemic outcomes, and prevention of cardiovascular (CV) events, but long-term data are lacking. This was a retrospective cohort study of 253 patients with a first prescription of a GLP-1 RA between 2009 and 2016 and a minimum follow-up of 5 years. The endpoints of the study were weight and glycemic outcomes. Secondary endpoints were the occurrence of renal and CV events, comparing patients with GLP-1 RA treatment durations over 5 years and under 5 years. Median follow-up was 8.15 years (5.01 to 11.74 years). Mean duration of GLP-1 treatment was 5.4 years (SD 3.2). The mean proportion of follow-up time on GLP-1 RA treatment was 69.6%. The proportion of patients still taking the GLP-1 RA was 85.1% at 1 year, 76.7% at 2 years, 64.1% at 4 years, 56.9% at 6 years, 57.7% at 8 years, and 56.3% at 10 years. Younger age at baseline, higher baseline HbA1c, and being hospitalized for heart failure were associated with a shorter time to GLP-1 RA discontinuation. Switching from any other GLP-1 RA to dulaglutide or semaglutide, and greater decreases in HbA1c at 1 and 2 years were associated to longer time to treatment discontinuation. Comparing patients who had withdrawn GLP-1 RA therapy and those with ongoing GLP-1 RA at each time point, there were significant differences in mean HbA1c (7.81% vs 7.16% at 6 years, 8.08% vs 6.85% at 8 years, 8.26% vs 6.69% at 10 years respectively), and mean weight loss (-1.4 vs -5.6 kg at 6 years, -1.0 vs -6.8 kg at 8 years respectively), except for mean weight loss at 10 years. In the shorter treatment duration group (<5 years on GLP-1) there was a higher proportion of strokes/transient ischemic attacks (7.5% vs 1.3% in the group treated for over 5 years, $P=0.014$). Acute coronary syndromes were more frequent in the shorter treatment duration group, although not statistically significantly (6.5% vs 3.8% respectively, $P=0.37$). No differences in arterial revascularization procedures, no differences in renal outcomes or hospitalizations for heart failure were observed. There were no deaths for CV causes. The study showed that GLP-1 RA treatment maintains its favorable effects on HbA1c and weight over time. The reduction in atherosclerotic events, mainly driven by stroke protection, is consistent with RCT studies and therefore reinforces the long-term use of these antidiabetic medications in real life.

Impact of Covid-19 disease on thyroid function: longitudinal study

Ilaria Muller[1,2], Matteo Varallo[3], Anita Daturi[3], Tiziana E Re[4], Davide Dazzi[5], Virgilio Longari[6], Andrea Gori[7,8], Giovanna Mantovani[1,2], Maura Arosio[1,2] & Mario Salvi[2]
[1]University of Milan, Department of Clinical Sciences and Community Health, Milan, Italy; [2]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico di Milano, Endocrinology, Milan, Italy; [3]University of Milan, Milan, Italy; [4]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico di Milano, Department of Medicine - Acute Medical Unit, Milan, Italy; [5]Casa di Cura Val Parma SRL; [6]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico di Milano, Nuclear Medicine; [7]University of Milan, Department of Pathophysiology and Transplantation; [8]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico di Milano, Infectious Diseases, Milan, Italy

Background
The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic disease (Covid-19) affects thyroid function with different mechanisms: non-thyroidal illness syndrome (NTIS), direct infection of thyroid gland and cytokine storm. We provided the first description of painless atypical thyroiditis coexisting with NTIS in patients hospitalised for moderate-to-severe Covid-19 disease. We aimed to: 1) correlate thyroid dysfunction with Covid-19 disease severity; 2) follow the evolution of thyroid function over time.
Methods
Baseline (at hospital admittance) and longitudinal study of patients hospitalised for moderate-to-severe Covid-19 disease, without known history of thyroid disfunction, assessing serum thyroid function and autoantibodies, inflammatory markers and thyroid ultrasound scan (US). Patients showing at US focal hypoechoic areas suggestive for thyroiditis (thyroiditis-areas) also underwent thyroid 99mTc or I123 uptake scan.
Results
183 Covid-19 patients were studied baseline, of whom 63 (34%) were already on steroid treatment before hospital admission, thus were not considered for TSH analysis. Decreased serum TSH positively correlated with albumin ($P=0.02$) and lymphocyte count ($P<0.01$) but not with C-reactive-protein ($P=0.12$) and interleukin-6 ($P=0.10$); TSH also progressively and inversely correlated to the need of oxygen support ($P=0.02$). Serum FT3 correlated positively with albumin ($P<0.01$) and inversely with D-dimer ($P=0.02$). Baseline thyroid US scan showed thyroiditis-areas in 18/65 (28%) patients, associated with reduced thyroid uptake at $^{99m}Tc/I^{123}$ scintigraphy in 14/17 (82%) cases. Thyroiditis-areas were more frequent among patients with baseline low TSH (6/10, 60%) compared with those with normal TSH (10/40, 25%, $P=0.034$). The patients with thyroiditis-areas also had higher baseline FT4 ($P=0.018$) and IL-6 ($P=0.016$) compared with those with normal thyroid US. Follow-up analysis was conducted in 75/183 (41%) patients; thyroid function and inflammatory markers normalized at all time-points in nearly all cases and no increase of thyroid autoantibodies positivity was observed. The thyroiditis-areas, even if often reduced in size, were still present after 6 and 12 months in 13/15 (87%) and 6/12 (50%) patients, respectively. After 9 months the thyroid uptake at $^{99m}Tc/I^{123}$ scintigraphy was still reduced in 4/6 (67%) patients, even if partially recovered (mean +28%) compared with baseline.
Conclusions
Thyroid dysfunction during moderate-to-severe Covid-19 disease is mild and transient, and thyroid hormones correlate with disease severity. Thyroiditis-areas at US occur frequently and may persist after one year, even if reduced in size; long-term consequences are unknown. The association of thyroiditis-areas with low TSH and high FT4 and IL-6 serum concentrations support the hypothesis of direct thyroid gland involvement in SARS-CoV-2 infection.

Subacute thyroiditis (SAT) during the COVID-19 pandemic: preliminary data from the "ESE Covid Grant 2021" project

Simona Loiacono[1,2], Eleonora Zanni[1,2], Roberta Sueri[1,2], Sara De Vincentis[1,2], Maria Laura Monzani[1,2], Francesco Di Marco[3], Ilaria Muller[4,5], Manuela Simoni[1,2], Daniele Santi[1,2] & Giulia Brigante[1,2]
[1]Unit of Endocrinology, Department of Medical Specialties, Azienda Ospedaliero-Universitaria of Modena, Modena, Italy, Italy; [2]Unit of Endocrinology, Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy; [3]School of Specialisation in Endocrinology, University of Milan, Milan, Italy; [4]Department of Clinical Sciences and Community Health, University of Milan, Milan, Italy; [5]Department of Endocrinology, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy

Introduction
A possible association between the severe acute respiratory syndrome coronavirus (SARS-CoV)-2 pandemic, in terms of infection and/or vaccination, and subacute thyroiditis (SAT) has been recently reported. Although a higher SAT incidence in pandemic has been described, data are still conflicting.
Aim
To determine SAT incidence in Italy during the SARS-CoV-2 pandemic and to characterize clinical peculiarities and response to medical treatment of SAT cases, correlating them to virus exposure and/or vaccine.
Methods
We are performing a prospective, longitudinal, observational, 3-year, multicentre study. All subjects with clinical diagnosis of SAT since November 2020 are enrolled and followed-up for 12 months. During medical history collection, SARS-CoV-2 infection (defined as a positive *rhino*-pharyngeal *swab* obtained before SAT onset) and vaccination were recorded. In order to evaluate SAT course, patients were evaluated at 1, 3, 6 and 12 months after onset with thyroid ultrasonography and blood examinations. This is an interim analysis considering baseline visit performed in two centres (Modena and Milan).

Results
A total of 51 subjects (40 females, 11 males) with SAT have been enrolled so far (age: 50.1 + 11.6 years, BMI: 23.5 + 3.5 kg/m^2). Personal or familiar thyroid disease history was reported in 14 (28%) and 25 (50%) patients, respectively. One (2%) patient had familiar history of SAT. At SAT diagnosis, 36 patients were thyrotoxic (72%) and 5 hypothyroid (10%). TSH serum level was 2.3 + 7.3 microUI/ml, with mean fT4 20.0 + 14.0 pg/ml, and fT3 4.8 + 2.6 pg/ml. Moreover, 30 patients (60%) had elevated erythrocyte *sedimentation rate* (ESR), 27 (54%) elevated high-sensitivity C-reactive protein (hs-CRP), 12 (24%) high thyroglobulin (Tg) serum levels. The cohort was divided according to either SARS-Cov2 infection (9 patients – 18%) or vaccination (18 patients – 36%) . Considering patients with previous infection, the thyrotoxicosis rate raised up to 88.9%. However, the thyrotoxicosis rate ($P = 0.286$), ESR ($P = 0.520$), hs-CRP ($P = 0.585$) and Tg ($P = 0.178$) elevations were not significantly different between patients with or without SARS-Cov2 infection. Similarly, thyrotoxicosis rate (72.2 vs 64.9%, $P = 0.468$), ESR ($P = 0.268$), hs-CRP ($P = 0.173$) and Tg ($P = 0.712$) elevations were not different between patients with or without SARS-Cov2 vaccination.
Conclusion
Our preliminary data suggest that both SARS-CoV-2 infection and vaccination have no impact on the general clinical SAT presentation. Only high thyrotoxicosis rate at diagnosis, especially in patients with previous SARS-CoV-2 infection has emerged. SAT incidence during pandemic will be evaluated at the end of the study.

Is the pre-conceptional TSH optimization useful in women submitted to assisted reproduction technology?

Guia Maria Vannucchi[1], Irene Campi[1], Serena Cagnina[2], Danila Covelli[3], Luca Persani[1], Mario Mignini Renzini[4] & Laura Fugazzola[1]
[1]Italian Auxological Institute San Luca Hospital Emergency Room, Milano, Italy; [2]Università Degli Studi Di Torino Dipartimento Scienze Mediche, Torino, Italy; [3]ASST Bergamo EST, Seriate, Italy; [4]Zucchi Monza Clinical Institute, Monza, Italy

Background
thyroid function (TSH levels) and thyroid autoimmunity are involved in the immunomodulation of early pregnancy stages and can affect assisted reproductive technology (ART).
Aims
1) to evaluate if pre-conceptional TSH is associated with an increased risk of miscarriage, 2) to identify a TSH cut-off significantly associated with risk of miscarriage, 3) to assess the impact of TSH levels on primary and surrogate outcomes.
Methods
We retrospectively studied 1484 infertile women (mean ± age 36.7 ± 4.1 years, mean ± SD BMI 22.7 ± 4) submitted to IVF in a single center from 2004 and 2014. 60,8% and 39.2% of cycles were performed in women affected with primary and secondary infertility, respectively. Primary outcomes were biochemical pregnancy, clinical pregnancy, miscarriage and delivery. Surrogate outcomes were the number of oocytes, the number of embryos and the transfer of embryos.
Results
In 86% of cycles an embryo transfer was performed. 369/1274 (29%) of patients had a biochemical pregnancy and 146 of them experienced a pregnancy loss. Moreover, among the 146 women with pregnancy loss, 52 (36%) were clinically pregnant and had a miscarriage in the first trimester, while in 94 patients (64%) a biochemical pregnancy without clinical evolution was documented. No significant differences in mean TSH levels were recorded between women with different time of miscarriage. By a ROC curve analysis we found that a TSH of 3 mU/l was significantly associated with miscarriage ($P = 0.001$), while a TSH of 2.3 mU/l was associated with a higher chance to have a biochemical pregnancy. We further studied the relationship between the two TSH thresholds (2.5 or 3 mU/l) with surrogate outcomes and we observed a weak association between TSH $<= 2.5$ mU/l with the number of retrieved oocytes ($P = 0.04$) while no significant correlation was found with the number of embryos either obtained or transferred ($P =$ NS).
Conclusion
In women undergoing IVF, lower pre-conceptional TSH levels seems to favor the embryo implantation and reduce the risk of early pregnancy loss. These data strongly indicate the need for TSH screening prior to IVF procedures and suggest LT4 treatment in order to optimize TSH before ovarian stimulation.

The "real-life" thyroid function tests results during pregnancy in the longitudinal observation

Malgorzata Trofimiuk-Muldner[1], Andrzej Nowak[2], Grzegorz Sokolowski[1], Monika Buziak-Bereza[4], Andrzej Lewiński[3], Małgorzata Karbownik-Lewińska[4] & Alicja Hubalewska-Dydejczyk[1]
[1]Jagiellonian University Medical College, Chair and Department of Endocrinology, Kraków, Poland; [2]Medical University of Warsaw, Department of Gynecological Endocrinology, Warszawa, Poland; [3]Medical University of Lodz, Chair and Department of Endocrinology and Metabolic Diseases, Lodz, Poland; [4]Medical University of Lodz, Chair and Department of Oncological Endocrinology, Lodz, Poland

The reference ranges of thyroid function tests during pregnancy are still being debated, even in ethnically homogenous populations. The defining of the normal range is of importance, as it influences therapeutic decisions, particularly the use (or over-use) of levothyroxine in this vulnerable population. The study was aimed at the longitudinal assessment of thyroid function tests results in marginally iodine sufficient Polish population of pregnant women. The study was performed between 2007-2017 as a part of the Polish National Programme for Elimination of Iodine Deficiency. The study included 1405 pregnant women (222 – 1st trimester, 561 – 2nd trimester, 622 – 3rd trimester of pregnancy) of median age 29 years (IQR - 6 years). In each woman serum TSH, FT4, FT4 and aTPO, as well as urinary iodine concentration (UIC) in a urine spot sample, were measured.
Results
Median TSH was, respectively: 1st trimester – 1.22 mIU/l (IQR – 1.42 mIU/l; 2.5–97.5 percentile: 0.04–4.02 mIU/l); 2nd trimester – 1.63 mIU/l (IQR – 1.28 mIU/l; 2.5–97.5 percentile: 0.19–4.42 mIU/l), 3rd trimester – 1.61 mIU/l (IQR – 1.13 mIU/l; 2.5-97.5 percentile: 0.3–4.28 mIU/l). There was no significant yearly difference in TSH concentrations. Median FT4 was, respectively: 1st trimester 15.19 pmol/l (IQR-2.37 pmol/l; 2.5–97.5 percentile: 11.65-21.68 pmol/l), 2nd trimester - 12.69 pmol/l (IQR-2.61 pmol/l; 2.5p–97.5 percentile: 9.29-17.32 pmol/l), 3rd trimester – 11.95 pmol/l (IQR -2.97 pmol/l; 2.5-97.5 percentile: 8.56–17.26 pmol/l). ATPO positivity was found in 18%, 15%, and 9% of pregnant women in the 1st, 2nd and 3rd trimester, respectively. Median TSH in aTPO-negative women was, respectively: 1st trimester – 1.11 mIU/l (2.5-97.5 percentile: 0.03–3.75 mIU/l), 2nd trimester 1.57 mIU/l (2.5-97.5 percentile: 0.18-4.18 mIU/l), 3rd trimester 1.60 mIU/l (2.5-97.5 percentile: 0.35-4,23). ATPO negative and positive women in the 1st and 2nd trimester of pregnancy differed significantly in mean TSH concentrations (1st trimester: 1.31 vs 2.24 mIU/l, $P = 0.002$; 2nd trimester: 1.73 vs 2.25 mIU/l, $P = 0.001$; 3rd trimester 1.78 vs 2.02 mIU/l, $P = 0.230$). The significant difference in FT4 according to aTPO status was found only for the 3rd trimester ($P = 0.020$). No difference was found between those groups in FT3 and UIC concentrations. The stepwise regression model failed to find significant relation between TSH and pregnancy week, aTPO positivity, and UIC.
Conclusions
Our results support the view that the upper TSH range in pregnancy is only slightly lower than in a general population. Therefore, more caution is needed while diagnosing hypothyroidism and deciding on treatment with levothyroxine during gestation.

Which factors can influence the occurrence of two nondiagnostic results in fine-needle aspiration cytology of the same thyroid nodule?

Ines Cosme, Catarina Silvestre & Maria João Bugalho
Centro Hospitalar Universitário Lisboa Norte, Serviço de Endocrinologia, Diabetes e Metabolismo, Portugal

Introduction
Fine-needle aspiration cytology (FNAC) of thyroid nodules can be associated with non-diagnostic (ND) results, despite the usage of ultrasound (US) guidance. It is recommended to repeat the FNAC because of the possible risk of malignancy in these nodules.
Aim
To evaluate the influence of demographic, clinical and echographic characteristics in the recurrence of ND FNAC in a thyroid nodule.
Methods
Retrospective review of ND thyroid FNAC performed between 2017-2020. Demographic and clinical data (age, gender, cervical radiotherapy, presence of *Hashimoto's* thyroiditis and TSH value) and US characteristics (nodules' size, echogenicity, composition and microcalcifications) were collected at the moment of the first ND FNAC.
Results
Of 230 nodules with a first ND FNAC (patients' mean age 60.2 ± 14.1 years, 83% women), 195 (84.8%) were submitted to another FNAC, 9 (3.9%) were submitted

to surgery (only 1 had a malignant histology) and 26 (11.3%) remained under US surveillance. The second FNAC result was: benign in 121 cases, non-diagnostic in 63, indeterminate in 9 and malignant in 2. Concerning demographic and clinical data, there was a higher risk of a second ND FNAC in patients treated with anticoagulant/anti-aggregating agents (OR 2.2, 1.1-4.7, $P=0.03$). Men had a reduced risk of a second FNAC (OR 0.4, 0.2-0.9, $P=0.016$). Patients who had a second ND FNAC were older (63.4 ± 14 vs 59 ± 14 years; $P=0.032$). Previous cervical radiotherapy and *Hashimoto's* thyroiditis did not influence the risk of a second ND FNAC. Regarding echographic characteristics, nodules' echogenicity differed between the ND and diagnostic FNACs (hypoechogenic 71.9% vs 52.4%, hyperechogenic 1.6% vs 6.6% and isoechogenic 26.6% vs 41.8%; $P=0.031$); however, nodules' composition was not significantly different between them. Nodules' microcalcifications increased the risk of ND FNAC (OR 2.2, 1.1-4.5, $P=0.03$). Nodules' size and TSH value were not significantly different between ND and diagnostic FNACs. Eight out of 63 cases with a second ND FNAC were submitted to surgery (all with benign histology), 17 were submitted to a third FNAC (8 benign, 6 ND and 3 indeterminate), in 21 was decided US follow-up and 17 patients dropped out of the study. No malignant diagnosis was found in the nodules with 3 ND FNAC.

Conclusion

In the current series, a second ND FNAC occurred in almost one third of cases. Female gender, older age, treatment with anticoagulant or antiaggregating agents, hypoechogenic nodules and the presence of microcalcifications are likely to influence results. In addition, these nodules were rarely malignant (1.3%).

Association of thyroid hormones with clinical status and cardiovascular outcomes of HFpEF patients

Ana Rita Leite[1], Joao Sergio Neves[1,2], Francisco Vasques-Nóvoa[1,3], Francisca A Saraiva[1], Ana Cristina Oliveira[1], Madalena von Hafe[1,4], Catarina Vale[1,3], António Angélico-Gonçalves[1] & Adelino F Leite-Moreira[1]
[1]Department of Surgery and Physiology, Faculty of Medicine, University of Porto, Porto, Portugal; [2]Department of Endocrinology, Centro Hospitalar Universitário de São João, E.P.E, Porto, Portugal; [3]Department of Internal Medicine, Centro Hospitalar Universitário de São João, E.P.E, Porto, Portugal; [4]Department of Pediatrics, Centro Hospitalar Universitário de São João, E.P.E, Porto, Portugal

Introduction

Heart failure with preserved ejection fraction (HFpEF) is a clinical syndrome with high mortality, for which there are few disease modifying therapeutics. Thyroid axis dysfunction is common in heart failure (HF) and may contribute to the pathogenesis of HFpEF. However, the association of thyroid hormones (TH) with the clinical status of HFpEF patients and their prognostic impact in this syndrome are not clear.

Methods

We evaluated 93 participants with stable HFpEF followed in our centre. We categorized participants according to TH tertiles. A cross-sectional analysis was performed to analyse associations of TH with clinical parameters, and B-type natriuretic peptide (BNP) and high-sensitivity troponin I (hs-TnI) levels. Ordered logistic and linear regression models were used. Associations between TH and a composite endpoint of diuretic intensification, HF hospitalization or all-cause death were assessed using Cox proportional hazard models. These analyses were adjusted for clinically relevant variables.

Results

The mean age of the participants was 73.9 years and 46% were women. Half (51%) had a NYHA class II. In comparison to participants with free T3 (FT3) levels in the upper tertile (2.74 – 3.5 pg/ml), participants with FT3 levels in the lower tertile (1.86 - 2.44 pg/ml) had a higher prevalence of orthopnea (OR= 5.57 [1.14 - 27.16]; $P=0.034$) and higher levels of BNP (= 0.53 [0.02–1.03]; $P=0.041$). On the other hand, participants with free T4 (FT4) levels in the lower tertile (0.72 – 0.98 ng/dl) had a trend for a lower prevalence of orthopnea (OR= 0.28 [0.07 – 1.06]; $P=0.061$) and lower levels of hs-TnI (=-0.41 [-0.82 – 0.00]; $P=0.050$), comparing with participants with FT4 levels in the upper tertile (1.10–1.65 ng/dl). Over a median of 1037 days of follow-up, 48 persons had at least one of the events included in the composite endpoint. Participants with FT3/FT4 ratio levels in the lower tertile had a higher risk of the composite outcome (HR=2.19 [1.01 – 4.76]; $P=0.047$), comparing with participants with FT3/FT4 ratio levels in the upper tertile.

Conclusions

Lower levels of FT3 and higher levels of FT4 are associated with a worse clinical status. A lower FT3/FT4 ratio at baseline is associated with increased risk of a combined outcome of diuretic intensification, HF hospitalization or all-cause mortality. These results lead us to the hypothesis that FT4 to FT3 conversion might be impaired in patients with HFpEF. This impairment could be an important player in the progression of the disease.

Background

Hashimoto's thyroiditis (HT), the most prevalent autoimmune disorder of the thyroid (AITD) is characterized by the presence of circulating autoantibodies, induced by a not fully understood dysregulation of the immune system. MicroRNAs (miRNAs) are small noncoding RNAs, which can play a pivotal role in immune functions and the development of autoimmunity. The aim of the present investigation was to evaluate whether a panel of nine selected miRNAs differs in serum expressions of patients with HT and to analyse possible relations to thyroid antibody levels.

Methods

Participants of the BioPersMed cohort ($n=1022$), an ongoing single-centre, prospective, observational study to evaluate novel biomarkers for the assessment of cardiovascular and common metabolic diseases, were screened for previously diagnosed HT patients ($n=27$) as well as age and sex matched participants suitable as healthy controls ($n=22$). Thyroid function and common autoantibodies were evaluated by serum levels of thyroid stimulating hormone (TSH), free triiodothyronine (fT3), free thyroxine (fT4), thyroid peroxidase autoantibody (TPOAb) as well as thyroglobulin autoantibodies (TgAb), determined by luminescence immunoassays (Siemens, Erlangen, Germany). MiRNA profiles were analysed in the selected samples using quantitative reverse transcription polymerase chain reaction (qRT-PCR).

Results

Systemic expressions of miR-21-5p, miR-22-3p, miR-22-5p, miR-142-3p, miR-146a-5p and miR-451 were significantly upregulated in patients with HT ($P<0.01$, respectively) and indicate HT in receiver-operating characteristic (ROC) analysis with an area under the curve of at least 0.76 (95% confidence interval 0.61-0.91) for miR-22-5p. Subgroup analyses within HT patients showed significantly higher miRNA expression for miR-22-5p and miR-142-3p in HT patients with higher thyroid antibody levels (TgAb and/or TPOAb >60 U/ml, $n=13$) as compared to HT patients with lower thyroid antibody levels (TgAb and/or TPOAb <60 U/ml, $n=11$).

Conclusion

Upregulated systemic expression levels of miR-22-5p and miRNA-142-3p indicate HT and were related with higher levels of thyroid antibodies suggesting a contribution to the pathogenesis of HT.

RS 2247911 polymorphism of GPRC6A gene and serum under-carboxylated-osteocalcin are associated with testis function

Kenda Jawich[1], Maria Santa Rocca[2], Sahar Al Fahoum[1], Marwan Alhalabi[3], Andrea Di Nisio[4], Carlo Foresta[4], Alberto Ferlin[4] & Luca De Toni[4]
[1]Damascus University, Department of Biochemistry and Microbiology, Faculty of Pharmacy, Syria; [2]Padova University Hospital, Department of Medicine, Italy; [3]Damascus University, Department of Embryology and

Reproductive Medicine, Faculty of Medicine, Syria; [4]University of Padova, Department of Medicine, Italy

Purpose
Undercarboxylated-OCN (ucOCN), acting on the receptor GPRC6A, was shown to stimulate of testosterone (T) production in Leydig cells in rodents, in parallel with the hypothalamus/pituitary/gonadal axis mediated by luteinizing hormone (LH). Hence, reduced serum ucOCN and/or inactivating gene variants of GPRC6A, are supposed to affect testis function in humans. The aim of this study is to evaluate the association among serum ucOCN, rs2247911 GPRC6A gene polymorphism and the endocrine/reproductive pattern in a cohort of Syrian infertile males, possibly confirming the role of ucOCN/GPRC6A axis on testis function.
Methods
A total of 172 males, including 62 oligozoospermic,51 azoosperminc patients and 59 age-matched normozoospermic controls, were prospectively recruited at the Orient Hospital for Assisted Reproduction Treatment (Syria) and evaluated for the hormonal pattern, serum OCN, glycemic and lipid profile. Screening for rs2247911 GPRC6A gene polymorphism was also performed.
Results
Serum ucOCN correlated positively with total sperm count, sperm morphology and motility, total T, E2 and HDL-cholesterol, and negatively with LH, FSH, and LDL-cholesterol. Patients bearing the GG genotype of rs2247911 polymophism had higher sperm count ($P=0.008$), progressive motility($P=0.05$), normal morphology($P=0.009$), T ($P=0.003$), HDL-cholesterol ($P=0.008$) and lower triglycerides levels ($P<0.001$) compared to patients bearing AG and AA genotypes. Aside of LH levels, rs2274911 gene polymorphism ($P=0.024$), and to a minor extent ucOCN, were major predictors of serum T at linear stepwise regression analysis.
Conclusions
The novel ucOCN/GPRC6A axis was confirmed to participate in the regulation of the endocrine and reproductive function of the testis through the production of T.

Proteomic changes in response to electrical stimulations in skeletal muscle of women with PCOS

Gustaw Eriksson[1], Emma Nilsson[2], Roberto Boi[3], Jenny Nyström[3], Elisabet Stener-Victorin[1] & Anna Benrick[3]
[1]Karolinska Institute, Dept. of Physiology and Pharmacology, Stockholm, Sweden; [2]Lund University, Department of Clinical Sciences, Lund University Diabetes Centre, Malmö, Sweden; [3]University of Gothenburg, Inst. of Neuroscience and Physiology, Gothenburg, Sweden

Polycystic ovary syndrome (PCOS) is an endocrine and metabolic disorder affecting women of reproductive age. The main features of PCOS are hyperandrogenism and reproductive and metabolic dysfunctions. We have previously shown that muscle contractions induced by either electrical stimulations or exercise act through partially similar signaling pathways in the muscle to induce glucose uptake in the acute response. Long-term electrical stimulations decrease circulating testosterone, HOMA-IR, and HbA1c in overweight/obese women with PCOS, but the mechanism is largely unknown. Here, we used transcriptomic and proteomic analyses to provide new mechanistic explanations to the improved glucose homeostasis in response to 30 min of electrical stimulations, 3 times/week for 5 weeks. Skeletal muscle biopsies from 10 women with PCOS were subjected to global methylation, transcriptomics and proteomic analysis at baseline and after 5 weeks of treatment. Changes in protein expression between baseline and after treatment were based on Student's t-test ($P<0.05$) and a fold change $>50\%$. Changes in skeletal muscle DNA methylation and gene expression in response to electrical stimulation were based on linear regression analysis ($P<0.01$) and a fold change $>20\%$. 12 unique transcripts exhibited increased expression in skeletal muscle after 5 weeks of treatment. Four types of collagens were upregulated, and together with *VCAN* and *LUM*, these genes were confirmed by gene ontology analysis to play a role in extracellular matrix organization and skeletal system development. Next, we analyzed if the response to electrical stimulation involved DNA methylation changes in skeletal muscle. The absolute changes in methylation were small and ranged from -1.29% to $+0.72\%$ points. The vast majority of the 43 significant CpG sites (75%) displayed decreased DNA methylation in response to electrical stimulation. Since relatively few genes and methylation sites were regulated in response to repeated electrical stimulations, we investigated if the long-term effects were regulated at the protein level. More than 300 proteins changed expression after treatment. 97% of these were upregulated and enriched pathways involved exocytosis, extracellular matrix organisation, integrin-mediated signalling, transforming growth factor production, and protein metabolic processes. Collagen 1A1 and 1A2 were upregulated both at the gene and protein expression level after electrical stimulation. One can speculate that up-regulation of integrins, collagens, and transforming growth factor-beta-1 likely lead to ECM remodeling, which can provide protective adaptation to repeated stimulation, and improved muscle strength and function. In conclusion, changes at the protein level mediate the response to long-term electrically stimulated muscle contractions.

Binding affinity affecting SHBG SNPs do not majorly affect calculated estimates of free testosterone

Joeri Walravens[1], Thiberiu Banica[1] , Tibbert Van Den Eynde[1], Gido Snaterse[1], Tim Reyns[2], Nick Narinx[3], Leen Antonio[3], Tom Fiers[2] , Jean-Marc Kaufman[1] & Bruno Lapauw[1]
[1]Ghent University Hospital, Department of Endocrinology, Ghent, Belgium; [2]Ghent University Hospital, Laboratory for Clinical Biology, Ghent, Belgium; [3]Leuven University Hospital, Department of Endocrinology, Leuven, Belgium

Introduction
According to the free hormone transport hypothesis, only free testosterone (FT) is considered biologically active. Due to low circulating levels and technical challenges of direct FT measurements, calculators have been developed to estimate FT from serum total T, sex hormone-binding globulin (SHBG) and albumin levels. However, genetic polymorphisms altering SHBG's binding affinity or capacity might result in calculation imprecisions with consequent incorrect diagnosis in these individuals.
Objective
Investigating the prevalence of SHBG single-nucleotide polymorphisms (SNPs) in healthy men and evaluating differences in SHBG, total T, calculated FT (cFT) and measured FT (mFT) levels in SHBG SNP-carriers.
Methods
Population-based sibling-pair study, comprising 999 healthy men aged 24-46 years in whom genotyping was performed (LGC Genomics) for SNPs suggested to affect binding affinity and/or concentration of SHBG (rs6258, rs6259, rs146779355, rs145273466, rs368589266, rs143269613, rs373769356, rs143521188). SHBG and total T concentrations were measured by immunoassay and LC-MS/MS, respectively. FT levels (cFT; using the Vermeulen-formula) and free T-ratio (FT/total T) were calculated. In a subset of participants (145, 10 and 40 individuals for WT/WT, WT/rs6258 and WT/rs6259, respectively) FT was measured directly using LC-MS/MS after equilibrium dialysis (mFT). The difference between cFT and mFT was calculated and expressed as percentage of mFT (delta%). Parameters were compared by t-test or Mann-Whitney test depending on normality; method-comparison was performed using Passing-Bablok regression.
Results
11/971 (1%) and 0/971 participants were hetero- and homozygote for rs6258; 135/681 (20%) and 9/681 (1%) were hetero- and homozygote for rs6259, respectively. No other SNPs were detected. Versus wild-type, heterozygote rs6258 carriers had lower SHBG (26.5 nmol/l vs 38.5 nmol/l) and total T levels (468.8 ng/dl vs 583.9 ng/dl) but higher free T-ratio (2.3% vs 2.0% for cFT; 2.2% vs 1.7% for mFT). Heterozygote rs6259 carriers had higher SHBG levels (42.8 nmol/l vs 38.5 nmol/l) and lower free T-ratio (1.9% vs 2.0% for cFT) than non-carriers. Comparing cFT and mFT showed a significant difference in heterozygote rs6258 carriers (delta% 5.1% vs 15.4% in wild-type). No other differences nor differences in homozygote rs6259 carriers vs wild-type were observed.
Conclusion
Genetic polymorphisms suggested to affect SHBG concentration or steroid-hormone binding affinity are relatively rare in this population-based cohort of healthy men. Although carriers did present with different SHBG levels and free T-ratios compared to non-carriers, our results do not disprove the calculators' accuracy in men heterozygous for rs6258 or rs6259, despite in vitro experiments suggesting a 1.8 reduced binding affinity and reduced clearance rate respectively compared to wild-type SHBG.

Unraveling the link between metabolism and reproduction in obese men

Georgios Papadakis[1], Favre Lucie[1], Yassine Zouaghi[1], Nathalie Vionnet[1], Nicolas Niederlander[1], Michela Adamo[1], James Acierno[1], Federico Santoni[1], Dassine Berdous[1], Alexia Spoerl[1], Emmanuelle Paccou[1], Yasser Aleman[2], Olivier Salamin[3], Patrick Hagmann[2], Andrea Messina[1] & Nelly Pitteloud[1]

[1]Lausanne University Hospital - CHUV, Service of Endocrinology, Diabetes and Metabolism, Lausanne, Switzerland; [2]Lausanne University Hospital - CHUV, Service of Diagnostic and Interventional Radiology, Lausanne, Switzerland; [3]Romand University Center of Legal Medicine, Swiss Laboratory for Doping Analyses, Epalinges, Switzerland

Introduction
Obesity is a worldwide pandemic, and in men can often be associated with hypogonadotropic hypogonadism (HH), a finding consistent with a clear link between sex steroids and reproduction. In this study, we aimed to characterize the phenotypic spectrum of male obesity, focusing on the metabolic and reproductive effect of weight loss after bariatric surgery, as well as to explore the role of central inflammation.
Methods
We conducted an observational study on 32 morbidly obese men (BMI $>$ 35 kg/m^2) scheduled to undergo Roux-en-Y Gastric Bypass (RYGB) and prospectively followed for 12 months thereafter. Nine lean men with strictly normal metabolic and reproductive status were also recruited. Obese men were categorized as either HH (ObHH, $n=15$; testosterone $<$ 10.4 nmol/l) or non-HH (ObnHH, $n=17$; testosterone $\geq$ 10.4 nmol/l). In addition to standard metabolic and reproductive profiles, a deep phenotyping consisted of Dual X-ray absorptiometry, metabolomics and blood transcriptomics. We also performed brain MRI – Diffuse Tensor Imaging (DTI) in a subset of patients before and after RYGB.
Results
Despite comparable BMI, ObHH exhibited more severe insulin resistance (HOMA-IR, $P=0.01$), a trend for expanded visceral fat ($P=0.08$) and higher systemic (serum hs-CRP, $P=0.09$) and hypothalamic inflammation (lower fractional anisotropy and higher diffusivity at DTI, $P<0.05$) as compared to ObnHH. Blood transcriptomics revealed a distinct expression profile in ObHH related to overexpression of genes implicated in inflammation and mitochondrial function, especially oxidative phosphorylation. In addition to lower testosterone levels, higher FGF21 and lower morning cortisol in the cohort of obese men strongly correlated with the transcriptomic changes. Following RYGB, all men lost substantial weight (21-39% at month 12) independent of the baseline gonadal status. Longitudinal assessment in nine men revealed a rise in plasma FGF21 at day 28 post RYGB ($P=0.04$), concomitant to the early decrease in HOMA-IR. FGF21 subsequently returned to baseline levels and decreased by month 12 ($P=0.02$). A significant reduction in plasma isoleucine levels (day 2, $P=0.01$) preceded the FGF21 peak. The extent of the FGF21 peak at day 28 significantly correlated with the degree of HH reversal at month 12 ($P=0.04$).
Conclusions
HH is a marker of metabolic syndrome in obese men, accompanied by MRI signs of altered hypothalamic structure. Serum levels of cortisol and FGF21 are additional predictors of metabolic defects. Post RYGB, FGF21 showed a unique bimodal change, tightly associated with the metabolic improvement and the recovery of obesity-induced HH.

Association of Early Adulthood Hyperandrogenemia With Hypertension and Cardiovascular Events in Women

Katri Tuorila[1] , Meri-Maija Ollila[1] , Marjo-Riitta Järvelin[2,3,4,5], Juha Tapanainen[1,6], Stephen Franks[7], Terhi Piltonen[1], Kari Kaikkonen[8] & Laure Morin-Papunen[1]
[1]Department of Obstetrics and Gynecology, University of Oulu and Oulu University Hospital, Medical Research Center, PEDEGO Research Unit, Oulu, Finland; [2]MRC-PHE Centre for Environment and Health, Department of Epidemiology and Biostatistics, School of Public Health, Imperial College London, London, United Kingdom; [3]Center for Life Course Health Research, Faculty of Medicine, University of Oulu, Oulu, Finland; [4]Unit of Primary Health Care, Oulu University Hospital, OYS, Oulu, Finland; [5]Department of Life Sciences, College of Health and Life Sciences, Brunel University London, London, United Kingdom; [6]Department of Obstetrics and Gynecology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland; [7]Institute of Reproductive and Developmental Biology, Imperial College London, London, United Kingdom; [8]Division of Cardiology, Department of Clinical Medicine, Medical Research Center, University of Oulu and Oulu University Hospital, Oulu, Finland

Background
Cardiovascular diseases (CVD) present sex specific characteristics, suggesting sex-hormones playing a role in the pathophysiology of CVDs. Hyperandrogenemia (HA) is a common condition in fertile age women but whether HA is a risk factor for CVD is still controversial.
Aims
To clarify the association of HA with the development of hypertension and CVDs in women.
Study population and methods
A general population-based birth cohort ($n=5889$ women) followed at ages 1, 14, 31 and 46. We investigated the association of serum levels of testosterone (T, measured using LC-MS/MS) and free androgen index (FAI) at age 31 with blood pressure (BP), hypertension (HT, defined as B $P\geq$ 140/90 mmHg and/or use of antihypertensive medication) at age 31 and with CVD risk [angina pectoris (AP) and/or acute myocardial infarction (AMI), and transitory cerebral ischemia (TIA) and/or stroke] with 22-year follow-up. After excluding women being pregnant ($n=212$) and those with lacking data, the final study population included 2820 women at age 31.
Results
After adjusting for body mass index (BMI), there was an independent positive association of T and FAI with systolic BP (T:$\beta=1.93$, 95% CI:0.93–2.93, FAI:$\beta=1.68$, 95% CI:0.67–2.70) and diastolic BP (T:$\beta=1.80$, 95% CI:0.93–2.67, FAI:$\beta=1.96$, 95%CI:1.10–2.82) at age 31. The prevalence of HT was significantly higher among women with elevated T (cut-off 2.3 nmol/l defined in this population) compared to normoandrogenic women (27.1% vs 11.9%, $P=0.002$). Conversely, women with HT at age 31 had significantly higher T levels (1.12 [0.82; 1.47] vs 0.97 [0.73; 1.25] nmol/l, $P<0.001$) and FAI (2.92 [1.95; 4.72] vs 2.16 [1.50; 3.09], $P<0.001$) compared to normoandrogenic women after adjusting for BMI. In logistic regression analysis, T and FAI associated positively and independently of BMI with HT (Odds ratio (OR) for T: 1.81, 95% CI:1.37–2.39, OR for FAI: 1.87, 95% CI:1.42–2.47). HA at age 31 did not associate significantly with TIA and/or stroke. Sex hormone binding globulin (SHBG) associated inversely [crude Hazard ratio (HR):0.97, 95% CI: 0.95–0.99] and FAI positively (crude HR:1.16, 95% CI: 1.04–1.30) with increased risk of incident CV events (AP/AMI) during the 22-years follow-up. However, after adjusting for BMI at age 31, the significances disappeared.
Conclusions
Women with HA at reproductive age had elevated risk for HT. They had a significantly increased CVD event risk during the 22-years follow-up, but this risk seemed to be mainly driven by BMI. A longer follow-up of this cohort is needed to clarify the long-lasting metabolic risks linked to HA.

Is Turner syndrome at risk for thyroid carcinoma?

Elisabetta Belardinelli, Paola Dionese, Carolina Cecchetti, Valentina Vicennati, Andrea Repaci, Uberto Pagotto & Alessandra Gambineri
IRCCS Azienda Ospedaliero-Universitaria di Bologna, Department of Medical and Surgical Sciences (DIMEC), Alma Mater Studiorum, University of Bologna, Division of Endocrinology and Diabetes Prevention and Care, Italy

Background
Many questions concerning Turner Syndrome (TS) remain unresolved, such as the long-term complications and, therefore, the optimal care setting for adults. Most controversials regard tumors. Very few data are available on thyroid carcinoma and no specific screening protocol of monitoring is advised in the current official guidelines. This long-term cohort study was primarily aimed at estimating the incidence and time to comorbid conditions along the life course, including thyroid carcinoma and tumors in general.
Methods
The study cohort consisted of 160 TS women, the vast majority recruited during childhood (mean age= 9.4 years, median=9 years, IQR 2-16) and followed up for a median of 27 years (IQR 12-42) at the S. Orsola University Hospital of Bologna using the same multidisciplinary monitoring protocol (including thyroid ultrasound every one to two years). The last follow-up was carried out for all patients in December 2019.
Results
Autoimmune diseases (such as Hashimoto's thyroiditis, celiac disease and autoimmune polyendocrine syndrome) were the comorbidities with the highest incidence (61.2%), followed by osteoporosis and hypertension (23.8% for both), then by type 2 diabetes (16.2%) and by tumors (15.1%). Median age of onset ranged from 22yrs for autoimmune diseases to 39yrs for type 2 diabetes. Malignant tumors (including thyroid carcinoma, renal cell cancer, skin cancer, breast cancer, ovarian cancer and central nervous system tumors) were the most prominent form of neoplasms, with a cumulative incidence of 11.9% and an incidence rate of 0.44 per 100 person-year. Thyroid carcinoma (histologically all papillary -PTC- in our cohort) was the most common form of cancer with a cumulative incidence of 5% and an incidence rate of 0.56 per 100 person-year

(incidence rate of 0.037 per 100 person-year in a cohort of Italian women of similar age range). Median age of onset of PTC was 28.9yrs. No association with a specific karyotype of the TS was observed.
Conclusions
These findings demonstrate that TS patients are at risk of developing thyroid carcinoma, particularly the papillary form, thus suggesting, differently from current practice, the need to include thyroid ultrasonography within the structured follow-up protocol of this syndrome.

Pubertal induction in girls with hypogonadism: insight into estrogen replacement therapy outcomes and optimization of progesterone introduction

Giulia Rodari[1], Silvia Federici[2,3], Alessandro Cattoni[4], Tommaso Todisco[5], Graziamaria Ubertini[5], Federico Giacchetti[6], Eriselda Profka[6], Alberta Dall'Antonia[7], Biagio Cangiano[2,3], Maura Arosio[1,6], Marco Bonomi[2,3], Marco Cappa[5] & Claudia Giavoli[1,6]
[1]University of Milan, Department of Clinical Sciences and Community Health, Milan, Italy; [2]University of Milan, Department of Medical Biotechnology and Translational Medicine, Milan, Italy; [3]IRCCS Istituto Auxologico Italiano, Dept. of Endocrine and Metabolic Diseases and Lab. of Endocrine and Metabolic Research, Milan, Italy; [4]Fondazione MBBM, San Gerardo Hospital, Department of Pediatrics, Università degli studi di Milano-Bicocca, Monza, Italy; [5]University-Hospital Pediatric Department (DPUO), Bambino Gesù Children's Hospital, IRCCS, Endocrinology Unit, Rome, Italy; [6]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Endocrinology Unit, Milan, Italy; [7]University of Milan, Milan, Italy

Background
Pubertal induction in girls with hypogonadism through estrogen replacement therapy (ERT) aims at mimicking physiological puberty. To date, the best induction regimen is still to be established.
Aims
By setting up a multicentre clinical registry, we analysed longitudinal data on pubertal induction in girls with hypogonadotropic hypogonadism or premature ovarian insufficiency (congenital, acquired, isolated or associated with multiple pituitary hormone deficiency, either associated with Turner Syndrome or secondary to late effects of cancer treatment) in order to insight into auxological and uterine outcomes in the light of different underlying diagnosis and regimens used.
Methods
Out of 106 hypogonadal girls (chronological age > 10.9 years, Tanner stage $\leq$ 2) who received ERT for pubertal induction included in the register, we considered 95 girls (median age 13.5 years) treated with transdermal (TD) 17β-estradiol patches for at least one year (median 3.3 years). Induction was started at a median dose of 0.14 mg/kg/day TD 17β-estradiol, with a six-monthly increase. Auxological, biochemical (estradiol levels) and radiological (pelvic US) data were collected at baseline and during follow-up. In 61/95 girls, progesterone was introduced after a median of 2.2 years. Induction was considered completed for the 49/95 patients who were started on combined oral contraceptive (COC) or progesterone *plus* at least 50 mg/day or 1 mg/kg/day of TD 17β-estradiol.
Results
at the end of induction, 90.0% patients had achieved Tanner stage B4 and 41.0% B5, the latter being associated with 17β-estradiol dose at progesterone introduction ($P = 0.034$). Uterine longitudinal diameter (ULD) showed a gradual increase during ERT and a significant correlation with 17β-estradiol dosage ($P < 0.0001$) at any point of induction. Nonetheless, final ULD was > 65 mm in only 17/45 (38%). At multiple regression analysis, a history of pelvic irradiation represented the major determinant of reduced final ULD ($P = 0.034$). After correction for uterine irradiation and other clinical confounders, ULD was associated with 17β-estradiol dose at progesterone introduction ($P = 0.043$). Final ULD was not significantly different from the one assed after COC introduction.
Conclusions
reaching an appropriate 17β-estradiol dose at the end of the induction seems to play a crucial role in uterine development and Tanner stage 5 achievement. Indeed, progesterone should be started only in the presence of a concomitant adequate ERT dose and an appropriate uterus and breast development, given the evidence that progestins may hamper the subsequent changes in uterus volume or the achievement of the last Tanner stage. At present, we aim to confirm present results on a larger scale.

Ethinyl estradiol in a combined contraceptive exerts greater effect on serum proteome than estradiol valerate – a randomized trial

Marika Kangasniemi[1], Riikka Arffman[1], Sakari Joenväärä[2,3], Annina Haverinen[4], Kaisu Luiro[4], Tiialotta Tohmola[2,3], Risto Renkonen[2,3], Oskari Heikinheimo[4], Juha Tapanainen[4] & Terhi Piltonen[1]
[1]Oulu University Hospital, University of Oulu, Department of Obstetrics and Gynecology, PEDEGO Research Unit, Medical Research Center, Oulu, Finland; [2]Haartman Institute, University of Helsinki, Transplantation Laboratory, Helsinki, Finland; [3]Helsinki University Hospital, HUSLAB, Helsinki, Finland; [4]University of Helsinki, Helsinki University Hospital, Department of Obstetrics and Gynecology, Helsinki, Finland

Background
Combined oral contraceptives (COC) are known to have multiple beneficial effects besides contraception, but also cause some unwanted health outcomes. They interfere, for example, with metabolism, inflammation, hepatic protein synthesis and blood coagulation. COCs containing natural estrogens have recently been developed, yet little is known about their non-contraceptive effects compared to conventional COCs with ethinyl estradiol (EE). The aim of this study was to compare the impacts of COCs containing EE or estradiol valerate (EV) and dienogest (DNG) alone on the serum proteome.
Methods and findings
Fifty-nine healthy women participated in a randomized, controlled clinical trial. They were allocated to use either EE + DNG, EV + DNG or DNG alone continuously for nine weeks. Serum samples were collected before and after nine weeks of exposure. Samples from 44 women were available for this analysis (EE + DNG $n = 14$, EV + DNG $n = 16$ and DNG $n = 14$). Changes in serum proteins were analyzed using quantitative label-free proteomics. Altogether, 514 different proteins were detected. Number of proteins that changed within the study groups were 145 for EE + DNG, six for EV + DNG and zero for DNG-only preparation. Significant change between the groups was detected in 70 proteins, of which 64 were detected between the EE + DNG and EV + DNG groups. Most affected pathways were the complement system, acute phase response signaling, metabolism related LXR&FXR/RXR activation, and the coagulation system.
Conclusions
The COC containing EE exerts a broader effect on serum proteome compared with EV combination or DNG-only preparation. These results signal a need for further studies comparing the clinical health outcomes between COCs containing EE and natural estrogens.

HPA axis modulation by a potent inhibitor indicates 11β-hydroxy-steroid dehydrogenase type 1 (HSD-1) is a main source of cortisol that can bind intracellular receptors

David Katz[1] & Mark Mortier[2]
[1]Sparrow Pharmaceuticals, Portland OR, United States; [2]Emanate Biostats, Carlsbad CA, United States

Background
HSD-1 converts cortisone to cortisol in tissues in which cortisol excess is associated with morbidity including liver, adipose, bone, and brain. SPI-62 is a potent HSD-1 inhibitor in clinical development for treatment of Cushing's syndrome and autonomous cortisol secretion, and as adjunctive therapy to prednisolone in polymyalgia rheumatica. In Phase 1 clinical trials SPI-62 was generally well tolerated and associated with maximal liver and brain HSD-1 inhibition.
Methods
We analyzed multiple dose trial[1] data to characterize the contribution of HSD-1 to cortisol that can bind to intracellular receptors and HPA/HPG axis modulation by SPI-62. Data from subjects who received SPI-62 doses that achieved maximal liver HSD-1 inhibition were combined for analysis. ANCOVA models with treatment effect and baseline covariate were conducted; statistics are least squares mean [standard error].
Results
Compared to placebo ($n = 10$), single SPI-62 doses ($n = 40$) were associated with 24-hour urinary tetrahydrocortisol (2.27[0.134] v 4.44[0.269] mmol) and allotetrahydrocortisol (2.98[0.146] v 4.80[0.291] mmol) decreases, and tetrahydrocortisone (32.71[1.149] v 9.19[2.300] mmol) increase. Serum cortisol was decreased at 2-hours (152.2[11.64] v 226.6[24.00] nM) but not 4- or 12-hours post-dose. ACTH was increased at 4- and 12-hours (45.6[1.64] v 32.1[3.29]; 38.5[1.67] v 26.3[3.33] pg/ml) but not 2-hours post-dose. After 14 daily doses, SPI-62 was

associated with 24-hour urinary tetrahydrocortisol (2.05[0.154] v 4.36[0.321] mmol), allotetrahydrocortisol (2.75[0.181] v 4.13[0.377] mmol), and tetrahydrocortisone (42.73[1.968] v 8.51[0.410] mmol) changes. ACTH was increased at predose and 2-, 4-, and 12-hours post-dose (45.6[1.71] v 27.0[3.61]; 45.3[1.79] v 35.2[3.72]; 34.4[1.71] v 18.8[3.57]; 47.3[2.13] v 30.4[4.45] pg/ml). No differences on urinary cortisol or cortisone, serum cortisone, or CRH were observed after single or multiple doses. After multiple doses, SPI-62 was associated with increased DHEA-S (342.2[9.94] v 155.0[20.52] mg/dl) and, in females, testosterone (2.1[0.11] v 1.4[0.25] nM). No differences on aldosterone, estradiol, FSH, LH, progesterone, or SHBG were observed.

Discussion

SPI-62 resulted in ~40-50% decreases of urinary cortisol metabolites which indicate similar decrease of hepatocellular cortisol. Following a corresponding decrease, circulating cortisol homeostasis was restored rapidly by ACTH increase. Urinary cortisol was unaffected. SPI-62 is associated with moderate androgen increases that, to date, appear not associated with adverse effects. As HSD-1 contributes much of the intracellular cortisol that can access intracellular receptors, we hypothesize that HSD-1 inhibitors are potential treatments for conditions of cortisol excess such as Cushing's syndrome and autonomous cortisol secretion.

Age- and gender-specific cut-off levels may improve DHEAS as a marker for suppressed HPA-axis

Shobitha Puvaneswaralingam[1] & Henrik Olsen[2]

[1]Department of Endocrinology, Skånes University Hospital, Lund, Sweden; [2]Department of Endocrinology, Clinical Sciences, Lund University, Lund, Sweden

Background

Low levels of DHEAS, such as <1.04 µmol/l, have been used as a criterion for autonomous cortisol secretion (ACS) in patients with adrenal incidentalomas. Age- and gender-specific cut-off levels could theoretically improve DHEAS as a marker of HPA-axis suppression and as a criterion for ACS.

Objective

We aimed to find cut-off levels of DHEAS that are best associated with HPA-axis suppression and determine whether they are correlated with clinical outcomes.

Methods

We studied 989 patients with adrenal incidentalomas, investigated between 2005 and 2015 at two hospitals in southern Sweden and followed up for 14 years. Patients were divided into 10 groups according to age, separated as age <50, 50-<60, 60-<70, 70-<80 or ≥ 80 years, and gender.

Results

In patients with ACTH <2.0 pmol/l, DHEAS was <1.04 µmol/l in 0, 14, 10, 22, and 33% of males and in 40, 26, 46, 50, and 100% of females in the described age groups. Therefore, the sensitivity for HPA-axis suppression may be low in males, and females <60 years. ACTH was not related to age in males or females. Therefore, we studied DHEAS levels below the 25th percentile as a marker of HPA-axis suppression. The levels for the different age groups were <2.50, <2.10, <1.20, <0.93, and <0.81 µmol/l in males and <1.10, <1.00, <0.81, <0.81, and <0.81 µmol/l in females and were termed "low DHEAS". The odds ratio for cortisolDST ≥ 50 nmol/l was higher for low DHEAS than DHEAS <1.04 µmol/l in males, 1.92 (1.17-3.14) vs 1.59 (0.92–2.76), but was similar in females, 1.73 (1.19-2.51) vs 1.67 (1.17-2.38), adjusted for age. Low DHEAS was associated with pre-existing cardiovascular disease, odds-ratio 1.63 (1.14-2.33) and mortality, relative risk 1.57 (1.14-2.18), both adjusted for gender, age, and smoking.

Conclusion

Age-specific DHEAS is a more appropriate marker of HPA-axis suppression in men but seems not to perform better in females. Furthermore, the proposed age- and gender-specific cut-off levels were associated with pre-existing cardiovascular disease and increased mortality.

Steroidomic approach for the characterization of patients with non-alcoholic fatty liver disease

Mirko Parasiliti Caprino[1], Chiara Rosso[2], Federico Ponzetto[1], Gian Paolo Caviglia[2], Chiara Lopez[1], Angelo Armandi[2], Giorgio Maria Saracco[2], Ezio Ghigo[1], Elisabetta Bugianesi[2] & Mauro Maccario[1]

[1]University of Turin, Endocrinology, Diabetes and Metabolism, Turin, Italy; [2]University of Turin, Unit of Gastroenterology, Turin, Italy

Introduction

The onset and progression of liver damage in non-alcoholic fatty liver disease (NAFLD) is tightly associated with metabolic derangements. Steroids may affect lipid metabolism but their alterations in the setting of NAFLD remain to be fully explored.

Patients and Methods

We analyzed data from 121 patients with biopsy-proven NAFLD and 108 controls (CT). A panel of 26 steroids (including glucocorticoids, mineralocorticoids, androgens, and progestogens as well as representative glucuro- and sulphoconjugated metabolites) were measured on plasma samples by liquid chromatography coupled to mass spectrometry (LC-MS/MS). Severe hepatic fibrosis was defined by $F \geq 3$.

Results

Compared to CT, NAFLD patients were older (median age 51 vs 43, $P<0.001$) and were characterized by a higher rate of MS (47% vs 2%, $P<0.001$). More than a half of steroids were deregulated in patients compared to CT. At liver histology, the prevalence of absent/mild, moderate, and severe fibrosis was 50.4%, 10.8% and 38.8%, respectively. Circulating levels of 16 compounds showed a significant stepwise decrease according to the degree of hepatic fibrosis. At univariate analysis, testosterone, and its derivatives, androsterone metabolites, etiocholanolone metabolites and glicoandrogens metabolites were differentially expressed in patients with severe fibrosis compared to those with absent/moderate fibrosis. After multivariable logistic regression analysis adjusted for age, gender and type 2 diabetes, epitestosterone sulphate, 5α-androstan-3α,17β-diol-3-glucuronide and androsterone sulphate levels were significantly associated with $F \geq 3$. The diagnostic accuracy of the model for the identification of $F \geq 3$ was 0.91 with a sensitivity and specificity of 87% and 85 %, respectively, and with a positive and negative predictive value of 78% and 91%, respectively.

Conclusions

In NAFLD patients, alterations in androgens and their glucuro- and sulphoconjugated metabolites levels could be expression of compromised 1) liver steroidogenesis or 2) liver steroid homeostasis regulation and are strongly associated with severe fibrosis. This research has been supported by the Italian MIUR under the programme "Dipartimenti di Eccellenza 2018-2022", project code D15D18000410001.

Analysis of the body composition and glucose metabolism in relation to bcli glucocorticoid receptor polymorphism in women with adrenal incidentalomas

Sanja Ognjanovic, Bojana Popovic, Dusan Ilic, Valentina Elezovic, Jadranka Antic, Milica Opalic[1], Lena Radic & Djuro P Macut

Clinic for Endocrinology, Diabetes and Metabolic Diseases, University Clinical Centre of Serbia, Department for Endocrine Tumors and Hereditary Cancer Syndromes, Belgrade, Serbia

Single nucleotide polymorphisms in the glucocorticoid receptor (GR) gene influence tissue sensitivity of GR. Several studies have shown different effects of *Bcl*I GR polymorphism on body composition and metabolic parameters. The objective of this study was to explore the effect of *Bcl*I GR polymorphism on the body composition and glucose metabolism. Biochemical tests and hormonal evaluation were performed in 106 consecutive women with adrenal incidentalomas (AIs). Non-diabetic patients underwent an oral glucose tolerance test with 75 g glucose. Body composition was measured with dual-energy X-ray absorptiometry. DNA was obtained from peripheral blood leucocytes. The polymorphism was detected using PCR, RFLP and DNA sequencing. We observed no differences in mean age (57 ± 9.6 vs 56.5 ± 11.8, $P=0.823$), percent of postmenopausal women (76% vs 7%, $P=0.550$), and prevalence of metabolic syndrome (31.9% vs 21.3%, $P=0.158$) between carriers of the C allele of *Bcl*I polymorphism and non-carriers. *Bcl*I carriers have lower prevalence of impaired glucose tolerance (2.6% vs 17.5%, $P=0.031$), type 2 diabetes mellitus (T2DM) (9.1% vs 26%, $P=0.034$), and reduced glucose area under the curve, the mean difference of 2.62 (95% CI, 1.11-4.14), $P=0.001$. *Bcl*I carriers have a tendency towards lower lean body mass (41.7 ± 6.9 vs 44.1 ± 5.7, $P=0.08$) and a significantly higher percentage of legs fat (43.36 ± 5.75 vs 39.84 ± 7.6, $P=0.020$). *Bcl*I polymorphism was significantly associated with sum of legs fat mass (FM) percentage ($\beta=0.327$, $P=0.048$). Also, subjects with greater legs/trunk FM ratio had higher odds to be *Bcl*I carriers, OR 1.046 (95% CI, 0.046-23.565, $P=0.045$). Logistic regression analysis showed that presence of T2DM was significantly negatively correlated with *Bcl*I polymorphism after adjusting for

possible confounding factors such as age, truncal FM, appendicular lean mass index, and legs fat sum (OR = 0.158, 95%CI 0.031-0.806, $P = 0.027$). *Bcl*I carriers predispose to increased legs fat mass and greater legs/trunk FM ratio indicating reduced sensitivity to GC, which could explain why some women with AIs preserve more gluteo-femoral subcutaneous adipose tissue with beneficial effects on glucose metabolism.

Skeletal muscle mass in patients with adrenal incidentaloma

Giacomo Colombin[1,2], Giulio Vara[1,2], Flaminia Fanelli[2,3], Matteo Magagnoli[2,3], Lorenzo Tucci[1,2], Kimberly Coscia[1,2], Cristina Mosconi[1,2], Uberto Pagotto[1,2], Valentina Vicennati[1,2] & Guido Di Dalmazi[1,2]

[1]S. Orsola-Malpighi Polyclinic, Bologna, Italy; [2]Alma Mater Studiorum - Università di Bologna, Bologna, Italy; [3]CRBA, Bologna, Italy

Background and aim

The relationship between sarcopenia and overt cortisol excess as in Cushing's syndrome is well-known. However, only a few studies investigated the relationship between autonomous cortisol secretion (ACS) in adrenal incidentalomas and skeletal muscle mass. The aims of our study were to analyze the skeletal muscle mass in patients with adrenal incidentalomas and to investigate the correlations with hormonal data.

Methods

We enrolled 200 adult patients (>18 years) without clinical signs of Cushing syndrome, bearing monolateral and bilateral benign adrenal incidentaloma detected at CT scan. We classified the adrenal tumors as non-secreting (NS) or ACS according to cortisol levels after 1-mg dexamethasone suppression test (DST) < or >50 nmol/l, respectively. Skeletal muscle mass was evaluated by Skeletal Muscle index (SMI) through a threshold segmentation (-19HU – +150HU) of the Skeletal Muscle Area on an L3 slice of the basal acquisition, subsequently divided by the height squared. Subjects underwent measurement of an 11-steroid profile in serum by Liquid Chromatography-Tandem Mass Spectrometry (LC-MS/MS).

Results

SMI was lower in ACS than NS subjects (40.6 ± 1.2 vs 44.2 ± 1.2; $P = 0.007$). Accordingly, the prevalence of sarcopenia was higher in ACS than NS patients (59.4% vs 39.6%; $P = 0.012$). Similar results were confirmed after analyzing the data separately by sex. Overall, we identified correlations between SMI and age ($r = -0.34$; $P < 0.001$), body mass index (BMI) ($r = 0.39$; $P < 0.001$), basal cortisol ($r = -0.155$; $P = 0.041$) and post-DST cortisol ($r = -0.180$; $P = 0.018$). When analyzed separately by sex, similar correlations were confirmed in males, whereas only the correlations between SMI and basal cortisol, age, and BMI were observed in post-menopausal women. Additionally, in post-menopausal women, SMI was associated positively with DHEAs levels ($r = 0.318$; $P = 0.004$) and negatively with corticosterone ($r = -0.259$; $P = 0.007$). Multivariable analysis by generalized linear model (GLM) showed a positive correlation between SMI and BMI (B = 0,009; 95% C.I. 0.005 - 0.013; $P < 0.001$), independently of age ($P = 0.205$) and post-DST cortisol ($P = 0.078$) in males. In post-menopausal females, GLM highlighted an independent correlation between SMI and DHEAs levels (B = 0.036; 95% C.I. 0.005-0.068; $P = 0.024$), with an independent contribution of BMI (B = 0.004; 95% C.I. 0.002-0.007; $P = 0.001$) and age (B = -0.002; 95% C.I. -0.004-0.000; $P = 0.017$).

Conclusions

ACS is associated with impaired skeletal muscle mass, despite patients may not report symptoms of sarcopenia. A differential hormonal contribution to impaired skeletal muscle mass has been identified according to sex.

Mild autonomous cortisol secretion in patients with adrenal incidentalomas and raised cardiovascular risk

Rebecca Sagar[1], Sheila Fraser[2], Emma Collins[2], Russell Frood[2], Andrew Scarsbrook[2], Paul M Stewart[1,3] & Afroze Abbas[1]

[1]Leeds Teaching Hospitals Trust, Leeds Centre for Endocrinology and Diabetes, Leeds, United Kingdom; [2]Leeds Teaching Hospitals Trust, Leeds, United Kingdom; [3]University of Leeds, School of Medicine, Leeds, United Kingdom

Background

Adrenal incidentalomas are common and require investigation to exclude malignancy and evidence of hormone overproduction. Clinical guidelines recommend overnight dexamethasone suppression tests (ONDST) to assess for cortisol hypersecretion with cortisol levels of 50-138 nmol/l termed "mild autonomous cortisol secretion" (MACS). MACS may be associated with both cardiovascular and metabolic morbidity. We assessed cardiovascular risk in patients with MACS using QRISK3. This is a validated algorithm used in the UK to predict cardiovascular risk, calculating a predicted percentage risk of myocardial infarction (MI) or stroke over the next 10 years.

Methods

Data were collected retrospectively on patients over a two-year period, who had an adrenal incidentaloma with a cortisol between 50-138 nmol/l following ONDST. Presence of cardiovascular co-morbidities including hypertension, type 2 diabetes mellitus (T2DM), atrial fibrillation and ischaemic heart disease (IHD) was recorded. Relative Risk (RR) of cardiovascular disease (MI or stroke) was calculated using the QRISK3. Statistical analysis was conducted using PRISM v9.3.1.

Results

228 patients (50% male), mean age 69 years ± 11.4 (SD), mean BMI 30.5 kg/m^2 ± 15.1 were identified with MACS. 79.8% of patients had a diagnosis of hypertension with 62% on more than one anti-hypertensive medication. 73% of patients were on statin therapy. 34.5% of patients had a diagnosis of T2DM. 27.1% of patients had ischaemic heart disease and 8% had congestive cardiac failure. Mean QRISK3 score was 26.7 ± 13%, compared with 16.6 ± 10% in age/sex matched healthy controls as per the QRISK3 algorithm. Relative risk for MI or stroke was 2.2 compared to the healthy age/sex matched controls. 88% of the cohort had a relative risk >1. There was no clear correlation between radiological characteristics and QRISK.

Conclusions

Amongst our unselected cohort of patients with adrenal incidentalomas and biochemistry consistent with MACS, there was high prevalence of hypertension, T2DM and IHD compared with the background population. Additionally cardiovascular QRISK-3 demonstrated this patient cohort had >2 times the likelihood of having an MI or stroke within the next 10 years compared with healthy age and sex matched people. Although the data suggests an association, it is possible other confounders such as BMI may influence both ONDST results and CV risk. CV risk assessment should be considered in all patients with an adrenal incidentaloma and MACS.

An observational retrospective study on the association of urine metanephrine levels with cardiometabolic risk in patients with nonfunctioning adrenal incidentaloma

Maria Chiara Di Carlo[1], Mirko Parasiliti Caprino[1], Chiara Lopez[1], Martina Bollati[1], Fabio Bioletto[1], Chiara Sola[1], Federico Ponzetto[1], Iacopo Gesmundo[1], Fabio Settanni[2], Ezio Ghigo[1], Giulio Mengozzi[2], Mauro Maccario[1] & Roberta GIORDANO[1]

[1]University of Turin, Endocrinology, Diabetes and Metabolism, Turin, Italy; [2]University of Turin, Clinical Biochemistry Laboratory, Turin, Italy

Background

Several studies argued that the cardiovascular evaluation of patients with nonfunctioning adrenal incidentaloma is of particular importance, even if a direct association seems difficult to underline.

Objective

We aimed to evaluate the possibility of stratifying cardiometabolic risk through metanephrine levels in patients with incidentally discovered nonfunctioning adrenal adenoma.

Design

In this retrospective cross-sectional study, we collected data of metanephrine levels in 828 patients with nonfunctioning adrenal incidentaloma, referred to the Division of Endocrinology, Diabetes and Metabolism of the University Hospital of Turin between September 2007 and September 2021.

Results

The univariate analysis showed associations between urine metanephrines and cardiometabolic variables/parameters, particularly considering the noradrenaline metabolite. At univariate regression, normetanephrine was associated with

metabolic syndrome (OR = 1.13, 95% CI 1.05-1.22; $P = 0.002$), hypertensive cardiomyopathy (OR = 1.09, 95% CI 1.01-1.18; $P = 0.026$), microalbuminuria (OR = 1.14, 95% CI 1.00-1.25; $P = 0.024$), and with eGFR < 60 ml/min/1.73 m^2 (OR = 1.11, 95% CI 1.02-1.19; $P = 0.013$), while metanephrine was associated with microalbuminuria (OR = 1.50, 95% CI 1.11-1.85; $P = 0.008$). At multivariate regression, considering all major cardiovascular risk factors as possible confounders, normetanephrine retained a significant association with metabolic syndrome (OR = 1.10, 95% CI 1.01-1.19; $P = 0.037$). Moreover, metanephrine retained a significant association with the presence of microalbuminuria (OR = 1.66, 95% CI 1.21-2.98; $P = 0.003$).

Conclusions

The present study demonstrated a further role for metanephrines in the cardiovascular risk stratification of patients with nonfunctioning adrenal incidentaloma. Individuals with high levels of these indirect markers of sympathetic activity should be carefully monitored and may benefit from an aggressive treatment to reduce their additional cardiometabolic burden.

Gut dysbiosis in patients with cushing's syndrome in remission. relationship with cardiometabolic risk

Elena Valassi[1,2,3], chaysavanh Manichanh[4] , Luciana Maria Martel Duguech[5], Pedro González Fernández[6], Sonia Gaztambide[3,6], Manel Puig-Domingo[3,7,8] & Susan Webb Youdale[3,9,10]

[1]Hospital Germans Trias i Pujol and Research Institute, Endocrinology, Badalona, Spain; [2]Universitat Internacional de Catalunya (UIC); [3]Centro de Investigación Biomédica en Red (CIBERER); [4]Gut Microbiome Group, Vall d'Hebron Institut de Recerca (VHIR), Barcelona, Spain; [5]Hospital Sant Pau, Barcelona, Spain; [6]Hospital Cruces, Endocrinology, Bilbao, Spain; [7]Hospital Germans Trias i Pujol and Research Institute, Badalona, Spain; [8]Universitat Autònoma de Barcelona, Barcelona,; 9Hospital Sant Pau, Barcelona, Spain; [10]Universitat Autònoma de Barcelona, Barcelona, Spain

Background

Patients with Cushing's syndrome (CS) in remission show residual cardiometabolic derangements leading to increased cardiovascular risk. Impaired characteristics of gut microbiome (dysbiosis), such as richness, diversity and composition, have been associated with several cardiometabolic risk factors, including obesity, insulin resistance and atherosclerosis. Whether CS patients present with intestinal dysbiosis is currently unknown. Our study was aimed at evaluating the relationship between the characteristics of gut microbiome and both body composition indexes and cardiometabolic risk factors in "cured" CS.

Methods

Twenty-seven female non-diabetic patients with CS in remission [mean (±SD) age, 51±9 years, mean (±SD) BMI, 26±3.8, median (IQR) duration of remission, 11(4) years] and 27 gender-, age-, and BMI-matched controls were included. Genomic DNA was extracted from fecal samples. The V4 region of the bacterial 16S rDNA was amplified by PCR, and sequencing was applied to analyze microbial richness (alpha diversity; Chao 1 index, observed number of species, effective Shannon index) and microbial community structure (beta diversity analysis through the Principal Coordinates Analysis (PCoA) of weighted and unweighted UniFrac distances). Inter-group difference in microbiome composition was analysed using ANCOM (Analysis of Composition of Microbiomes), a plugin from the QIIME2 pipeline. Lipid and coagulation profiles, fasting glycemia and fasting insulin were assessed using standard assays. Body composition was measured using dual-energy x-ray absorptiometry (DXA).

Results

The Chao 1 index was significantly lower in CS patients as compared with controls (Kruskal-Wallis test, q = 0.002), indicating that the former had lower microbial richness. Beta diversity analysis showed that fecal samples from CS patients clustered together and separated from the control samples (Adonis test, $P < 0.05$). The Analysis of Composition of Microbiomes showed that several microbial groups at phylum, family, order and genus categories were associated with CS. In particular, *Collinsella*, a form genus of the Actinobacteria phylum, was present in all CS patients but not in controls. In CS, the Chao 1 index was associated with fibrinogen levels ($\rho = 0.44$; $P = 0.034$), and inversely correlated with both triglyceride concentrations ($\rho = -0.48$; $P = 0.035$) and the HOMA-IR index ($\rho = -0.45$; $P = 0.038$).

Conclusions

Patients with CS in remission have gut microbial dysbiosis with decreased microbiota richness and diversity, and specific variations in the bacterial community structure. Dysbiosis in CS may be one of the mechanisms whereby cardiometabolic dysfunctions persist after "cure".

Long-term thyroid complications in haematological cancer survivors following systemic chemotherapy, neck radiotherapy and/or haematopoietic stem cell transplantation

Francesco Carlomagno, Christopher Nardi, Alessandra Tomaselli, Carla Pandozzi, Paola Mazzotta & Daniele Gianfrilli

Sapienza University of Rome, Dept. of Experimental Medicine, Roma, Italy

Introduction

With the increasing survival rates from cancer the focus has been shifting towards the adverse sequelae, occurring both acutely, or developing as late effects, deriving from its multimodality treatment.

Aim

We investigated the occurrence of thyroid complications in patients with haematological malignancies treated with chemotherapy, radiotherapy involving the neck and/or haematopoietic stem cell transplantation (HSCT), referred to our endocrine sequelae clinic over the course of 20 years.

Patients and Methods

We prospectively enrolled 343 patients (172 females, 50.1%), with median age at diagnosis of 17 years (range: 1-76), and median follow-up of 12.4 years. Diagnoses were similarly distributed across: acute myeloid leukaemia, acute lymphoblastic leukaemia, chronic myeloid leukaemia, Hodgkin's lymphoma, non-Hodgkin's lymphomas, myelodysplastic syndromes and multiple myeloma. All patients underwent systemic chemotherapy, radiotherapy involving the neck was needed in 103 patients and 208 subjects received HSCT. We investigated the occurrence of: overall thyroid complications, transient and permanent thyroid dysfunction, low T3 syndrome, thyroid autoimmunity, benign and malignant thyroid nodules using Kaplan-Meier survival analyses and Cox proportional hazards models with bootstrapping.

Results

Overall 58.7% of patients experienced thyroid complications, with a median latency time of 3.7 years. Primary hypothyroidism was encountered in 15.6% and transient hypothyroidism in 6.3% of patients; Cox regression revealed female sex ($P = 0.008$), adult age ($P = 0.035$) and radiotherapy ($P < 0.001$) as independent predictors. Low T3 syndrome was diagnosed in 10.1% of patients, and female sex and radiotherapy were independent predictors ($P = 0.027$ and 0.009, respectively). Transient hyperthyroidism was found in 2.1%, mostly after neck radiotherapy. Thyroid autoimmunity was encountered in 32%, and adult age at diagnosis (> 18 years) was the only independent predictor ($P = 0.028$). Thyroid nodules were encountered in 41.1%, with adult age at diagnosis as the only independent predictor ($P = 0.032$); 5 patients were diagnosed with papillary thyroid carcinomas. With regards to overall thyroid complications, female sex and adult age at diagnosis were associated with the highest risk ($P < 0.001$ and 0.001, respectively). Neck radiotherapy was associated with an increased risk of complications after a median of 18 years, whereas HSCT was not, after multiple adjustments.

Conclusions

Thyroid comorbidities are highly prevalent among patients treated for haematological malignancies, with specific associations with treatment modality, requiring long-term endocrine follow-up.

Prevention of glucocorticoid-induced adipose dysfunction and hepatic lipid deposition through cold acclimation in aged mice

Manuel Gado[1], Zahra Ghane[1], Annett Heinrich[1], Denise Wiedersich[1], Stefan R Bornstein[2,3,4,5], Martina Rauner[1,2], Lorenz C Hofbauer[1,2] & Holger Henneicke[1,2]

[1]Center for Regenerative Therapies Dresden, Technische Universität Dresden, Dresden, Germany, Dresden, Germany; [2]Medizinische Klink III, Universitätsklinikum Carl Gustav Carus, Technische Universität Dresden, Dresden, Germany; [3]Division of Diabetes & Nutritional Sciences, Faculty of Life Sciences & Medicine, King's College London, London, United Kingdom; [4]University Hospital Zurich, Department of Endocrinology and Diabetology, Zurich, Switzerland; [5]Paul Langerhans Institute Dresden (PLID) of the Helmholtz Center Munich at Universitätsklinikum Carl Gustav Carus and Faculty of Medicine at Technische Universität Dresden, Dresden, Germany

Glucocorticoids (GC) are one of the most potent anti-inflammatory pharmacological agents. However, owing to their pleiotropic nature, their clinical effectiveness is frequently limited by their deleterious off-target effects. Frequently, metabolic abnormalities arise from GC excess involving the

development of dyslipidaemia, insulin resistance and muscle atrophy as well as excessive fat accumulation in both white adipose tissue (WAT) and the liver. In addition, suppressed thermogenic capacity in brown adipose tissue (BAT) has been observed during GC excess in rodents. Cold exposure is an established activator of sympathetic innervation of BAT triggering adaptive thermogenesis and lipid utilisation in BAT as well as WAT. Therefore, our investigation aimed to characterize the interaction between cold-induced thermogenesis and systemic GC excess on the adipose organ. To this end, we treated 32-week-old mice with corticosterone at either 29°C (thermoneutrality) or 13°C (cold temperature). Following 6 weeks of treatment, mice housed at 29°C gained more weight than their temperature-matched controls, which was coupled with excessive accumulation of white fat and consecutive adipocyte hypertrophy. Interestingly, mice maintained in the 13°C environment were protected from GC-driven obesity as well as adipocyte hypertrophy in WAT. Interestingly, the thermogenic capacity, as well as the sympathetic innervation of BAT, was partially preserved in mice maintained at 13°C in spite of corticosterone treatment, whereas mice housed at 29°C showed a considerable reduction in BAT thermogenic capacity and number of sympathetic nerve endings following GC excess. Moreover, treatment with corticosterone at 29°C resulted in increased hepatic lipid accumulation, while livers from mice maintained in the cold showed markedly fewer lipid deposits. On the systemic level, cold adaptation of mice partially prevented the development of GC-induced hyperinsulinemia and hyperleptinemia, both of which were readily observed at 29°C. Taken together, our data demonstrate that prolonged cold exposure prevents the onset of not only GC-induced adipose dysfunction but also related metabolic comorbidities including steatosis of the liver and hyperinsulinemia. Thus, activation of adaptive thermogenesis may be a potential therapeutic target for the prevention of GC-induced metabolic dysfunction.

Can early postoperative hypocalcemia be predicted preoperatively in patients operated with minimally invasive technique for primary hyperparathyroidism ?

Fatma Dilek Dellal Kahramanca[1], Esra Çopuroğlu[2], Beril Turan Erdogan[1], Husniye Baser[2], Didem Ozdemir[2], Oya Topaloglu[2], Reyhan Ersoy[2] & Bekir Cakir[2]
[1]Ankara City Hospital, Endocrinology and Metabolism, Ankara, Turkey; [2]Ankara Yildirim Beyazit University, Faculty of Medicine, Endocrinology and Metabolism, Ankara, Turkey

Aim
Postoperative hypocalcemia is seen in 26-42% patients after parathyroidectomy.There are quite a lot of studies investigating preoperative factors that might be used to predict postoperative hypocalcemia in thyroidectomized patients, however there are less studies in parathyroidectomized patients.In this study, our aim was to determine whether any preoperative clinical, laboratory or ultrasonographical feature anticipate hypocalcemia in parathyroidectomized patients due to primary hyperparathyroidism (PHPT).
Material and Methods
All patients operated for PHPT between 2019–2022 were retrospectively evaluated.Patients undergoing minimally invasive parathyroidectomy were enrolled.Demographic, clinical, ultrasonography and histopathology results were noted and compared in patients with and without hypocalcemia (Group-1 and Group-2,respectively) within two days after surgery.
Results
Of 179 parathyroidectomized patients, 93 were operated with minimally invasive procedure. Postoperative hypocalcemia was observed in 21 (22.6%) patients.Group-1 was younger compared to Group-2 ($P=0.036$).Gender distribution and presence of osteoporosis were comparable.Nephrolithiasis was less prevalant in Group 1 ($P=0.046$).Preoperative levels of corrected calcium, phosphorus, magnesium, parathyroid hormone, alkaline phosphatase, 25 OH vitamin D were similar in two groups. Fractional excretion of calcium (FECa) was lower in group-1 ($P=0.048$).The optimal cut-off level of FECa that was predictive for postoperative hypoprathyroidism was 0.0216 with a sensitivity of 61.9% and specificity of 54.9% (AUC 0.643 ± 0.062, $P=0.048$).Ultrasonographic and histopathologic diameters and volumes of parathyroid lesions were not different in both groups ($p>0.05$ for all).Histopathological diagnosis was parathyroid adenoma in 76 (64.5%) patients, parathyroid hyperplasia in 9 (9.7%) patients, and cell-rich parathyroid gland in 8 (8.6%) patients.The distribution of the histopathological results were similar in two groups($P=0.750$).
Conclusions
Younger patients, patients with lower FECa and without nephrolithiasis undergoing minimally invasive parathyroidectomy for PHPT might require closer follow-up for the development of postoperative hypocalcemia. FECa lower than 0.0216 might help to predict occurrence of postoperative hypocalcemia.

Sequential primary adrenocortical culture system for genetic transformation and adrenocortical tumorigenesis using CRISPR/Cas9-mediated genome editing

Carmina Teresa Fuss[1], Oliver Hartmann[2], Michaela Reissland[2], Nikolett Pahor[2] , Laura-Sophie Landwehr[1], Martin Fassnacht[1] & Markus E Diefenbacherc[2]
[1]Division of Endocrinology and Diabetes, University Hospital, University of Würzburg, Germany; [2]Protein Stability and Cancer Group, Department of Biochemistry and Molecular Biology, University of Würzburg, Germany

Adrenocortical carcinoma (ACC) is a rare malignancy with an incidence of 0.7–2.0 per million per year. Prognosis of ACC is generally poor but variable and therapeutic approaches are scarce. While surgical resection presents the best option for definitive cure, mitotane remains the only approved drug for adjuvant therapy in ACC to date. Advancements regarding novel treatment strategies as well as fostered understanding of potential drivers of adrenocortical carcinogenesis have been limited by the lack of tumour models reflecting genetic disease heterogeneity. Currently available cell culture and mouse models for ACC only comprise single patient derived cell lines, corresponding mouse xenograft models and few conventional genetically engineered mouse models mainly targeting components of the Wnt-signaling pathway. To overcome this gap, we developed a workflow for culturing adrenocortical cells from C57BL/6-WT, and C57BL6/J$^{6Rosa26Sor\text{-}CAGG\text{-}SpCas9\text{-}IRES\text{-}eGFP}$ mice. After isolation and longitudinal

culture of murine adrenal cortices, we performed LC-MS/MS based steroid hormone analyses in supernatant showing sustained secretion of aldosterone (day 7: 1535 ± 697 ng/l), corticosterone (day 7: 1111 ± 123 µg/l), 11-deoxycorticosterone (day 7: 74 ± 14 µg/l) and progesterone (day 7: 9 ± 2 µg/l). Furthermore, qRT-PCR of adrenal targets showed mRNA expression of several steroidogenic enzymes e.g. HSD3B2, HSD11B1, CYP11A1, CYP11B1 and CYP11B2, as well as SF-1, StAR and SCARB1. After confirmation of adrenocortical origin, cultured cells were immortalized via CRISPR/Cas9-mediated targeting of *Trp53*. This *ex vivo* setup holds the potential to study adrenal cell homeostasis and biology, and will allow us to replicate oncogenic transformation of adrenocortical cells using CRISPR/Cas9-mediated genome editing. It presents starting point for the development of versatile and clinically relevant isogenic mouse models for adrenocortical tumours.

Calcitonin washout in the diagnosis of medullary thyroid cancer

Berna Evranos Ogmen, Nurcan Ince, Leyla Akdogan, Aysegul Aksoy Altınboga, Cevdet Aydin[1], Oya Topaloglu, Reyhan Ersoy & Bekir Cakir
Ankara Şehir Hastanesi, Ankara, Turkey

Background
Medullary thyroid cancers (MTC) originate from parafollicular C cells and constitute 3-5% of all thyroid cancers. Calcitonin (CT) measurement is useful in the diagnosis of MTC. The sensitivity and specificity of CT are low in the measurement alone, and the sensitivity and specificity increase when used with pentagastrin and calcium stimulation tests. However, the difficulty of accessing pentagastrin, the uncertainty of the cut-off value in calcium stimulation tests, the differences in calcitonin assay and the costs complicate the use of serum CT and stimulation tests in the diagnosis. For this reason, guidelines do not offer opposing or supportive recommendations about the routine measurement of CT in patients with thyroid nodules. In this study, we aimed to investigate the contribution of CT washout of the nodule (WO) to routine CT measurement for MTC diagnosis.
Methods
In our clinic for the last three years, calcitonin values have been routinely measured in patients with nodular thyroid disease. CT-WO is performed for the nodules of patients whose calcitonin values are still above the laboratory cutoff levels in repeated measurements after excluding confounding factors. CT-WO was implemented after the thyroid fine-needle aspiration biopsy specimen was spread on a slide. The remaining material was washed with 1 mL of saline, and then the CT level was measured. In this study, the results of 33 patients who were operated on will be presented.
Results
Papillary thyroid cancer (PTC) was found in 12 (36.4%), MTC in 14 (42.4%) and benign pathology in 7 (21.2%) of the patients. CT washout was performed on 69 nodules of these patients before surgery. According to the pathology reports, eleven of these nodules were PTC, 13 were MTC, and 45 were benign. PTC and MTC were detected incidentally in two separate patients. In patients with MTC, serum CT and CT-WO values were significantly higher than the other two pathology groups ($P=0.001$). ROC analysis was performed for serum CT value, and the level 29.9 determined MTC with 100% sensitivity and 90% specificity (AUC=0.975 (0.932-1), $P<0.001$). Also, ROC analysis was performed for the CT-WO values of the nodules, and level 413.5 determined MTC with 100% sensitivity and 86% specificity (AUC=0.987 (0.965-1), $P<0.001$). The median MTC diameter in the thyroidectomy specimens was 1 cm (0.6-5.5). Micro MTC was detected in 8 (61.5%) of the patients.
Conclusion
CT-WO appears to be useful in diagnosing MTC early and accurately.

Does the knowledge about type 2 diabetes mellitus is capable of interfering in adherence to self-care in patients?

Thielsen Cardoso da Silva[1], Laura Vilas Boas[1], Camila Alexandre Xavier[2], João Guilherme Bernart Sernajotto[3], Mariana Regina Rompkovski[4], Rafael Paulino Schuitek[5], Victória Chechetto Segalla[6] & Mirnaluci Paulino Ribeiro Gama[1]
[1]Evangelical Mackenzie Faculty of Parana, Brazil; [2]Universidade Federal do Paraná, Brazil; [3]Positivo University - Campus Ecoville, Brazil; [4]Federal University of Paraná, Brazil; [5]Positivo University, Brazil; [6]Pontifical Catholic University of Paraná, Curitiba Campus, Brazil

Introduction
Self-care plays a fundamental role in the treatment and prevention of complications of diabetes mellitus (DM). The patient knowledge about DM and its potential complications are among the factors that are associated with treatment adherence. The process of understanding the disease provides the patient better communication with professionals, better metabolic and psycho-social results which may influence on their emotional well-being and quality of life.
Objective
The present study aims to evaluate the patients' knowledge about DM 2 and adherence to self-care.
Methods
Analytical, observational, cross-sectional, descriptive study. Diabetic patients being monitored at the outpatient clinic were evaluated regarding their knowledge about DM and adherence to self-care through two questionnaires validated for the Brazilian population – Diabetes Knowlege Scale (DKN-A) and Self-Care Activity Questionnaire (QAD). The first is composed by 15 items about five major dimensions of knowledge in DM - basic pathophysiology, hypoglycemia, food groups and substitutions, complications, and general care with the disease. The second, has 6 dimensions and 15 assessment items related to self-care with diabetes (general diet, specific diet, physical activity, blood glucose monitoring, foot care, medication use, smoking).
Results
Sixty-one patients with DM2 participated in the study. In the QAD, patients' low adherence to daily self-care practices was observed, with the physical activity domain having the lowest adherence, followed by blood glucose monitoring. As for the results obtained in the DKN-A, it is noted that most reached a score equal to or greater than 8, suggesting satisfactory knowledge about the disease. The questions about food groups and substitutions were the ones with the lowest average of correct answers.
Conclusions
When analyzing the results obtained about the knowledge of diabetic patients about their disease, it is observed that the majority (67.2%) reached a score equal to or greater than 8, suggesting satisfactory knowledge about the disease. Despite this, the majority showed low adherence to the expected changes in lifestyle and self-care. Therefore, it is necessary to differentiate knowledge from the level of information - knowledge goes beyond the act of reproducing information, as it presupposes changes in attitudes, behaviors, and habits acquired throughout life. In this way, education about diabetes can be placed as one of the pillars for a satisfactory treatment, promoting a better quality of life for the patient and reducing the chances of complications.

Prognostic value of contralateral suppression on eGFR after surgery in primary aldosteronism

Jesper Krogh[1], Nathalie Voss[1], Claus Larsen Feltoft[2], Sara Mørup[1], Caroline Clausen[3] & Mikkel Andreassen[1]
[1]Rigshospitalet, Department of Endocrinology and Metabolism, Copenhagen, Denmark; [2]Herlev Hospital, Herlev, Denmark; [3]Rigshospitalet, Department of Radiology, Copenhagen, Denmark

Adrenalectomy for primary aldosteronism has been associated with post-surgical kidney failure. It has been proposed that elimination of excess aldosterone demask an underlying failure of the kidney function. Contralateral suppression (CLS) is considered an indication of aldosterone excess and disease severity and the purpose of this study was to assess the hypothesis that CLS would predict change in kidney function after adrenalectomy in patients with primary aldosteronism. We included patients diagnosed with primary aldosteronism referred for adrenal venous between May 2011 and August 2021 and who were subsequently offered surgical or medical treatment. A total of 138 patients were included and after adrenal venous sampling 85/138 (61.6%) underwent adrenalectomy while 53/138 (38.4%) were treated with MR-antagonists. Among surgically treated patients, 59/85 (69.4%) were classified as having CLS. In this patient group, eGFR was reduced by 17.5 (SD 17.6) ml/min/1.73 m^2 compared to an increase of 1.8 (SD 12.8) mL/min/1.73 m^2 in patients without CLS ($P<0.001$). The association between contralateral suppression and the change in kidney function remained unchanged in multivariate analysis. Post-surgery, 16/59 (27.1%) patients with CLS developed hyperkaliemia compared to 2/26 (7.7%) in patients without CLS ($P=0.04$).This retrospective study found that CLS is a strong and independent predictor of a marked reduction of eGFR and

an increased risk of hyperkalemia after adrenalectomy in patients with primary aldosteronism.

Insulin resistance prevents SHBG increase after VLCKD in non-diabetic obese male subjects

Valentina Annamaria Genchi, Angelo Cignarelli, Simona Di Leo, Fiorella Giordano, Eleonora Conte, Sebastio Perrini, Annalisa Natalicchio, Luigi Laviola & Francesco Giorgino
University of Bari, Department of Emergency and Organ Transplantation, Bari, Italy

Hepatocytes are both insulin sensitive and the primary site for synthesis of SHBG. Thus, it is possible that a condition of hepatic insulin resistance may impair hepatic synthesis of SHBG. In this study, we assessed SHBG circulating levels after 30 days of a very low-calorie ketogenic diet (VLCKD) based on high-biological value protein preparations diet (ISOMED) and natural food in a cohort of insulin-resistant obese male subjects. Moreover, we investigated the effects of exposure of different concentrations of glucose (5.5 mM, 10 mM, 30 mM) and human insulin (HI, 100 nM) on SHBG protein levels and analyzed the expression levels of insulin receptor (InsRec) in the hepatoma cell line HepG2. Twenty-two patients (mean age 39.3 $\pm$ 11.7 years, mean BMI 38.2 $\pm$ 6.4 kg/m^2) displayed fasting glycaemia within the normal range (77.5 $\pm$ 10.4 mg/dl), but elevated levels of insulin (29.3 $\pm$ 17.8 µIU/ml) and HOMA-IR (5.9 $\pm$ 3.7). Mean serum SHBG level was 20.3 $\pm$ 8.9 nmol/l at baseline. After VLCKD, a decrease of body weight (-9.3 $\pm$ 1.9 Kg), BMI (-3.0 $\pm$ 0.7 Kg/m^2), and fat mass (-6.4 $\pm$ 2.1 kg) ($P < 0.01$) was observed. A significant increase in serum SHBG levels ($+$ 7.7 $\pm$ 10 nmol/l) was also achieved after VLCKD, with a change of smaller magnitude in high ($+2.9$) vs low ($+12.4$) insulin resistance subjects. Interestingly, basal insulinemia (ß -0.6, $P<0.01$) and HOMA-IR (ß -3.2, $P<0.05$) appeared as negative predictors of SHBG variation at day 30, independently of BMI. *In vitro* results showed that 96-h treatment of HepG2 with high glucose concentrations (10 mM and 30 mM) resulted in higher SHBG protein levels (2-fold and 7-fold, respectively) and InsRec expression (1,5-fold and 2-fold, respectively) as compared to normal (5 mM) glucose. Conversely, the co-incubation with HI for 96 h blunted the augmentation of SHBG observed in the absence of insulin (-40% at 10 mM of glucose; -32% at 30 mM of glucose). Likewise, co-incubation with HI resulted in reduced InsRec expression by -67% and -60%, at 10 mM and 30 mM glucose respectively, compared to the absence of insulin. Altogether, these results suggest that high insulin levels may counteract the induction of SHBG during weight loss. *In vitro* data show that high insulin levels may favor hepatic insulin resistance by inhibition of insulin receptor expression and impair SHBG expression.

Familial hyperaldosteronism in a Singaporean kindred

Kevin Kwek & Eng Joo Phua
Khoo Teck Puat Hospital, Singapore, Singapore

Familial hyperaldosteronism type I (FH-I) is a rare subset of primary aldosteronism (PA) with an autosomal domintant pattern of inheritance. The molecular basis was determined to be from the unequal crossing over of the 11β-hydroxylase (CYP11B1) and aldosterone synthase (CYP11B2) genes, resulting in a chimeric gene duplication. This in turn leads to the ectopic synthesis of aldosterone in the zona fasciculata of the adrenal glands under the regulation of adrenocorticotropin along with hybrid steroids. While affected subjects typically have early onset hypertension, there is considerable phenotypic diversity. We describe the first ever series of three individuals with FH-I in a Singaporean kindred. The proband, an 18-year-old Chinese male, was initially diagnosed with primary aldosteronism during evaluation of normokalemic hypertension detected at health screening. A strong family history of early onset hypertension prompted further assessment of the proband's affected family members. His brother (aged 20) was diagnosed with essential hypertension, and his father (aged 50) had a personal history of early onset hypertension and coronary artery disease. Biochemical evaluation of both the proband and his brother revealed hyperaldosteronism, suppressed plasma renin activity with an elevated plasma aldosterone to renin ratio. Intravenous saline loading failed to suppress plasma aldosterone confirming primary aldosteronism. Computed tomographic imaging did not reveal any adrenal adenoma or hypertrophy. As FH-I was suspected, genetic analysis with long polymerase chain reaction was performed and all three subjects tested positive for the chimeric CYP11B1/B2 gene. The proband and his brother were initially treated with low-dose dexamethasone up to 0.5 mg/day and while this led to improvement in hypertension, blood pressure readings did not normalize. Due to the development of steroid-induced acne and weight gain, dexamethasone was switched to spironolactone with good effect. The proband's father was managed at another centre and declined a change in therapeutics as his blood pressure control was satisfactory. To our knowledge, this is the first report of FH-I in a Singaporean Chinese kindred and possibly the first in the region. This contributes to our local experience in managing this rare hereditary form of PA, and forms the basis for genetic screening and surveillance of this pedigree. In agreement with the Endocrine Society Clinical Practice Guidelines for PA, we recommend genetic testing for FH-I in subjects with young onset of PA (<20 years), in those with a family history of PA or strokes at a young age (<40 years).

A rare ARMC5 mutation causing bilateral macronodular adrenal hyperplasia and Cushing's syndrome

Janki Panicker[1], Alison Waghorn[2] & David Ewins[3]
[1]Liverpool University Hospitals NHS Foundation Trust, Diabetes and Endocrinology Department, Liverpool, United Kingdom; [2]Liverpool University Hospitals NHS Foundation Trust, Endocrine Surgery Department, Liverpool, United Kingdom; [3]Countess Of Chester Hospital NHS Foundation Trust, Diabetes and Endocrinology Department, Chester, United Kingdom

Introduction
Primary bilateral macronodular adrenal hyperplasia (PBMAH) is a highly heterogeneous disorder and is the cause of $<2\%$ of cases of Cushing's syndrome. Around 20-25% of patients with primary bilateral macronodular adrenal hyperplasia (PBMAH) have a mutation in ARMC5.
Case report
47 year old gentleman was incidentally found to have bilateral adrenal lesions when he had a CT scan of his chest performed for chest and back pains. He had a past history of hypertension, diagnosed 8 years ago, on treatment. He had plethoric face but no striae or easy bruising, but had central obesity and thin legs. His BMI was 33 on presentation. CT scan of adrenals showed bilateral macronodular hyperplasia (right adrenal mass 5 cm and left adrenal mass 3.5 cm) not typical of adrenal adenoma. Random ACTH was suppressed. Overnight dexamethasone suppression test, low dose and high dose dexamethasone suppression tests failed to suppress cortisol with suppressed ACTH levels. Dexamethasone level, post dexamethasone suppression test showed adequate absorption/metabolism. 24 hour urinary cortisol was normal. MRI pituitary showed normal pituitary gland with no abnormal enhancement. He had slightly elevated mid night salivary cortisol and cortisone. His 17OHP level was normal. His urinary steroid profiling was normal (except low 5 alfa reductase level). His 24 hour urine catecholamines were negative and plasma renin and aldosterone level was normal. His DEXA scan was normal. All his investigations were in keeping with ACTH independent Cushing's disease. He underwent bilateral adrenalectomy and subsequently commenced on replacement dose of steroids. In view of radiological and histological diagnosis of bilateral macronodular adrenal hyperplasia, he was consented for screening for genetic mutations and this showed heterozygous ARMC5 mutation NM_001105247.1:c.2097_2099del p.(Phe700del) which was likely to be pathogenic and associated with ACTH independent macronodular adrenal hyperplasia Type 2. This particular variant has been reported in another case previously in 2015, but not reported in gnomAD database and so is only the second patient reported with such a variant in literature, as far as we know.
Conclusion
A significant proportion of what is thought to be sporadic cases of bilateral macronodular adrenal hyperplasia are due to ARMC5 genetic mutations and family history is not a reliable indicator. Patients with large multinodular adrenal gland and cortisol excess may be more likely to harbour ARMC5 germline mutation and there should be a low threshold for genetic testing.

Background
Congenital adrenal hyperplasia (CAH) and long-term glucocorticoid treatment may be associated with an increased risk of developing cardiometabolic sequelae such as abnormal glucose homeostasis, hyperlipidaemia, hypertension, cardiovascular (CV) disease, obesity and osteoporosis.
Objectives
To study the current practice amongst expert centres for assessing cardiometabolic outcomes in adult patients with 21-hydroxylase CAH and to assess the prevalence of cardiometabolic morbidity.
Methods
Data were collected using a structured questionnaire sent between January and August 2020 to 46 centres managing adults with CAH within three overlapping networks: International Congenital Adrenal Hyperplasia (I-CAH) Registry, CaH Adult Study Executive (CaHASE) Consortium UK and European Reference Network on Rare Endocrine Conditions (Endo-ERN). Information collected included current therapy and surveillance practice of adults with CAH particularly focusing on cardiometabolic conditions.

Results
Of the 31 (67%) centres from 15 countries that completed the survey, 30 (97%) screened for hypertension by measuring blood pressure, 30 (97%) screened for obesity by mainly using BMI (90%) and weight (83%), 26 (84%) screened for abnormal glucose homeostasis by mainly using Hb1Ac (73%) or fasting plasma glucose (50%), 25 (81%) screened for osteoporosis mainly by DXA (92%), 20 (65%) screened for hyperlipidaemia using fasting lipids and 6 (19%) routinely screened patients for additional CV disease. Of the 31 centres, 12 provided more information on 235 patients with a median age of 33 yrs (range 19,94). Of these, 121 (51%) were females and 165 (70%) took fludrocortisone in addition to glucocorticoids which included prednisolone (42%), hydrocortisone (34%), dexamethasone (9%) or a combination (13%). Of 235 adults, 73 (31%) were on therapy for at least one of the six cardiometabolic comorbidities; of these 73, 15 (21%) were treated for more than 2 comorbidities. Of 73, the number of patients who received therapy for osteoporosis/osteopaenia, hyperlipidaemia, type 2 diabetes/hyperinsulinaemia, hypertension, CV disease, obesity was 43 (59%), 17 (23%), 16 (22%), 10 (14%), 8 (11), 3(4%) respectively. The median age at start of these therapies was 34 (18, 63), 55 (19,79), 26 (14,78), 55(39,72), 65(55,72), 24(19,28) respectively. For some conditions such as hypertension there was a wide range of drugs used (6 drugs in 10 patients).
Conclusions
Cardiometabolic morbidities are not uncommon in adults with CAH. There is a need for greater standardisation of the screening for these morbidities from early adulthood and a need to explore optimal therapy through routine collection of standardised data.

Patients with chronic kidney disease present HPA axis disregulation due to impaired glucocorticoid negative feedback

Laura Boswell[1,2,3], Miquel Blasco[4], Luis F. Quintana[4], Arturo Vega-Beyhart[2], Judith Viaplana[5], Gabriela Rodríguez[6], Daniela Díaz[2], Carme Vilardell[3], Mireia Mora[1,2,7,8], Irene Halperin[1,2,7], Antonio J. Amor[1], Gregori Casals[6] & Felicia A. Hanzu[1,2,7,8]
[1]Hospital Clínic de Barcelona, Endocrinology and Nutrition Department, Barcelona, Spain; [2]Institut d'Investigacions Biomèdiques August Pi i Sunyer (IDIBAPS), Barcelona, Spain; [3]Althaia, Xarxa Assistencial Universitària de Manresa, Endocrinology and Nutrition Department, Manresa, Spain; [4]Hospital Clínic de Barcelona, Nephrology Department, Barcelona, Spain; [5]Fundació Clínic per la Recerca Biomèdica, Barcelona, Spain; [6]Hospital Clínic de Barcelona, Biochemistry and Molecular Genetics Department, Barcelona, Spain; [7]Universitat de Barcelona, Barcelona, Spain; [8]Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Carlos III Health Institute, Madrid, Spain

Aims
A few studies have shown disturbances in the hypothalamic-pituitary-adrenal (HPA) axis in chronic-kidney-disease (CKD), of unknown extent and clinical implications. We aimed to study the HPA axis in patients with CKD and its association with kidney impairment and metabolic disturbances.
Methods
Cross-sectional controlled study. Patients with CKD stages I-II (estimated glomerular filtration rate [eGFR] through CKD-EPI equation >60), stage III (eGFR 30-60) and stage IV (eGFR 15-30) CKD with preserved diuresis ($n=16$, 15 and 15, respectively) were included and paired with 17 healthy controls by age, sex and body mass index (BMI). Exclusion criteria were: active glucocorticoid, immunosuppressive or anti-inflammatory treatment, diabetes mellitus, morbid obesity, drugs interfering with the HPA axis or pseudo-Cushing states. Subjects underwent clinical and analytical assessment of metabolic comorbidities, body composition analysis using DEXA and a thorough evaluation of the HPA axis.
Results
We included 63 subjects (age 53 ± 12years, 52% women, BMI 26 ± 4kg/m^2). A stepped increase in hypertension and dyslipidaemia prevalence as well as increasing levels of glucose, triglycerides and 24h-urinary protein excretion were observed with worsening kidney function ($P<0.05$ for all). Both plasmatic insulin levels (7.3mIU/L in stages I-II, 11.3 in stage III, 11.4 in stage-IV-CKD, 6.3 in controls; $P<0.001$) and visceral adipose tissue volume measured using DEXA (663 cm^3 in stages I-II, 1042 in stage III, 1347 in stage-IV-CKD, 458 in controls; $P<0.001$) increased with worsening kidney function. A higher ACTH (23 vs. 17pg/ml, $P=0.048$) and less cortisol supression after 1 mg dexamethasone-suppression-test (DST) (1.2 vs. 0.9μg/dL, $P<0.001$) were seen in patients with CKD compared to controls. No differences in ACTH were observed according to CKD stage. 24h-urinary-free-cortisol was decreased in stages III-IV compared to CKD stages I-II and controls ($P<0.001$). Of all, 11 (24%) patients with CKD had a post-DST cortisol >2 mg/dL (2 [14%] in CKD stage III and 9 [60%] in the stage-IV-group); 45% of them persisted with cortisol >2 mg/dL after a low-dose 2-day-DST (2 mg/6h), all with stage IV ($P<0.001$ for all). No differences were observed in basal cortisol or cortisol-binding-globulin levels. In the whole cohort, cortisol after DST was lineally inversely correlated with eGFR (β -19.8, $P<0.001$). Cortisol after DST (OR 11.9, 95%CI 1.5-97, $P=0.021$) and glucose (OR 1.3, 95%CI 1.1-1.5, $P=0.003$) were independently associated with an eGFR <30 ml/min/m^2.
Conclusions
Negative feedback of the HPA axis is impaired in patients with CKD and correlates with disease stage. This should be taken into account when hypercortisolism is suspected and explored in this context.

Group education programme for patients with adrenal insufficiency: evaluation based on patients experiences

Kirsten Davidse, Wanda Geilvoet, Lotte Brinkman, J.P. van Eck, Richard Feelders & Aart Jan Van der Lely
Erasmus University Medical Center, Internal Medicine, Division of Endocrinology, Rotterdam, Netherlands

Introduction
Adequate hormone replacement therapy in adrenal insufficiency is essential. Patients should have basic knowledge about their condition and what to do in situations which could trigger an adrenal crisis. Education on how and when hydrocortisone replacement therapy should be adjusted as well as instruction and practice an emergency injection are considered important measures to prevent an adrenal crisis. A standardized nurse-led group-based education programme (GEP) was developed based on a national guideline.
Methods
Sixty-seven patients, who attended the GEP from September 2018 until April 2020, were recruited to fill in a questionnaire in retrospect. The questionnaire categories assessed patients' experiences with the GEP on content, approach by the clinical nurse specialist and applicability in daily life. The questionnaire contained self-reported marks before and after the GEP, multiple choice questions and open questions. In addition to the questionnaire, electronic medical records for demographic data were studied.
Results
Of the 67 patients 48 responded, of whom 7 indicated they did not wanted to participate. Thirty-nine patients completed the part about the GEP-content. Three patients scored the content moderate, nine patients self-assessed the highest achievable score. On average, the patients scored a 8.6 on a scale of 10. The average reported score of 37 patients about the approach during the GEP was a 9.6 on a scale of 10. Twenty-six of the 37 patients gave the clinical nurse specialists the highest possible score. The part about applicability to apply the education in daily life was filled in by 38 patients. In this category the average score was above adequate, with a 7.7 on a scale of 10. Two patients scored below moderate, another seven patients scored average and 29 patients scored above average. Fifteen patients wrote additional comments. Strikingly, eight patients noted they would like the GEP to be given repeatedly. The greatest advantage of a group-based education reported by patients is sharing experiences and having contact with patients with the same condition. The self-reported marks were significantly improved after the GEP (p 0.003).
Conclusion
Overall, the patients who attended a two-hour group-based education programme were positive about the content of the education programme, the approach by the clinical nurse specialists and applicability of education in daily life. Repeated education and training was explicitly indicated by a large proportion of participating patients. Whether the results were affected by, for example, age or origin of adrenal insufficiency, needs to be further investigated.

Primary aldosteronism and microprolactinoma: a new syndromic variant?

Chiara Parazzoli[1], Vittoria Favero[1], Valentina Morelli[2], Carmen Aresta[2], Iacopo Chiodini[1,2] & Alberto Falchetti[2]
[1]University of Milan, Department of Medical Biotechnology and Translational Medicine, Milan, Italy; [2]IRCCS Istituto Auxologico Italiano, Department of Endocrine and Metabolic Diseases, Milan, Italy

Introduction
Primary aldosteronism (PA) has been described in association with endocrine and non-endocrine neoplasms. Aldosterone-producing adenomas mainly associate with hyperparathyroidism, prolactinomas and pancreatic endocrine tumors, particularly in the context of multiple endocrine neoplasia type 1 MEN1 syndrome. Next-generation sequencing (NGS) studies have shown frequent somatic mutations underlying PA and, rarely, germline mutations of *CYP11B1/CYP11B2*, *KCNJ5*, *ATP1A1*, *ATP2B3*, *CACNA1D*, *CACNA1H*, *CLCN2* genes.
Case Report
We describe a 27-years-old PA female patient with microprolactinoma in whom we found a new variant at *KIF1B* gene. No other endocrine abnormalities have been detected, so far. She suffered for arterial hypertension and then was screened for secondary hypertension. In the context of this setting emerged a strong suspicion of PA (aldosterone-to-renin ratio 11.5). Therefore, a saline infusion test was performed confirming the diagnosis of PA. Subsequently, abdomen computed tomography revealed a left adrenal adenoma sized 14 mm in diameter. The patient was adrenalectomized with both biochemical and clinical remission. Twenty months after, she complained of oligomenorrhea, and further investigation showed a hyperprolactinemia and a microadenoma was detected on pituitary gland. Therapy with Cabergoline was initiated with remission of symptoms and normalization of prolactin levels. Considering the coexistence of an aldosterone-secreting adrenal adenoma and microprolactinoma in a young patient, an NGS genetic analysis was performed for genes linked to endocrine tumors and hereditary endocrine hypertension. The result of the genetic analysis revealed the rare heterozygous variant *c.782A > G* (p.Lys261Arg) at exon 8 of the *KIF1B* gene, classified as a variant of uncertain significance. Genetic analysis for the *KIF1B* mutation was also extended to patient's parent and her brother. The same mutation has been identified in the father, who suffers from hypertension too, and therefore we are going to screen him for PA.
Discussion
In literature, it has been suggested a direct role of hyperprolactinemia on aldosterone secretion, indicating a potential pathophysiological link between prolactin levels and PA when coexisting. However, the age of onset and the finding of hormone-secreting adenoma prompted us to perform a genetic evaluation, with the finding of the rare *KIF1B* variant. The tumor suppressor *KIF1B* gene is frequently deleted in neural-derived tumors, including neuroblastoma and pheochromocytoma, and non-neural tumors, such as hepatocellular carcinoma and lung adenocarcinoma. Considering the co-segregation of the variant with the phenotype in our family, *KIF1B* could likely play a role in tumorigenesis, possibly including also PA. Currently, the somatic genetic analysis on the adrenal adenoma is in progress.

Waking salivary cortisone as screening test for adrenal insufficiency

Miguel Debono[1,2], Charlotte Elder[1], Jen Lewis[1], Jane Fearnside[1], Sharon Caunt[2], Simon Dixon[1], Richard Jacques[1], John Newell-Price[1], Brian Keevil[3] & Richard Ross[1]
[1]The University of Sheffield, Oncology and Metabolism, Sheffield, United Kingdom; [2]Sheffield Teaching Hospitals NHS Foundation Trust, Sheffield, United Kingdom; [3]The University of Manchester, Manchester, United Kingdom

Introduction
In many endocrine centres the 250μg Short Synacthen (Cosyntropin) Test (SST) is the reference standard for the diagnosis of adrenal insufficiency (AI) [1], but it is time consuming, expensive, and requires hospital attendance and venepuncture. The morning physiological peak of cortisol shortly after waking is a good predictor for a negative SST; however, a morning serum cortisol requires venepuncture. Serum cortisol and salivary cortisone correlate strongly[2], but salivary cortisone is far more convenient as can be collected at home, posted to the laboratory, and is stable at room temperature. We hypothesised that waking salivary cortisone (WSC) could predict a positive or negative SST in patients assessed for AI.
Methods
A prospective, diagnostic accuracy study of WSC was performed in 220 people at high risk of AI (majority on exogenous glucocorticoids). All patients collected a salivary cortisone sample on waking, and then attended the endocrine unit for a 250μg SST. AI was defined as a SST 30minute serum cortisol <430nmol/l. Baseline and 30minute serum cortisol was measured by LC-MS/MS and Roche Elecsys Cortisol II immunoassay, and WSC by LC-MS/MS. Questionnaires were used to assess patient views on home WSC vs SST in hospital. ROC curves were computed to assess diagnostic accuracy. Sensitivities, specificities, PPV and NPV (95%CI) were estimated.
Results
Insufficient salivary collection excluded 5.5% of samples. By SST the prevalence of AI in 208 subjects was 45% using LC-MS/MS and 44% using Immunoassay. Using the diagnostic thresholds in the table below with at least 95% sensitivity/specificity on valid WSC samples we achieved 96% NPV and 95% PPV, to exclude and confirm AI respectively. 82% of subjects preferred the home salivary cortisone.
Conclusion
Home WSC testing is a highly accurate screening tool for AI. We have shown that using WSC at 95% sensitivity/specificity avoids performing a SST in 76% (measured by LC-MS/MS) and 74% (measured by immunoassay) of patients at high risk for AI. WSC is also the preferred test by patients.

Gennimatas' General Hospital of Athens, Third Department of Surgery, Athens, Greece; [5]'G. Gennimatas' General Hospital of Athens, Department of Anesthesiology, Athens, Greece

Introduction
Pheochromocytomas (PCs) and paragangliomas are rare tumours occurring in about 0.6 cases per 100,000 person-years. Biochemically silent PCs with normal catecholamine levels due to lack of catecholamine secretion or subtle secretion within the established normal levels are even rarer. Up to date, biochemically silent PCs are poorly investigated.
Aim
To assess the pre-, peri- and post-operative characteristics of patients with biochemically silent PCs
Design
Observational multicentre retrospective study between 2014-2021 in three tertiary hospitals.
Patients and methods
Records of patients diagnosed with biochemically silent PC and followed-up at each participating centre were reviewed and clinical, laboratory and imaging data, as well as treatment outcomes were recorded.
Results
Ten patients (5 men) with biochemically silent PC [median age 52.5 years (24-72) and BMI 25.26 Kg/m^2 (16-34.2)] were included. The adrenal masses were incidentally discovered in all patients except one who presented with paroxysmal hypertension, palpitations and postural hypotension. Twenty-four-hour urine

metanephrine and normetanephrine levels were found in the low-normal, normal and high-normal range in 4, 4 and 2 patients and in 1, 6 and 3 patients, respectively. Tumours were unilateral in all cases (7 on the right side) with a median size of 46 mm (17-125). High tumour density on pre-contrast CT imaging [median density 35 HU (22-45)] or high signal intensity on T2-weighted MRI scan was found in all cases; cystic and/or necrotic component was evident in 7 cases. ^{131}I-MIBG scan was performed in 4 cases and it was positive in all of them. Alpha-adrenergic receptors blockade with phenoxybenzamine at a median total daily dose of 70 mg (20-100) was offered in 5 patients. Intra-operatively, 4 patients developed hypertension requiring glyceryl trinitrate administration (2 of them had no pre-operative treatment with phenoxybenzamine) and 8 developed hypotension; vasoconstrictors were required in 5 cases (3 of them did not receive pre-operative alpha-adrenergic receptors blockade). One patient, not pre-operatively treated with phenoxybenzamine, developed Takotsubo cardiomyopathy requiring admission in the ICU. On histology, PASS score was $\geq$4 (2-9) in all but one cases. During a median 24-month (12-88) period of follow-up, one patient had disease progression (a right retroperitoneal paraaortic metastasis detected 88 months after surgery).

Conclusions

Patients with biochemical silent PCs were in the vast majority asymptomatic and had lesions suspicious for PC on CT or MRI scan. Despite these tumours being biochemically silent, hemodynamic instability could manifest during surgical management. A multidisciplinary approach with experienced endocrinologist, surgeon and anaesthesiologist is mandatory.

Objective

Various features have been identified as predictors of relapse after complete resection of pheochromocytoma, but a comprehensive multivariable model for recurrence risk prediction is lacking. The aim of this study was to develop and internally validate an integrated predictive model for post-surgical recurrence of pheochromocytoma.

Methods

The present research retrospectively enrolled 177 patients affected by pheochromocytoma and submitted to radical surgery from 1990 to 2016, in nine referral centers for adrenal diseases. Cox regression analysis was adopted for model development, and a bootstrapping procedure was used for internal validation.

Results

Variables independently associated with recurrence were tumor size (HR 1.01, 95%CI 1.00–1.02), positive genetic testing (HR 5.14, 95%CI 2.10–12.55), age (HR 0.97, 95%CI 0.94–0.99), and PASS (HR 1.16, 95%CI 1.04–1.29). The predictive performance of the overall model, evaluated by Somers' D, was equal to 0.594, and was significantly higher than the ones of any single predictor alone ($P=0.002$ compared to tumor size; $P=0.004$ compared to genetic testing; $P=0.048$ compared to age; $P=0.006$ compared to PASS). Internal validation by bootstrapping techniques estimated an optimistic bias of 6.3%, which reassured about a small tendency towards overfit.

Conclusions

We proposed a multivariable model for the prediction of post-surgical recurrence of pheochromocytoma, derived by the integration of genetic, histopathological and clinical data. This predictive tool may be of value for a comprehensive tailoring of post-surgical follow-up in radically operated pheochromocytoma patients.

Background & Objective

Late night salivary cortisol (LNSC) and 1 mg overnight dexamethasone suppression test (DST) are two of the three recommended screening tests for Cushing's syndrome (CS). The classical DST uses serum cortisol, but analysis of salivary cortisol and cortisone has shown high diagnostic accuracy at DST (1). Salivary cortisol can be analysed with immunoassays, which suffer from variable degree of cross reactivity with other steroids, or with LC-MS/MS, highly specific for cortisol but more time consuming and expensive. For optimal diagnostic accuracy the reference interval and diagnostic cut-off for CS should be determined for each analytical method. We aimed to establish reference intervals and compare diagnostic accuracy for late-night and post-DST salivary cortisol and cortisone analysed with clinical routine methods used in Sweden.

Design & Method

Saliva was collected at 23:00 and after DST at 08:00 in 155 reference subjects and 22 patients with CS. Samples were aliquoted and analysed with three immunoassays for salivary cortisol and three LC-MS/MS methods for salivary cortisol and cortisone. The upper reference limit (URL) was calculated as the 97.5th percentile of the reference population and sensitivity and specificity for CS was calculated. The diagnostic accuracy for each method was compared with our published LC-MS/MS using area under the curves (AUCs) for receiver operating characteristics (ROC) curves (1).

Results

The URL for LNSC with the LC-MS/MS methods were 3.4–3.9 nmol/L, and with the immunoassays; Roche 5.8 nmol/L; Salimetrics 4.3 nmol/L; and Cisbio 21.6 nmol/L. After DST, the URL for salivary cortisol were 0.7–1.0 nmol/L for LC-MS/MS, 2.4 nmol/L (Roche), 4.0 nmol/L (Salimetrics) and 5.4 nmol/L (Cisbio). The URL for salivary cortisone were 13.5 – 16.6 nmol/L in late night samples and 3.0 – 3.5 nmol/L after DST. ROC AUCs for CS diagnosis were high for all tested methods both for late night samples (0.974 – 0.986) and after DST (0.964 – 0.996). For late night samples salivary cortisol (Roche) and salivary cortisone (LC-MS/MS) showed a slightly, but significantly, higher diagnostic accuracy.

Conclusions

We present robust reference limits for salivary cortisol and cortisone in late night samples and after DST for six clinically used methods. Reference limits vary considerably for different methods. However, using method specific cut offs, all methods show high diagnostic accuracy for CS.

Associations of age, BMI, and renal function to cortisol after dexamethasone suppression in patients with adrenal incidentalomas

Henrik Olsen[1,2], Shobitha Puvaneswaralingam[3] & Martin Olsen[4]
[1]Department of Endocrinology, Clinical sciences, Lund University, Lund, Sweden; [2]Department of Medicine, Ångelholm Hospital, Ängelholm, Sweden; [3]Department of Endocrinology, Skånes University Hospital, Lund, Sweden; [4]Department of Business Development and Technology, Aarhus University, Herning, Denmark

Introduction
The specificity of cortisol after 1 mg dexamethasone ($cortisol_{DST}$) $\geq$50 nmol/l as a criterion for mild autonomous cortisol secretion (MACS) is approximately 80% in patients with adrenal incidentalomas (AI). The aim was to study the associations of $cortisol_{DST}$to age, BMI, and renal function. We used machine learning models to uncover potential non-linear associations.
Methods
We studied 1129 patients with AI examined from 2005 to 2015 at Skåne University Hospital and Helsingborg Hospital. $Cortisol_{DST}$was ln-transformed in the analyses. The covariates studied were gender, age, BMI, eGFR, treatment with inhalation steroids, size of the AI, and size of the smallest AI in patients with bilateral AI (set to 0 in unilateral AI). Various machine learning models were trained to fit the data and examined using feature importance analysis and partial dependence plots. Partial dependence plots show the marginal effect on $cortisol_{DST}$of a covariate averaging over other covariates.
Results
$Cortisol_{DST}$ was strongly associated to the size of the AI but had weaker associations to age, BMI, and eGFR according to permutation importance. The partial dependence plots indicated relatively linear relationships for $cortisol_{DST}$to age (positively) and eGFR (negatively). There was a negative relationship to BMI at levels below 30 kg/m^2. Using linear regression, we found that $cortisol_{DST}$ increased 10% (95% CI, 7–14%) for each 10-year increase in age. In patients with BMI below 30 kg/m^2, $cortisol_{DST}$decreased 19% (95% CI, 14–23%) for each 5 kg/m^2 increase in BMI. We found no association at BMI levels above 30 kg/m^2. $Cortisol_{DST}$ increased 9% (95% CI, 6–11%) for each 10 ml/min/1.73m^2 decrease in eGFR.
Conclusions
$Cortisol_{DST}$ is positively associated to age, negatively to BMI if below 30 kg/m^2, and negatively to eGFR. These associations should be considered before diagnosing MACS.

Introduction
Simulation via Instant Messaging – Birmingham Advance (SIMBA) for Students is an online education model used to teach diabetes and endocrine topics to preclinical medical and pharmacy students using simulated clinical cases delivered over WhatsApp. It was developed in 2020 to provide an engaging alternative to online small group teaching (SGT). This study investigated the efficacy and acceptability of SIMBA for students compared with traditional SGT.
Methods
Each session included three 15-minute interactive clinical cases on a specific area of endocrinology, followed by a 30-minute Q&A session with an expert. All students were invited to participate in sessions relevant to their year-group curriculum. The sessions focused on the curriculum learning objectives and took place between the topic lecture and SGT. Students who attended SIMBA completed a post-SIMBA survey, including 15 multiple choice questions (MCQs). All students were asked to complete a post-SGT survey after the associated SGT, containing the same questions. Median MCQ score was compared between SIMBA only, SGT only and SIMBA + SGT groups using Wilcoxon signed rank test. The answers to Likert scale questions were expressed as percentages. Open-ended questions from surveys underwent thematic analysis.
Results
106 students attended 10 SIMBA sessions in 2020 and 2021 covering adrenal, metabolic bone, thyroid, diabetes, and reproductive endocrinology. All participants were year 1, year 2 medical, or year 1 pharmacy students. The median MCQ result was significantly higher in the SIMBA only group than both the SGT only group and SIMBA + SGT group ($P < 0.05$). There was no significant difference in score between the SGT only group and the SIMBA + SGT group ($P = 0.7103$). Most students agreed that SIMBA was well-structured (93%), engaging (76%), stimulated their interest in endocrinology (82%), promoted knowledge (91%) and an in-depth understanding (93%) and prepared them for exams (78%). Only 53% agreed that time for each case was sufficient. 80% enjoyed the session, and 85% would like to have SIMBA alongside SGT. Positive themes from thematic analysis were knowledge application through case-based learning, interaction, and instantaneous feedback. Benefits of SGT over SIMBA included peer-peer discussion and smaller group size for tutor interaction; however, tutor quality varied.
Conclusions
SIMBA is a good alternative model for SGT to teach endocrinology to pre-clinical medical and pharmacy students by providing engaging, interactive, and interesting sessions. A study is currently underway to assess improvements to the model and wider impacts on academic performance in a larger cohort.

ARMC5 is a tumor suppressor gene responsible for 20 to 40% of Primary Bilateral Macronodular Adrenal Hyperplasia (PBMAH) with a function that remains unclear. Based on pathway analysis from RNAseq results obtained on zebrafish models of transient *Armc5* up- and down-regulation, we identified transcriptional alterations of several members of SIRT1 (sirtuin (silent mating type information regulation 2 homolog) 1) signaling in our models and hypothesized that ARMC5 can regulate SIRT1 and its signaling in adrenocortical cells. Accordingly, the expression of the desacetylase SIRT1 is significantly increased in PBMAH tissues mutated for *ARMC5* compared to tumors without mutations. However, this overexpression of SIRT1 is associated with an elevation of the profile of acetylated protein in the absence of *ARMC5* suggesting that SIRT1 activity is actually decreased and that SIRT1 expression could increase to maintain its activity. Consistently, the measurement of SIRT activity on PBMAH tissues demonstrate a decrease of its activity when *ARMC5*is mutated. Similar results are obtained in adrenal cells of 18-month-old $Armc5^{+/-}$ mice that are also hypercorticosteronemic. Altogether, these data support that ARMC5 could regulate SIRT1 expression and/or activity. *In vitro* measurement of purified SIRT1 activity in the presence of ARMC5-enriched protein extracts demonstrated that the presence of ARMC5 protein does indeed alter SIRT1 activity. We hypothesize, therefore, that ARMC5 may be a new regulator of SIRT1 function but the underlying mechanism and the consequences of abnormal acetylated proteins on adrenocortical function require further investigation.

Profound changes of inflammatory and cardiovascular biomarkers in patients with autonomous cortisol secretion and Cushing syndrome

Grethe Åstrøm Ueland[1], Paal Methlie[1,2], Kristian Løvås[1], Åse Bjorvatn Sævik[2], Anette Heie[1] & Eystein Sverre Husebye[1,2]
[1]Haukeland University Hospital / Health Bergen, Norway; [2]University of Bergen, Bergen, Norway

Objective
Determine inflammatory and cardiometabolic biomarkers in patients with autonomous cortisol secretion (ACS), compared with healthy controls and patients with overt Cushing syndrome (CS).
Method
Serum from prospectively included patients with ACS ($n=65$), overt CS ($n=8$), and healthy subjects ($n=120$) were analysed for 92 different inflammatory biomarkers using proximity extension assay.
Results
ACS and CS patients revealed significant differences in levels of 49/92 inflammatory and cardiometabolic biomarkers (46 raised/3 decreased) compared with healthy subjects. No difference in biomarker levels were found between ACS and overt CS, and the biomarker levels did not correlated with the degree of hypercortisolsim. Among the 46 raised biomarkers, 20 were cardiometabolic, and 13 were inflammatory markers. Several of the biomarkers have previously been found to be elevated in patients with overt CS. The assays showed robustness, as only three biomarkers had one outlier each in healthy subjects. Seventeen patients delivered postoperative samples, median 24 months (range 6–40) after operation and hormonal cure. There was no significant normalisation of the biomarkers postoperatively.
Conclusion
We found a systemic rise in inflammatory and cardiometabolic biomarkers among patients with ACS and CS, unrelated to the degree of hypercortisolism. Curing ACS/CS did not lead to normalisation of these biomarkers after 24 (range 6–40) months.

Decreased steroidogenic enzymes activity in benign adrenocortical tumors is more pronounced in bilateral lesions as determined by steroid profiling in HPLC-MSMS during ACTH stimulation test

Objective
Large response of steroids precursors, including 17-hydroxyprogesterone and 11-deoxycortisol, to ACTH has been described in adrenocortical tumors, suggesting the existence of intra-tumoral enzymatic deficiencies. This study aimed to compare steroidogenic enzymes activity in unilateral and bilateral benign tumors using serum steroid profiling in HPLC-MS/MS in basal state and after ACTH 1-24 stimulation.
Design and Methods
A serum profile of seven consecutive adrenal steroids (progesterone, 17-hydroxyprogesterone, 11-deoxycortisol, cortisol, deoxycorticosterone, corticosterone, androstenedione) was determined in HPLC-MSMS in basal state (T0) and after ACTH 1-24 stimulation (T60) in 35 patients with bilateral adrenocortical tumors (BL), 38 patients with benign unilateral tumors (UL) and 37 control subjects (CT). Response amplitude of each individual steroid was evaluated by T60/T0 ratio whereas enzymatic activity was assessed by downstream/upstream steroid ratio. Adrenal volume was precisely quantified by a semi-automatic segmentation method.
Results
For the seven steroids assayed, the amplitude of response to ACTH was higher in BL than in UL and in CT. As illustration, on glucocorticoids pathway, T60/T0 17-hydroxyprogesterone ratio was higher in BL (11.5 [1.6-24.9]) than in UL patients (5.2 [1.1-24.0], $P=0.0030$) and CT subjects (3.3 [0.8-14.6], $P=<0.0001$) as well as T60/T0 11-deoxycortisol ratio, also higher in BL patients (8.6 [2.1-23.3]) than in UL patients (5.3 [1.2-15.9], $P=0.0070$) and in CT subjects (3.7 [0.5-12.5], $P<0.0001$). Finally, T60/T0 cortisol ratio was higher in BL patients (2.8 [1.6-5.9]) than in UL patients (2.2 [0.8-8.1], $P=0.0046$) and CT subjects (1.8 [0.8-4.1], $P<0.0001$). The difference between BL and UL persisted even after matching patients on adrenal volume. On glucocorticoids pathway, enzymatic activity of CYP11B1, catalyzing the last step for cortisol biosynthesis, was significantly decreased in BL (78.3 [43.1-199.4]) in comparison to both UL (122.7 [13.8-228.4], $P=0.0002$) and CT (186.8 [42.1-1236.3], $P<0.0001$). This was responsible for a lower T0 cortisol (309.8 [167.2-585.2] nmol/L) in BL than in both UL (379.2 [88.5-1078.6] nmol/L; $P=0.0317$) and CT (404.1 [191.6-777.8] nmol/L; $P=0.0036$). On mineralocorticoids and androgens pathways, enzymatic activity of distal steroidogenic enzymes CYP11B2 and CYP17A1-17,20 lyase was also lower in BL than UL and CT.
Conclusions
Decreased activity of distal steroidogenesis enzymes CYP11B1, CYP11B2 and CYP17A1-17,20 lyase, is responsible for an explosive response to ACTH of upstream precursors in bilateral tumors. It also limits the synthesis of bioactive steroids, explaining the lower basal cortisol, despite the increase in adrenal mass in these bilateral forms of adrenocortical tumors.

Prevalence and clinical features of ARMC5 mutations in a single centre cohort of patients with bilateral adrenal incidentalomas

Sofia Frigerio[1,2], Valentina Morelli[3], Francesca Marta Elli[1], Walter Vena[4], Maria Antonia Maffini[1], Camilla Lucca[1], Matteo Piu[1], Nicola Mora[1], Serena Palmieri[1], Giovanna Mantovani[1,2] & Maura Arosio[1,2]
[1]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Endocrinology Unit, Milan, Italy; [2]University of Milan, Department of Clinical Sciences and Community Health, Milan, Italy; [3]IRCCS Istituto Auxologico Italiano, Unit for Bone Metabolism Diseases and Diabetes & Lab of Endocrine and Metabolic Research , Milan, Italy; [4]IRCCS Humanitas Research Hospital, Unit of Endocrinology, Diabetology and Medical Andrology, Rozzano, Italy

Introduction
Primary bilateral macronodular adrenal hyperplasia (PBMAH) is a rare cause of Cushing's syndrome (CS). Some familial forms have been associated to gene *ARMC5* (Armadillo repeat-containing protein 5) inactivating mutations. This study aimed to evaluate the prevalence and the complications of *ARMC5* mutations in our cohort of patients with bilateral adrenal incidentalomas (BAI).
Methods
72 patients, referred to our Center for BAI, were analysed to identify pathogenetic single nucleotide variants (SNVs) and/or structural rearrangements (duplications/deletions, termed as copy number variants, CNVs) involving *ARMC5* gene. We also evaluated the prevalence of glycometabolic complications, arterial hypertension (AH), nodules dimension and HPA axis parameters. Subclinical hypercortisolism (SH) was defined by cortisol levels after 1 mg overnight dexamethasone suppression (1 mgDST) $\geq$1.8 µg/dl.
Results
48/72 patients presented SH. A germline mutation of *ARMC5*was found in 9 SH patients (12.5% of the whole population), 7 SNVs and 2 CNVs (Group1). The remaining 39 SH patients were found to be wild type (*WT*) (Group2). No germline mutations were found among patients without SH (Group3; $n=24$). Moreover, we also looked for the presence of somatic *ARMC5* mutations in the tissue of 7 patients who had undergone adrenalectomy and we found that 100% presented CNVs (2 patients of Group1 and 5 patients of Group2). Age, gender and prevalence of obesity, AH, diabetes mellitus, dyslipidaemia and osteoporosis were comparable among the three groups. Patients of Group1 showed a larger diameter of the adenoma than patients of Group3 (5.77 $\pm$ 2.64 cm vs 3.40 $\pm$ 1.18 cm.; $P=0.000$), but comparable to Group2 (5.77 $\pm$ 2.64 cm vs 4.82 $\pm$ 1.62 cm, $P=0.124$). However, all the 4 patients who presented at least one nodule over 5 cm of diameter belonged to Group1. Basal ACTH levels were higher in Group3 compared to Group1 and Group2 (16.41 $\pm$ 7.50 ng/l, 10.61 $\pm$ 2.82 ng/l, 11.37 $\pm$ 6.50 ng/l respectively, $P<0.05$). Similarly, cortisol suppression after 1 mgDST was significantly lower in Group1 (7.06 $\pm$ 6.32 µg/dl) as compared to Group2 (3.97 $\pm$ 3.27 µg/dl) and Group3 (1.26 $\pm$ 0.35 µg/dl) ($P<0.01$).
Conclusion
Prevalence of germline *ARMC5* mutations in our BAI cohort was 12.5%, reaching up to 18.8% in subjects with SH. Mutation carriers seem to have poorer cortisol suppression to low dose DST and larger nodule diameter but similar metabolic comorbidities as compared to *WT* patients. Further studies are needed to elucidate

the meaning of the somatic CNVs observed in patients without germline mutations.

Bilateral adrenal haemorrhages secondary to Rivaroxaban on a background of p-ANCA vasculitis

Mohammad Farhan Malik, Siva Sivappriyan, Jesse Kumar, Samantha Anandappa, Maliha Iqbal & Maha Khalid
Maidstone and Tunbridge Wells NHS Trust, United Kingdom

Background
A 73-year-old female presented to the hospital with a 3-day history of right upper quadrant abdominal pain and episodes of vomiting. Her past medical history included insulin treated Type 2 diabetes diabetes, deep venous thrombosis for which she was on rivaroxaban, COPD, right leg angioplasty and previous p-ANCA vasculitis. She also had flank tenderness and was noted to be hypertensive with a blood pressure of 225/93mmHg. A CT scan of the abdomen identified a new 4 cm right-sided indeterminate adrenal mass since her previous imaging where adrenal glands were reported normal in 2019. She became hypotensive and was treated with intravenous hydrocortisone for suspected unilateral adrenal haemorrhage. Two days later, she started to experience pain in the left flank. A dedicated MRI adrenal study showed the emergence of a new left adrenal lesion, similar in size, signal and characteristic to the lesion on the right adrenal gland. Synacthen test showed inadequate response, Aldosterone/renin ratio and adrenal androgens were not elevated. Whole body PET scan did not show any FDG avid lesions in the adrenal glands. Considering the acute history, rivaroxaban anticoagulation use, p-ANCA vasculitis, and new progressive bilateral adrenal lesions, the diagnosis was adrenal insufficiency secondary to bilateral adrenal haemorrhage. Rivaroxaban was replaced with warfarin after appropriate discussion with the haematology and adrenal MDT.
Discussion
Acute adrenal haemorrhage (adrenal apoplexy) is a rare, potentially life-threatening cause of adrenal crisis. Diagnosis can be challenging however needs to be considered especially with risk factors that include the use of anticoagulants as well as vasculitis. Abdominal CT can be useful in detecting haemorrhage within the adrenal glands. Management, after treatment of the adrenal insufficiency, often requires a multidisciplinary approach due to the complexity of the confounding risk factors. Surveillance imaging post haemorrhage can be used to monitor for resolution of the hematoma as well as investigating if there was any other underlying cause of adrenal enlargement.
Learning Points
1. Novel anticoagulant therapy can be a risk factor for developing the rare condition of bilateral adrenal haemorrhage especially in patients with a background of vasculitis. 2. Cortisol and catecholamines released by the expanding hematoma may initially precipitate hypertension and therefore adrenal insufficiency symptoms may be a late presenting feature. 3. Angiography and embolisation of adrenal haemorrhages may provide better outcomes compared with traditional surgical laparotomy and should be considered if the retroperitoneal bleeding is unresponsive to conservative management.

Covid-19 infection: incidental diagnosis of pheochromocytoma in an adolescent bearing an uncommon mutation

Zoi Efstathiadou[1], Apostolos Gogakos[1], Paraskevi Komzia[1], Sophia Goulopoulou[1], Dimitrios Linos[2] & Marina Kita[1]
[1]"Hippokration" General Hospital of Thessaloniki, Endocrinology, Thessaloniki, Greece; [2]"Ygeia" Athens Medical Center, Athens, Greece, Surgery, Athens, Greece

Introduction
Chest computed tomography imaging in patients with Covid-19 infection often reveals incidental adrenal lesions, which are subsequently investigated, after recession of the infection.
Purpose
Description of a pheochromocytoma that was accidentally diagnosed in a teenager, during her hospitalization with Covid-19.
Case description
A 17-year-old girl, who was diagnosed with covid-19 infection, by molecular testing 6 days before, arrived at the emergency department, with tachycardia and dyspnea, during the first wave of the pandemic. Due to hypocapnia and tachycardia (heart rate = 110'), she underwent CT angiography to rule out pulmonary embolism. A right adrenal lesion formation of 3 cm in diameter was incidentally discovered, which showed intense enrichment with the contrast medium. The patient reported no symptoms other than emotional instability observed by the parents in recent years, which was attributed to adolescence. The girl had no personal medical history and was not on any medication. Family history was also free, negative for neoplasia. The recovery of acute covid-19 disease was followed by a complete clinical and hormonal control. On physical examination, the patient appeared with normal somatic and pubertal growth (tanner stage 5). Regular menstruation was reported. Blood pressure was normal (101/78mmHg), with a heart rate of 102'. On further MRI imaging, the tumor showed a high signal in the T2 sequences and increased enrichment. Additionally, an ^{18}F-FDG PET scan showed increased activity of the lesion (SUVmax of 21.5), with absence of other foci. The hormonal tests confirmed the diagnosis of pheochromocytoma with total metanephrines >3 times the upper normal limit. The posterior retroperitoneoscopic excision of the pheochromocytoma, after preparation of the patient with phenoxybenzamine, was uncomplicated. Histology confirmed the diagnosis of pheochromocytoma with a PASS score of zero. Genetic testing was negative for mutations in known genes associated with pheochromocytoma-paraganglioma. However, a mutation of unknown significance in the MSH6 gene (exon 4, p.K295R), which expresses a DNA mismatch-repair protein, and which is associated with Lynch syndrome, was detected in heterozygosity. The association of MSH6 gene mutations with pheochromocytoma has been reported in only 3 cases worldwide.
Conclusions
Owing to covid-19 infection, an early diagnosis and effective treatment of a potentially dangerous tumor was achieved. Furthermore, the extremely rare association of a mutation in a gene related to Lynch syndrome has also emerged, broadening the range of tumors attributed to these genes.

The endocrine society practice guideline revisited: why do nowadays patients undergo screening for cushing' syndrome, and with which outcome?

Leah Braun[1], Frederick Vogel[1], Stephanie Zopp[1], Thomas Marchant Seiter[1], German Rubinstein[1], Christina M. Berr[2], Heike Künzel[1], Felix Beuschlein[3] & Martin Reincke[1]
[1]Endokrinologie, Nephrologie und weitere Sektionen - Medizinische Klinik und Poliklinik IV - Campus Innenstadt, München, Germany; [2]University Hospital Augsburg, Augsburg, Germany; [3]Klinik für Endokrinologie, Diabetologie und Klinische Ernährung USZ Campus, Zürich, Switzerland

Background
Cushing's syndrome (CS) is a rare but very severe condition with high morbidity and mortality. Patients are often diagnosed late in the course of the disease, many years after onset of symptoms. New approaches like extended screening of at risk populations, alternative biomarkers and clinical scores have been developed to improve diagnostic accuracy. However, there is still a debate, whether certain patient populations should be screened for CS outside the framework of current guideline recommendations.

Material and method
As part of the prospective German Cushing's registry, we studied 433 patients. They had suspected Cushing's syndrome or autonomous cortisol secretion. All patients underwent a standardized clinical examination including 20 clinical key items of CS. The main reason why they were referred to our department was documented. Finally, Cushing's syndrome was confirmed in 98 patients, autonomous cortisol secretion was diagnosed in 44 patients and CS was excluded in 291 subjects using the three standard screening tests urinary free cortisol, late-night salivary cortisol, the 1 mg-dexamethasone suppression-test and long-term clinical observation.
Results
Patients were referred for 18 different key presenting reasons. Five of them were more common in patients with Cushing's syndrome than in subjects in whom CS was excluded: osteoporosis (7% vs. 2%, $P=0.02$), adrenal adenoma (17% vs. 8%, $P=0.01$), metabolic syndrome (10% vs. 4%, $P=0.02$), myopathy (9% vs. 2%, $P=0.01$) and presence of multiple symptoms (16% vs. 1%, $P < 0.001$). Obesity was the single factor that was much more common in patients with exclusion of Cushing's syndrome (29% vs. 4%, $P < 0.001$). Obesity was also the most frequent reason to initiate a screening.
Conclusions
Obesity should not be a standard reason to screen a patient for CS. The results of our study confirm the current screening recommendations.

Characterization of adrenal miRNA-based dysregulations in Cushing's Syndrome

Ru Zhang[1], Sharmilee Vetrivel[1], Deepika Watts[2], Andrea Osswald[1], Mareen Engel[3], Felix Beuschlein[4], Alon Chen[3,5], Silviu Sbiera[6], Ben Wielockx[2], Martin Reincke[1] & Anna Riester[1]
[1]Medizinische Klinik und Poliklinik IV, LMU Klinikum, Ludwig-Maximilians-University; [2]Institute of Clinical Chemistry and Laboratory Medicine, Technische Universität Dresden; [3]Max Planck Institute of Psychiatry; [4]Klinik für Endokrinologie, Diabetologie und Klinische Ernährung, Universitätsspital Zürich; [5]Weizmann Institute of Science; [6]Department of Internal Medicine I, Division of Endocrinology and Diabetes, University Hospital, University of Würzburg

Introduction
Transcriptional regulation of gene expression by miRNAs is critical for the fine-tuning of stress response. However, its role in hypercortisolism has not been explored well. After exploring circulating miRNAs in Cushing' Syndrome (CS) as biomarkers our aim was to investigate their origin and their role in adrenal tissue.
Methods
Next generation sequencing (NGS) based miRNA profiling was performed in adrenal samples from patients of German Cushing's registry: (1) Cortisol-Producing-Adenoma (CPA, $n=8$), (2) adrenals of patients with Cushing's Disease after adrenalectomy (CD, $n=8$) and (3) controls (adrenal samples of patients with pheochromocytoma ($n=8$). NGS data analysis and principal component analysis (PCA) clustering was performed by R (version 4.1). miRNAs were additionally validated by QPCR in other subtypes of ACTH independent CS (PBMAH, $n=10$) and ACTH dependent CS (Ectopic Cushing's syndrome, $n=3$). ACTH stimulation were done in 12 weeks-old female C57Bl6J mice according to protocol established previously. Adrenal glands were collected from the mice at 0 min (baseline), 10, 30, and 60 min upon ACTH stimulation for miRNA extraction and QPCR analysis.
Results
miRNA based NGS revealed miRNA profiles to be significantly different amongst the groups of Cushing's Syndrome (CD, CPA) and controls. Interestingly, 17 miRNAs significantly differ between the CS subtypes ($P<0.05$). Of these, four miRNAs were found to be significantly upregulated in CPA, in comparison to both CD and Controls. These upregulated miRNAs were taken for validation by QPCR. Upregulated expression of hsa-miR-139-3p ($P=0.01$, $l2fc>1.4$), hsa-miR-1247-5p ($P=0.02$, $l2fc>2.5$) in CPA compared to both CD and Controls could be confirmed by QPCR. Next, the validated miRNAs were analysed in other subtypes of CS. Hsa-miR-1247-5p was upregulated only in ACTH independent forms of CS (PBMAH ($l2fc>2.24$ $P=0.003$) and CPA ($l2fc>2.24$ $P=0.003$)). Incidentally, miR-1247-5p was not found in the previously characterized circulating miRNA profile in both CPA and CD. Finally, hsa-miR-1247-5p was found to show no differential expression in the murine adrenal tissues at different time points in comparison to the positive control of miR-96-5p.
Conclusion
This study identifies adrenal miRNAs to be regulated in ACTH dependent and independent manner in CS. ACTH independent upregulation of miRNA-1247-5p as a possible contributor to the hypercortisolism pathology in CPA and PBMAH was identified.

Time from referral to definitive treatment in Cushing's syndrome

Amy Coulden[1,2,3], Simon Aylwin[4], Daniel Flanagan[5], Yaasir Mamoojee[6], Aparna Pal[7], Neil Gittoes[1,2,3] & Helena Gleeson[2,3]
[1]University Hospital Birmingham, Institute of Metabolism and Systems Research, Birmingham, United Kingdom; [2]Queen Elizabeth Hospital Birmingham, Endocrinology, Birmingham, United Kingdom; [3]Birmingham Health Partners, University of Birmingham, Centre for Endocrinology, Diabetes and Metabolism (CEDAM), Birmingham, United Kingdom; [4]Kings College Hospital NHSFT, Endocrinology, London, United Kingdom; [5]University Hospitals Plymouth NHSFT, Endocrinology, Plymouth, United Kingdom; [6]The Newcastle Upon Tyne Hospitals NHSFT, Endocrinology and Metabolic Medicine, Newcastle Upon Tyne, United Kingdom; [7]Oxford University Hospitals NHSFT, Endocrinology, Oxford, United Kingdom

Rapid diagnosis and treatment of Cushing's syndrome (CS) is essential for good outcomes. Current standards for appropriate timelines for referral are under review by NHSE. Data are required to substantiate standard setting. Knowledge of current referral pathways/processes are required to explore delays in accessing definitive surgical treatment. An audit of referral processes at Queen Elizabeth Hospital Birmingham was undertaken and further expanded to 4 additional tertiary centres in England. Data were collected on adult patients diagnosed with CS and referred for surgery at index hospitals between January 2018 and December 2019. Patients seen privately were excluded until seen in index hospital. Data were collected on demographics, initial referrer and referral pathway and dates of first clinic, subsequent referral to index hospital (if applicable), first index hospital clinic, MDT and definitive surgery. 72 patients were diagnosed with CS; 69 had definitive surgical treatment. 37 patients had pituitary CS, 34 adrenal CS, 1 had ectopic ACTH secretion. Demographics and referral pathways are outlined in table below. Results are given as median averages. Time from initial referral to secondary clinic (39.5 days in all patients, 45 days in pituitary and 35 days in adrenal patients) was shorter than those referred direct to index tertiary clinic (57 days in all-comers, 56 days in pituitary and 62 days in adrenal patients). However, total time from

Table 1

		All ($n=72$)	Pituitary ($n=31$)	Adrenal ($n=34$)
Median age (years)		49	44	48
M:F ratio		17:55	8:29	8:26
Initial referrer	GP	44(61.1%)	22(59.4%)	22(64.7%)
	Inpatient referral	25(34.7%)	13(35.1%)	12(35.3%)
Initial clinic	Secondary	44(61.1%)	20(54.1%)	24(70.6%)
	Index tertiary	22(30.6%)	14(37.8%)	7(20.6%)

referral to tertiary clinic via secondary pathway was significantly longer (158.5 days in all, 140 days in pituitary and 171 in adrenal patients). The number of diagnostic tests performed in secondary care was 6 in each group. Time from referral to index hospital to MDT was 32, 61 and 22.5 days for all, pituitary and adrenal patients respectively. Time to definitive surgical treatment was 183, 178 and 180 days for all, pituitary and adrenal patients respectively. By mapping average timeline from referral to definitive surgical treatment in CS patients, we've highlighted areas of national and hospital-specific delays which can be improved for better patient outcomes. Both secondary and tertiary centres should organise more rapid reviews of patients with a potential diagnosis of CS and minimal investigation criteria should be set before secondary centres involve tertiary centres in management of CS patients.

Mesenchymal Stem Cells exposed to persistently high glucocorticoid levels develop insulin-resistance and altered lipolysis: a promising in vitro model to study Cushing's Syndrome

Mariangela Di Vincenzo[1], Marianna Martino[1], Vincenzo Lariccia[2], Giulia Giancola[1], Caterina Licini[1], Giovanni Maria Di Benedetto[3], Monia Orciani[1] & Giorgio Arnaldi[1]

[1]Università Politecnica delle Marche, Department of Clinical and Molecular Sciences (DISCLIMO), Ancona, Italy; [2]Università Politecnica delle Marche, Department of Biomedical Sciences and Public Health, Ancona, Italy; [3]Università Politecnica delle Marche, Department of Experimental and Clinical Medicine, Ancona, Italy

Objective

In Cushing's Syndrome, chronic glucocorticoid excess and their disrupted circadian rhythm lead to insulin-resistance, diabetes mellitus, dyslipidemia and cardiovascular comorbidities. As undifferentiated, self-renewing progenitors of adipocytes, mesenchymal stem cells may display the detrimental effects of glucocorticoid excess, thus revealing a promising model to study molecular mechanisms underlying metabolic complications of Cushing's Syndrome.

Design and methods

mesenchymal stem cells isolated from the abdominal skin of healthy subjects were treated thrice daily with glucocorticoids according to two different regimens: lower, circadian-decreasing (Lower, Decreasing Exposure, LDE) *vs* persistently higher (Higher, Constant Exposure, HCE) doses, aimed at mimicking either the physiological condition or Cushing's Syndrome, respectively. Subsequently, mesenchymal stem cells were stimulated with insulin and glucose thrice daily, resembling food uptake, and both glucose uptake/GLUT-4 translocation and the expression of *LIPE*, *ATGL*, *IL-6* and *TNF-α* genes were analyzed at predefined timepoints (T1 to T7) over three days.

Results

A LDE to glucocorticoids did not impair glucose uptake by mesenchymal stem cells, whereas a HCE significantly decreased glucose uptake by mesenchymal stem cells only when prolonged. Persistent signs of insulin-resistance occurred after 30 hours of HCE to glucocorticoids ($P < 0.05$ from T5 on). As compared to LDE, mesenchymal stem cells experiencing a HCE to glucocorticoids showed a significant down-regulation of lipolysis-related genes in the acute period ($P < 0.05$ for *LIPE*, *ATGL* and *TNF-α* at T2), followed by a significant overexpression once insulin-resistance had established ($P < 0.05$ for *LIPE*, *ATGL*, *IL-6* and *TNF-α* at T7).

Conclusions

Preserving circadian glucocorticoid rhythmicity is crucial to prevent the occurrence of metabolic alterations. Like mature adipocytes, mesenchymal stem cells suffer from insulin-resistance and impaired lipolysis due to chronic glucocorticoid excess: mesenchymal stem cells could represent a reliable model to track the mechanisms involved in glucocorticoid-induced insulin-resistance throughout cellular differentiation.

Characterization of cytological assessments of adrenal lesions: A 12-year single center experience

Ana Maria Cristina Carasel[1,2], C Christofer Juhlin[3,4], Jan Calissendorff[1,2] & Henrik Falhammar[1,2]

[1]Karolinska Institutet, Department of Molecular Medicine and Surgery, Stockholm, Sweden; [2]Karolinska University Hospital, Department of Endocrinology, Stockholm, Sweden; [3]Karolinska Institutet, Department of Oncology-Pathology, Stockholm, Sweden; [4]Karolinska University Hospital, Department of Pathology and Cytology, Stockholm, Sweden

Background

The accuracy of the radiological and laboratory findings used to investigate adrenal masses are not optimal and therefore additional investigation methods, such as fine needle aspiration (FNA) are sometimes needed. Different methods are used for obtaining FNA such as endoscopic ultrasound (EUS), transabdominal ultrasound and computerized tomography (CT)-guided biopsy.

Methods

Using a search function incorporated in our institutional pathology database, patients who underwent FNAs of adrenal glands at Karolinska University Hospital, Stockholm Sweden between the years 2007-2019 were identified. Medical records for these patients were scrutinized from clinical, radiological, and cytological perspectives. Data included gender, age at time of FNAB, primary origin of the original tumor, uni- or bilateral disease, metastasis to other organs, tumor size, patient outcome during the observation time including survival, adequacy of the sample as well as subsequent histological diagnosis.

Results

A total of 139 adrenal FNAs were identified. Of those, 54 (38.8%) were obtained by EUS, 52 (37.4%) by transabdominal ultrasound and 26 (18.7%) were CT-guided. Preceeding radiological investigation suspected malignant lesions in 107 cases (77%). Adequate material for diagnosis was retrieved in 52 cases (96.3%) by EUS, 47 cases (90.4%) by transabdominal ultrasound and in 22 cases (84.6%) by CT-guided biopsies. By FNA adrenal lesions were diagnosed as distant metastasis in 82 cases (59%), adrenocortical cells were found in 54 cases (38.8%) and the diagnosis was unclear in 3 cases (2.2%). Of those in which adrenal cells were identified 5 were later diagnosed as adrenal cortical cancer (3.6%). Most metastases were from lung cancer (48 cases, 58.5%) followed by malignant melanoma (5 cases, 6.1%), renal cancer (4 cases, 4.9%), gynecological cancer (4 cases, 4.9%), and other malignancies (21 cases, 25.6%) (e.g., breast, prostate, hepatocellular, and gastrointestinal cancer). Complications due to the biopsy procedure such as bleeding and pneumothorax were reported in 10 cases (7.2%).

Conclusions

FNA of the adrenal glands is safe and provides useful information in diagnosis of adrenal tumors. Complications are rare regardless of method used. Overall adequacy rate for adrenal biopsy were high, with the EUS having the best results.

Keywords

fine needle aspiration, adrenal glands.

Midnight ACTH vs morning ACTH levels in Cushing's syndrome diagnosis

Thibault BAHOUGNE[1], Sarah Homsi[1], Françoise Ortega[1], Marion Munch[1], Laurent Meyer[1], Nathalie Reix[2], Michel Vix[3], Helene Cebula[4], Bernard Goichot[1] & Nathalie Jeandidier[1]

[1]CHRU Strasbourg, Endocrinology, France; [2]CHRU Strasbourg, Hormonology Laboratory, France; [3]CHRU Strasbourg, Endocrine Surgery, France; [4]CHRU Strasbourg, Neurosurgery, France

Cushing's syndrome (CS) is a rare and complex condition. Once the diagnosis of CS is confirmed, repetitive morning ACTH measurement is indicated to assess whether CS is ACTH dependent or independent. ACTH under 2,2 pmol/l characterises ACTH-independent CS and above 4,4 pmol/l ACTH-dependent CS. Some groups recommend midnight ACTH measurement rather than the morning. The purpose of our work was to evaluate 12PM ACTH vs 8AM ACTH measurement in the etiological diagnostic of CS, based on 42 patients with CS (Cushing's disease, adrenal adenomas and adrenal carcinomas histologically proven) between 2004 and 2021. In Cushing's disease ($n=12$), patients are correctly categorised "ACTH-dependent" whether ACTH is measured at 8AM (92%) or at 12PM (93%) ($P=0,6$). In adrenal carcinomas ($n=6$), patients are correctly categorised "ACTH-independent" whether ACTH is measured at 8AM (100%) or at 12PM (100%). In adrenal adenomas ($n=24$), patients are more accurately classified "ACTH-independent" when ACTH is measured at 12PM (96%) rather than 8AM (58%) ($P=0,003$). In the non-classified cases, the classification is corrected when both ACTH 12AM and 8Pm are performed. We

observed that the particular interest of a 12AM dosage was observed in patients with "milder" hypercortisolism (defined as serum cortisol at 8 am under 138 nmol/l after dexamethasone 1 mg (overnight) suppression test). The main limits of our study are a small patient's sample (histology needed), a retrospective data collection, and a possible measurement bias for ACTH due to the use of 3 different kit assays. Possible inclusion of subclinical CS cannot be ruled out. To our knowledge, no other study has compared 8AM and 12PM ACTH in the etiological diagnosis of CS. In summary, assessing the cause of CS by 8AM ACTH measurement seems appropriate in first line. Additional midnight ACTH may contribute to the etiological diagnosis in mild CS ACTH independent but requires patient's night hospitalisation.

Fibroblast growth factor 21 contributes to adrenal cortex renewal

Daniela Díaz Catalán[1], Arturo Beyhart[1], Mireia Mora[1,2,3], Maite Rodrigo[4], Laura Boswell[2], Gregori Casals[5] & Felicia Alexandra Hanzu[1,2,3,6]
[1]Institut d'Investigacions Biomèdiques August Pi Sunyer (IDIBAPS), Group of Endocrine Disorders, Barcelona, Spain; [2]Hospital Clínic de Barcelona, Endocrinology and Nutrition, Barcelona, Spain; [3]University of Barcelona, Barcelona, Spain; [4]Hospital Clínic de Barcelona, Pathology, Barcelona, Spain; [5]Hospital Clínic de Barcelona, Biochemistry and Molecular Genetics, Barcelona, Spain; [6]Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM),, Madrid, Spain

Objective
After Cushing Syndrome (CS) is cured, up to 70% of patients develop chronic adrenal insufficiency (AI) and hypothalamus-pituitary-adrenal (HPA) axis dysfunction. A long-term treatment with glucocorticoids (GC) is mandatory to overcome AI. However, this treatment implies non-desired complications. Fibroblast growth factor (FGF21), a key regulator of metabolism, has a bidirectional relationship with GC that bypasses the negative feedback of the HPA axis. In this study, we aimed to investigate the potential effects of FGF21 treatment in the HPA axis in a mouse model with AI post-CS.
Methods
Male C57B6/J mice ($n = 10$/group) received corticosterone (CORT) (500μg/mL) or vehicle (VEH) in the drinking water for 5 weeks, followed by 3 days tapering period. After this period, the animals developed AI post-CS, and then they were injected daily intraperitoneally with recombinant FGF21 or VEH for 7 days. Plasma circadian and stimulated CORT and ACTH levels were assessed by immunoassay. Steroidogenic and stem/progenitor genes in the adrenal gland were determined by qPCR.
Results
AI mice during the nocturnal circadian cycle had decreased plasma CORT levels and down-regulated adrenal steroidogenic genes, whereas plasma ACTH levels remained similar to non-treated (CTL) mice. Three hours after FGF21 administration, CTL-FGF21 and CTL-VEH had similar plasma ACTH levels. However, plasma CORT levels in the CTL-FGF21 mice were significantly increased compared with CTL-VEH mice. As expected, AI groups showed lower plasma CORT levels than CTL mice. Remarkably, between the AI groups, at 1 h the FGF21 treated mice exhibited higher plasma CORT levels and maintained significantly higher ACTH levels during the 3 h after FGF21 administration compared with the VEH group. CTL mice treated with FGF21 for 7 days, increased their circadian and hypoglycemic stimulated plasma CORT levels compared to the CTL-VEH group. In line with this result, the expression of adrenal steroidogenic genes (*StAR*, *Cyp11a1*,and *Cyp11b1*) and stem/progenitor markers (*Gli*, *Wt1*, *Wnt4*, and *Dlk*) were upregulated in the CTL-FGF21 group. In agreement with CORT withdraw, AI groups maintained lower plasma CORT levels in circadian and hypoglycemic conditions, together with upregulated stem/progenitor markers compared with their respective treatment CTL groups. Interestingly, under hypoglycemic conditions, AI-FGF21 mice presented higher expression levels of adrenal Sonic hedgehog (Shh) than CTL-FGF21 and AI-VEH mice.
Conclusion
Our data describe that FGF21 contributes to maintaining a sustained CORT secretion and suggests that FGF21 accelerates and supports the adrenocortical cell renewal during AI.

Prevalence of NCAH, defined by 17-hyroxyprogesterone levels after ACTH-stimulation test, in a population with adrenal incidentaloma

Fredrik Sahlander[1,2,3], Sophie Bensing[1,4] & Henrik Falhammar[1,4]
[1]Karolinska Institutet, Department of Molecular Medicine and Surgery, Stockholm, Sweden; [2]Falu hospital, Department of Medicine, Falun, Sweden; [3]Center for Clinical Research Dalarna, Falun, Sweden; [4]Karolinska University Hospital, Department of Endocrinology, Stockholm, Sweden

Background
Nonclassic congenital adrenal hyperplasia (NCAH) is a condition associated with adrenal masses and suggested by current European guidelines to be considered in case of bilateral adrenal lesions. NCAH is caused by different mutations in the *CYP21A2* gene coding for the 21-hydoxylase enzyme in the glucocorticoid synthesis leading to mild cortisol deficiency and elevated androgen and steroid precursor levels. 17-hydroxyprogesterone (17OHP) is the most important steroid precursor and used to diagnose NCAH. Elevated ACTH levels lead to development of adrenocortical hyperplasia and adrenal masses. NCAH is one of the most common autosomal recessive disorders and with an estimated prevalence of around 0.1% in the general population but up to 2-4% in some ethnic groups. The prevalence of NCAH in a population with adrenal incidentaloma (AI) is unknown but assumed to be higher than in the general population. The main reason to exclude NCAH is that a correct diagnosis can enable glucocorticoid replacement that can improve quality of life for individuals with symptoms of hyperandrogenism. The aim of this study was to investigate the prevalence of NCAH in a population of adrenal incidentalomas (AIs).
Method
After overnight fasting serum cortisol and 17OHP were measured before and 30 and 60 minutes after an intravenous injection of 0.25 mg ACTH (Synacthen®) in subjects, >18 years with AI fulfilling ESE's definition of AI at a single centre in Regional Sweden. A 17OHP >30 nmol/l before or after ACTH-stimulation was classified as NCAH.
Results
An ACTH-stimulation test was performed in 222 subjects (median age 66 (25–87) years, 58.6% women). None of the subjects presented a basal 170HP >30 nmol/l. Eight subjects (3.6%) presented a 17OHP >30 nmol/l (median 38 nmol/l (33–62) which could be compatible with NCAH. Four subjects (50%) with 17OHP >30 nmol/l had bilateral lesions.
Conclusion
The prevalence of NCAH based on the level of 17HOP after ACTH-stimulation in a population of patients with AI was 3.6%. The prevalence based on genetic analysis is probably lower, as the secretion of 17OHP can be slightly increased even from lesions without CAH. However, the prevalence of NCAH appears to be significant higher in a population diagnosed with AI than in the general population. Thus, screening for NCAH in AI may be considered even without bilateral AIs.

Multiplex serum steroid profiling using liquid chromatography mass spectrometry with post column infusion ammonium fluoride

Lina Schiffer[1], Fozia Shaheen[1], Lorna Gilligan[1], Karl Storbeck[2], James M Hawley[1,3], Brian Keevil[3], Wiebke Arlt[1] & Angela Taylor[1]
[1]Institute of Metabolism and Systems Research, University of Birmingham, Birmingham, United Kingdom; [2]Department of Biochemistry, Stellenbosch Univeristy, Stellenbosch, South Africa; [3]Wythenshawe Hospital, Biochemistry Department, Manchester, United Kingdom

Background
Development of multi-steroid profiling allows comprehensive investigation into the different branches of steroid metabolism. Immunoassays only allow analysis of a single steroid per assay and suffer from problems with specificity due to cross reactivity of similar steroids. Liquid-chromatography mass spectrometry has the specificity to analyse multiple steroids in a single experiment and the dynamic range to quantify steroids at high concentrations such as those observed for cortisol (50-600nM) and at low concentration such as DHT (0.07-2.5nM). Here,

we present the optimisation, validation and application of an ultra-high performance liquid chromatography-tandem mass spectrometry assay for the profiling of 25 steroids.
Methods and Results
Sensitivity in mass spectrometry can be enhanced by addition of mobile phase additives which aid ionisation. Typically for steroids this is an acidic additive such as formic acid. Ammonium fluoride significantly enhanced ionisation in a steroid structure-dependent fashion compared to the use of formic acid, with increases in average peak area ranging between 100% and 1280%. Therefore, we validated our method with ammonium fluoride as the additive. Quantification was performed on a Waters Xevo TQ-XS mass spectrometer using electrospray ionisation in positive ion mode. Steroids were extracted via liquid-liquid extraction (using 1ml tert-methyl butyl ether) from 200µL of serum after addition of an isotopically labelled internal standard mixture. Steroids were chromatographically separated using a Phenomenex Luna Omega C18 column (1.6µm, 100Å, 2.1 x 50mm) with a water-methanol gradient. To extend column lifetime ammonium fluoride was introduced via post-column infusion (6mmol/L at 5µL/min). This method was then clinically validated and applied to serum from a healthy control cohort (167 females and 125 males, aged 21-95 years) to obtain a reference range, 18 of the 25 steroids were quantifiable in serum. Lower limits of quantification ranged from 0.28 to 3.42nM. Extraction efficiencies ranged from 90-122% and matrix effects were -19 to + 19%. Imprecision and bias at four concentrations did not exceed 15% for the majority of analytes.
Conclusions
Ammonium fluoride used as a mobile phase additive significantly enhanced sensitivity for steroid multiplex analysis. Thus, allowing quantitative analysis of 25 steroids from glucocorticoid, mineralocorticoid and androgen biosynthetic pathways in a single assay- a comprehensive assessment of the steroid metabolome. This method can be applied to a variety of biological fluids, including serum, cell and tissue culture extracts.

Comparison of plasma metanephrines in patients with cyanotic and acyanotic congenital heart disease

Mojca Jensterle[1], Ana Podbregar[2], Andrej Janez[1], Matej Rakusa[1], Katja Goricar[3] & Katja Prokselj[4]
[1]Department of Endocrinology, Diabetes and Metabolic Disease, Ljubljana, Slovenia; [2]University Rehabilitation Institute Republic of Slovenia,, Ljubljana, Slovenia; [3]University of Ljubljana, Faculty of Medicine, Institute of Biochemistry, Pharmacogenetics Laboratory, Ljubljana, Slovenia; [4]Department of Cardiology, University Medical Center Ljubljana, Ljubljana, Slovenia

Background
Pheochromocytomas (PHEO) and paragangliomas (PGL) are rare neuroendocrine tumors that can lead to life-threatening conditions. The diagnosis of PHEO/PGL is established by measuring normetanephrine and metanephrine. Biochemical detection usually precedes clinical diagnosis of PHEO/ PGL by several years. Co-occurrence of cyanotic congenital heart disease (CCHD) and PHEO/PGL has been reported but potential association remains unclear. We aimed to compare plasma metanephrine and normetanephrine between patients with CCHD and patients with acyanotic congenital heart disease (ACCHD).
Material and Methods
We designed cross sectional study of prospective cohort including 44 patients with CHD (13 (29.5%) males, 31 (70.5%) females) of median age 37.5 (31.0-55.6) years at the time of follow up. Thirty-two (73%) patients had CCHD and 12 (27%) patients had ACCHD. Morning blood samples for plasma metanephrine and normetanephrine were collected and measured using the radioimmunoassay. Intra-assay coefficient of variation (CV) was 6–14%, inter-assay CV was 10–15%.
Results
Levels of plasma normetanephrine were significantly increased in patients with CCHD compared to ACCHD ($P=0.002$); 31.3% (10) patients with CCHD had increased levels of plasma normetanephrine, whereas all ACCHD patients had normal levels. Patients with lower oxygen saturation had significantly higher normetanephrine levels ($\rho=-0.444$, $P=0.003$).
Conclusions
Levels of plasma normetanephrine in patients with CCHD are higher than in patients with ACCHD, suggesting that chronic hypoxemia in CCHD contributes to the risk of PHEO/PGL development in this patients population. Routine biochemical screening for PHEO/PGL should be considered in the management of patients with CCHD, to allow timely detection of clinically important PHEO/PGL in this higher risk population. Future research is needed to better understand the association between chronic hypoxia in CCHD and PHEO/PGL.

The changing face of drug-induced adrenal insufficiency in the food and drug administration adverse event reporting system

Emanuel Raschi[1], Michele Fusaroli[1], Francesco Massari[2], Veronica Mollica[2], Andrea Repaci[2], Andrea Ardizzoni[1], Elisabetta Poluzzi[1], Uberto Pagotto[1] & Guido Di Dalmazi[1]
[1]Alma Mater Studiorum - Università di Bologna, Bologna, Italy; [2]S. Orsola-Malpighi Polyclinic, Bologna, Italy

Importance
Adrenal insufficiency is a life-threatening condition complicating heterogenous disorders across various disciplines, with challenging diagnosis and a notable drug-induced component.
Objective
To describe the spectrum and main features of drug-induced adrenal insufficiency through adverse drug event reports received by the Food and Drug Administration (FDA).
Design
We conducted a retrospective disproportionality analysis within one of the largest publicly accessible spontaneous reporting systems.
Setting
The FDA Adverse Event Reporting System (FAERS) collecting more than 15 million reports since 2004.
Participants
Adverse event reports extracted from FAERS over the past 2 decades, with a focus on the 2015-2020 period.
Main Outcomes and Measures
We assessed the reporting trend of drug-induced adrenal insufficiency through descriptive statistics. Cases were selected if they contained any of the preferred terms in the Medical Dictionary for Regulatory Activities describing adrenal hypofunctions. We computed the reporting odds ratio (ROR) with relevant 95% confidence interval (CI) using Bonferroni correction to identify signals of disproportionate reporting for drugs recorded in at least 10 cases as primary suspect.
Results
We identified 8496 cases of adrenal insufficiency, 97.5% serious and 41.1% requiring hospitalization. Adrenal insufficiency showed an exponential increase throughout the years, with 5282 (62.2%) cases in 2015-2020. Among 164 drugs, we identified 56 compounds associated with significant disproportionality within various pharmacological classes: glucocorticoids ($n=1971$), monoclonal antibodies ($n=1644$, of which 1330 associated with immune checkpoint inhibitors, reaching 76% in 2020), hormone therapy ($n=291$), anti-infectives ($n=252$), drugs used for hypercortisolism or adrenocortical cancer diagnosis and/or treatment ($n=169$), protein kinase inhibitors ($n=138$). Cases of adrenal insufficiency by glucocorticoids were stable in each 5-year period (22-27%), whereas those by monoclonal antibodies peaked from 13% in 2010-2015 to 33% in 2015-2020.
Conclusions and Relevance
Our study provides a comprehensive insight into the evolution of drug-induced adrenal insufficiency, highlighting the heterogeneous spectrum of culprit drugs classes, the consolidated role of topical and systemic corticosteroids, and the emerging increased reporting of immune checkpoint inhibitors. Our data claim for an urgent identification of predictive factors of drug-induced adrenal insufficiency, and the establishment of screening protocols and educational programs for patients and caregivers.

Background
Only few cases of patients with adrenal disorders affected by coronavirus disease 2019 (COVID-19) have been reported so far. In this study, clinical outcome data of patients with adrenal disorders and COVID-19 infection has been collected by the ESE Rare Disease Committee and ENDO-ERN via the European Registries for Rare Endocrine Conditions (EuRRECa) project.
Methods
This questionnaire included 32 questions on collecting quantitative and qualitative data. From 06/2020 onwards, 55 cases have been reported by 12 centres of 8 different European countries. In total, 48 cases of adrenal insufficiency (AI) and 7 cases of Cushing's syndrome were reported.
Results
Of the 48 cases of AI, 3 (6 %) were suspected to have COVID-19 infection and 45 (94 %) were confirmed by testing. 40 out of these 48 cases (83 %) were affected by primary adrenal insufficiency (42,5 % Addison's disease ($n=17$), 40 % congenital adrenal hyperplasia ($n=16$), 17,5 % others ($n=7$)). Affected AI patients (21 male, 27 female) had a median age of 41 (1-77) years at the timepoint of diagnosis. Of those 17 patients with Addison's disease, 76 % suffered from additional autoimmune endocrine disorders. Most relevant comorbidities were hypertension ($n=7$; 15 %), obesity ($n=7$; 15 %) and diabetes mellitus ($n=4$; 8 %). Most frequent symptoms of COVID-19 infected patients included fever ($n=29$; 60 %), tiredness or exhaustion ($n=27$; 56 %), cough ($n=23$; 48 %), muscle pain ($n=22$; 46 %), headaches ($n=16$; 33 %) and loss of taste and smell ($n=13$; 27 %). Two thirds of patients increased their daily glucocorticoid dose from a mean of 22 mg/d (SD 13 mg/d) to 42 mg/d (SD 23 mg/d). Only two of the surveyed patients administered i.m. injection of 100 mg hydrocortisone. Hospital admission was required in 8 % of cases either due to adrenal crisis or due to the severity of infection. One of the patients with AI had to be transferred to the intensive care unit. Despite one patient, who reported persistent SARS-CoV-2 infection, all others reported complete remission.
Conclusion
This European multicentric questionnaire is the first to collect data on the outcome of COVID-19 infection in patients with adrenal insufficiency. It suggests good clinical outcome in case of duly dose adjustments and emphasizes the importance of patient education on sick day rules.

DOI: 10.1530/endoabs.81.P259

Menopause and muscle mass of humans and increase in fat mass

Naween Kumar[1], Siddharth Singh[2] & A S Prakash[3]

[1]Global Healthcare & Diabetes Research Centre, Darbhanga, India; [2]IGIMS, Patna, India; [3]Prakash Diabetes Hospital, Patna, India

Background
Menopause has been related to a deficiency of bulk and an increment in fat mass. Testosterone treatment is being considered to further develop body organization in menopausal women. Notwithstanding, the portion reaction connections among testosterone and the progressions in body structure and muscle strength in women have not been set up. To decide the portion subordinate impacts of reviewed dosages of testosterone on body arrangement and muscle strength in precisely menopausal women.
Methods
76 surgically menopausal women got a normalized estrogen routine during the 12-week altercation period and were then randomized to one of 5 gatherings to get week after week IM infusions of fake treatment ($n=16$), 3 ($n=15$), 6.25 ($n=15$), 12.5 ($n=16$) or 25 mg ($n=14$) testosterone enanthate for quite some time. Aggregate and free testosterone levels were estimated by LC-MS/MS and balance dialysis, individually. Slender weight (LBM) and fat mass were estimated utilizing DXA output and muscle strength was evaluated by one-redundancy most extreme technique at pattern and week 24.
Results
76 women were randomized. A pattern, mean age was 53 yrs, BMI 30 kg/m^2, total testosterone 13.8 ng/dl and free testosterone 2.3 pg/ml. On-treatment nadir testosterone fixations were 15, 88, 107, 165 and 212 ng/dl at the 0, 3, 6.25, 12.5 and 25-mg portions, individually. Changes in LBM exceptionally corresponded with changes in testosterone focuses; the assessed between-individual contrast in LBM was 0.67 kg per 100 ng/dl change in testosterone (95% CI: 0.23, 1.11; $P=0.003$). There was a huge expansion in LBM in the 25-mg portion bunch (normal increment = 1.7 kg, $P=0.01$). No huge changes in fat mass and leg press strength were seen.
Conclusion
Testosterone organization in precisely menopausal women was related to portion and fixation subordinate additions in LBM. Long haul randomized paths are expected to decide if clinically significant enhancements in different results can be accomplished securely with testosterone dosages that don't deteriorate cardiovascular danger or incite virilization.

Bilateral adrenal haemorrhage due to e.coli sepsis precipitating adrenal crisis in pregnancy: a case report

Nabeel Ahmed & Sunil Nair
Countess of Chester Hospital NHS Foundation Trust, Chester, United Kingdom

A 25-year-old primi 26 weeks pregnant was admitted with B/L flank pain & pleuritic sounding chest pain. She was septic on initial assessment by the Obstetric team and preliminary investigations revealed high inflammatory markers, raised CRP of 336 & deranged LFT's. Her USS scan suggested possible hepatitis/cholangitis and blood cultures grew E. coli & she was started on IV Ceftriaxone & metronidazole for the same. At day 3 of her admission, she started deteriorating clinically with fluid responsive hypotension, tachycardia and generally unwell with an episode of hypoglycemia. She had stopped spiking temps by then & her CRP had improved to 151. Because of the initial suspicion of PE, she underwent an urgent low dose CTPA to rule out a massive PE causing hypotension which was negative for VTE. It did however suggest B/L bulky adrenals. She subsequently went on to have an MRCP the same due to worsening LFTs which was negative for obstructive jaundice but again suggested a possibility of B/L bulky adrenals. Her scans were reviewed in the Urology MDT and a possibility of B/L Adrenal Hemorrhage was suggested. Her 9 am cortisol was 177. She was given IV Hydrocortisone 100 mg iv and was started on Oral hydrocortisone

replacement which improved her BP & settled her tachycardia. She then had a dedicated MRI Adrenal scan which confirmed T2 hyper intensities in B/L Adrenal glands suggestive of B/L Adrenal Hemorrhage. Further workup was negative for Adrenal Antibodies & Autoimmune screen including Antiphospholipid Antibodies. She completed her 10-day course of IV Antibiotics for E. coli & was discharged on maintenance Hydrocortisone replacement for her Adrenal Insufficiency with a SST planned after her pregnancy to reevaluate her Adrenal reserve. Her baby thankfully remained stable throughout her torrid clinical course. This case was interesting as Adrenal Hemorrhage is usually described in the context of Meningococcal infections & there are only few reported cases of Adrenal Hemorrhage in pregnancy causing Adrenal Crisis.

Key role for vasopressin V2 receptors in hypertension development in Spontaneously Hypertensive Rats (SHRs)

Ignazio Verzicchio[1], Alice Bongrani[1], Stefano Tedeschi[1], Gallia Graiani[2], Stefania Cavazzini[3], Jessica Zappa[1], Barbara Palladini[1], Elena Cremaschi[1], Anna Calvi[1], Pietro Coghi[1], Vanni Vicini[1], Valentina Cannone[1], Riccardo Volpi[1,4], Alberico Borghetti[1] & Aderville Cabassi[1]
[1]Cardiorenal Research Unit - Clinica e Terapia Medica, Parma, Italy; [2]Histology and Histopathology Unit and Molecular Biology Laboratory, Dental School, Parma, Italy; [3]University of Parma, Laboratory of Industrial Toxicology, Department of Medicine and Surgery (DIMEC), Parma, Italy; [4]Endocrinology and Andrology Unit, Clinica e Terapia Medica, Parma, Italy

Water and electrolyte balance regulation plays a key role in essential hypertension pathogenesis. Indeed, alterations in kidney ability to excrete sodium and water in relation to intake have been proposed as a basic process of hypertension development. Vasopressin (AVP) acts through V2 receptors on the basolateral membrane of collecting duct principal cells to trigger the phosphorylation of Aquaporin 2 (AQP2) which moves from the cytoplasm to the apical membrane, making the cell water-permeable and resulting in water reabsorption. In Spontaneously Hypertensive Rats (SHRs), the alterations in water and sodium balance, as well as in osmoregulation, were evaluated from the pre-hypertensive phase to the establishment of hypertension and further to hypertension-related organ damage; early AVP V1 and V2 receptor antagonism was also evaluated on blood pressure time-course. At 4-5 weeks of age, pre-hypertensive SHRs ($n=58$) showed reduced daily urine volume ($P<0.01$), increased urine osmolality ($P<0.01$) and a trend towards lower urine sodium excretion ($P=0.079$) compared to normotensive Wystar Kyoto rats (WKYs, $n=46$). Circulating levels of AVP were not different, while the urine AQP2/creatinine ratio ($P<0.01$), as well as the expression of Na^+/K^+ ATPase and betaine-amino-n-butyric acid transporter 1 (BGT1) in thick ascending limb in outer medulla (mTAL) were higher in pre-hypertensive SHRs than in WKYs. At 28–30 weeks of age, hypertensive SHRs with moderate renal failure displayed no difference in urine osmolality and renal BGT1 expression but showed similar urine AQP2/creatinine ratios with significantly higher circulating AVP levels ($P<0.01$). Treatment of SHRs ($n=20$) with the V1-antagonist OPC 21268 from 25 to 40 days of age slightly decreased blood pressure but after its withdrawal did not prevent the hypertension onset in adult age. In contrast, administration of tolvaptan, a V2 antagonist, delayed hypertension development by 4-5 weeks. In addition, tolvaptan-treated rats showed a significantly increased urine volume ($P<0.01$), as well as a decrease in urine osmolality ($P<0.01$) and urine AQP2/creatinine ratio ($P<0.01$) compared to both untreated ($n=8$) and anti-V1-treated ($n=12$) SHRs. Thus, according to our results, increased plasma levels of AVP seem to play a key role in hypertension development in SHRs through the activation of V2 receptors in the principal cells of the collecting duct, suggesting that alterations in water balance, even before sodium balance perturbations, represent a cardinal element in the pathogenesis of high blood pressure in this experimental model of hypertension.

Development of a novel treatment strategy which involves thermal ablation of adrenal adenomas using electromagnetic energy

Richard Farnan[1], Anna Bottiglieri[2], Laura Farina[2], Russell Senanayake[3], Mark Gurnell[3], Punit Prakash[4], Martin O'Halloran[2], Grazia Cappiello[2], Caoimhe Newell[2], Muireann Keating[2], George Rahmani[2] & Michael Conall Dennedy[2]
[1]NUIG, Endocrinology, Galway, Ireland; [2]NUIG, Galway, Ireland; [3]University of Cambridge, Cambridge, United Kingdom; [4]Kansas State University, Kansas, United States

Primary aldosteronism (PA) arises from one or both adrenal glands and is a common cause of secondary hypertension accounting for approximately 5-12% of all hypertension. Current therapy involves mineralocorticoid receptor antagonists for bilateral disease (60%) or adrenalectomy for unilateral disease (30%). We investigate treatment planning of percutaneous adrenal ablation as an alternative definitive therapeutic modality for unilateral and bilateral disease. The main objectives of treatment planning model the following to inform optimal therapeytic approach: (i) Localisation of the aldosterone producing adenomas. (ii) Generation of optimal power input for ablation. (iii) Probe placement for precise targeting. (iv) Heat map generation to guide thermal applicator placement. Segmentation and reconstruction was performed to produce 3D models showing the adrenal glands and the surrounding vital structures using 3DSlicer® and iSeg® respectively. 11C Metomidate PET/CT images localized functioning adrenal lesions which were then rendered in a 3D virtual environment. Microwave thermal ablation transfers electromagnetic energy, targetted to the region of interest and requires temperatures >50C to ablate adrenal tissue. The necessary power to ablate was derived by applying Maxwell's equations. These involve a system of four partial differential equations and their utility in developing the power needed to ablate biological tissue. Models of specific adrenal glands are created using dielectric and thermal properties used to determine delivery of effective thermal energy. These parameters were used to inform power settings and probe placement necessary to safely ablate adrenal nodules.

Mitotane side effects in the treatment of patients with adrenocortical carcinoma - a retrospective study

Anja Barac Nekic[1], Karin Zibar Tomšić[2], Lana Sambula[3], Nino Matas[1], Martina Jambrović[4], Iva Petrak[5], Tina Dusek[2] & Darko Kastelan[2]
[1]General Hospital Dubrovnik, Department of Endocrinology, Dubrovnik, Croatia; [2]University Clinical Hospital Centre Zagreb, Department of Endocrinology and Diabetology, Zagreb, Croatia; [3]General hospital Dr. Tomislav Bardak, Koprivnica, Department of Endocrinology, Koprivnica, Croatia; [4]General Hospital Čakovec, Department of Endocrinology, Čakovec, Croatia; [5]General Hospital Nova Gradiška, Department of Endocrinology, Nova Gradiška, Croatia

Introduction
Mitotane is widely used to treat adrenocortical carcinoma (ACC) and remains the mainstay of treatment along with surgery. The aim of this study is to evaluate the adverse side effects of mitotane treatment.
Materials and Methods
This retrospective study included 36 patients with ACC, ENSAT stage I- IV, who were treated with mitotane in an adjuvant or palliative setting. Patients with ENSAT stage IV who died within 6 months after surgery were excluded ($n=6$). Patient demographic and clinical characteristics, as well as metabolic and hormonal side effects of mitotane, were collected from hospital medical records.
Results
The median age of patients was 48 (18-78) years, 72% of them were female. Twenty-seven patients (75%) received adjuvant mitotane whereas 9 patients (25%) received it in a palliative setting, as monotherapy ($n=3$) or in combination with chemotherapy ($n=6$). One patient permanently, and two temporarily, discontinued mitotane treatment due to side effects (severe liver lesion, exfoliative dermatitis and severe gastrointestinal disturbances). Of the remaining

33 patients, all achieved the target mitotane concentration (> 14 mg/L) after median time of 102 days (76-121). In 25 patients (76%), the target mitotane concentration was maintained during > 75% of the treatment period. As for the endocrine toxicity of mitotane, all patients required glucocorticoid substitution, 8 patients (24%) had mineralocorticoid insufficiency, 16 (49%) had central hypothyroidism whereas hypogonadism was observed in 89% of male patients (8/9). In addition, 29% of female patients (7/24) developed ovarian cysts and 15 (46%) patients had dyslipidaemia. Four patients had an Addison crisis during treatment. Fourteen patients (42%) experienced gastrointestinal side effects including nausea, vomiting, diarrhoea and weight loss, while 32 patients (97%) had elevated liver enzymes, predominantly GGT. Twelve patients (36%) had various neurological side effects such as dizziness, decreased ability to concentrate or speech disorders (stutter or aphasia).

Conclusion

Mitotane treatment is associated with a wide spectrum of side effects and their successful management is of paramount importance to improve patient adherence to treatment and avoid drug discontinuation.

Adrenergic crisis after SARS-COV-2 infection in a patient affected by pheochromocytoma

Roberto Novizio[1], Gaetano Emanuele Rizzo[1], Rosa Maria Paragliola[1], Ettore Maggio[1], Pietro Locantore[1] & Salvatore Maria Corsello[1,2]
[1]Fondazione Policlinico Universitario Agostino Gemelli IRCCS Universitaà Cattolica del Sacro Cuore, Unit of Endocrinology and Diabetes, Rome, Italy; [2]UniCamillus, Saint Camillus International University of Health Sciences, Rome, Italy

Background

SARS-CoV-2 infection is characterized by aspecific symptoms (e.g., fever, cough) and can be complicated by viral pneumonia and many other manifestations can occur. Endocrinological complications have also been described. Pheochromocytomas are rare tumors located in the adrenal medulla, causing symptoms due to catecholamines overproduction and abrupt release. Catecholamines release can be continuous or intermittent and there can be several triggers including stress, physical exercise and some foods. SARS-CoV-2 infections have not been previously described as a precipitator of adrenergic crisis in pheochromocytoma. We report a case of adrenergic crisis caused by SARS-CoV-2 infection in a patient affected by pheochromocytoma.

Case report

A 63-year-old Caucasian male affected by right adrenal pheochromocytoma waiting for surgical removal was admitted to the emergency department (ED) for fainting episode and hypertensive crisis. Patient was known for type 2 diabetes and hypercholesterolemia treated by slow-release metformin 500 mg/day and atorvastatin 40 mg/day and was not vaccinated for SARS-CoV-2. Two months before, he was hospitalized in another center formyocardial infarction with non-obstructive coronary arteries and a chest-abdomen CT scan showed a 1.5 cm right adrenal mass. The 24-h urinary metanephrines were >5000 µg/24h and normetanephrines >2500 µg/24h. Scintigraphy with 250MBq ^{123}I-MIBG showed uptake in the right adrenal gland formation, consistent with pheochromocytoma. Patient was started on alpha-blockers (Doxazosin 2 mg twice/day). Two weeks later, patient was also started on metoprolol 50 mg twice/day. In the ED, BP was 210/108 mmHg with a HR of 105 bpm. A routine nasopharyngeal swab for SARS-COV-2 was performed. After administration of 2 mg of doxazosin and 20 mg of nifedipine, symptoms addressed to catecholamine release disappeared. As the nasopharyngeal swab resulted positive for SARS-COV-2, the patient was transferred to infectious diseases unit. Since mean BP was persistently high, doxazosin was increased to 4 mg twice/day, with beneficial effect on BP and HR. After 10 days, the patient tested negative for SARS-CoV-2 and was discharged, with normal vital parameters and indication to continue the new increased dosage of doxazosin. No other crisis was reported until surgery, that was performed without any complication.

Discussion

Since adrenergic crisis is a life-threatening condition, we suggest close BP monitoring and therapeutic adherence in patients with pheochromocytoma waiting for surgery, living in areas characterized by outbreak of Covid-19 infection. In case of infection, we suggest considering an increase in alpha-blocker dosage in order to prevent crisis.

WBC count. A potential tool for suspecting Cushing's syndrome (CS)

Miguel Paja Fano[1,2], Ignacio Merlo-Pascual[1], Josune Rodríguez-Soto[1], M. Dolores Moure-Rodríguez[3], Andoni Monzón-Mendiolea[1], Nerea Egaña-Zunzunegui[4], Cristina Elías-Ortega[4], Elena Cruz-Iglesias[5] & Amelia Oleaga-Alday[1]
[1]OSI Bilbao-Basurto, Basurto University Hospital, Endocrinology, Bilbao, Spain; [2]Basque Country University (UPV-EHU), Medicine, Spain; [3]OSI Ezkerraldea-Enkarterri, Cruces University Hospital, Endocrinology, Barakaldo, Spain; [4]OSI Donostia, Donostia University Hospital, Endocrinology, Donostia, Spain; [5]OSI Bilbao-Basurto, Basurto University Hospital, Biochemistry. Hormonal Lab, Bilbao, Spain

Early diagnosis of CS could reduce the morbidity and mortality associated with endogenous hypercortisolism. Many clinical methods have been proposed to establish suspicion of CS, but they show a poor positive predictive value (PPV) and are sometimes difficult to assess. Assuming the well-known influence of hypercortisolism on white blood cell (WBC) count, we evaluated its potential usefulness as a screening test to trigger this suspicion. We analysed WBC count around the diagnosis of CS patients (cases) and compared them in a 1:2 ratio with age- and sex-matched controls who had undergone a negative Nugent's test (plasma cortisol <1.8 µg/dl after 1 mg DXM). We evaluated the predictive value of haematological parameters by applying ROC curves and tried to find a reference value to establish the suspicion of CS. We collected 72 confirmed CS cases and 144 matched controls from three centres. Mean age was similar (48.5 vs 48 years), both groups included 82% women. Controls had a higher mean BMI than cases (36 vs 29.2; $P<.001$). There was no significant difference in the incidence of diabetes (27.8% in controls and 31.9% in cases) and there was a significant higher prevalence of hypertension in cases than in controls (61.1% vs 37.5%; $P=.001$). The rate of active smoking showed no difference between the two groups. Mean WBC count, neutrophil count and percentage were significantly higher in cases, while mean lymphocyte count and percentage were significantly lower in cases than in controls. ROC curves showed an AUC greater than 0.7 for total WBC count, neutrophil count and percentage, lymphocyte count and percentage, and for the difference of total WBC count minus lymphocytes, the difference of both WBC subtypes (neutrophils minus lymphocytes) and the neutrophil/lymphocyte ratio. The two highest levels of discrimination were obtained with the ratio of neutrophil to lymphocyte count (N/L) and the percentage of lymphocytes, which both had an AUC equal to 0.865. The combination of an N/L ratio greater than 2.73 and a lymphocyte percentage less than 25% gave a sensitivity of 77.8% and a specificity of 80.5% for detecting CS, with a PPV of 66.7%. In conclusion, a simple assessment of white blood cell count could be a valuable and inexpensive clue to the suspicion of Cushing's syndrome. Its routine application in patients with metabolic syndrome could lead to increased detection of CS in endocrinology clinics and reduce the burden of late diagnosis of this disease.

Screening for non-classic congenital adrenal hyperplasia revisited: proposal for a new serum 17-hydroxyprogesterone threshold for which a cosyntropin stimulation test is indicated

Afif Nakhleh[1,2], Leonard Saiegh[1,3], Lia Supino-Rosin[4], Raya Gendelman[5], Naim Shehadeh[1,2] & Moshe Zloczower[2]

[1]Maccabi Healthcare Services, Diabetes and Endocrinology Clinic, Haifa, Israel; [2]Rambam Health Care Campus, Institute of Endocrinology, Diabetes and Metabolism, Haifa, Israel; [3]Bnai Zion Medical Center, Department of Endocrinology, Haifa, Israel; [4]Maccabi Healthcare Services, Central Laboratory, Rehovot, Israel; [5]Rambam Health Care Campus, The Endocrinology Laboratory, Haifa, Israel

Introduction
The 250 μg cosyntropin stimulation test (CST) is used to diagnose non-classic congenital adrenal hyperplasia (NCCAH). The current recommendation to perform CST is when follicular morning 17-hydroxyprogesterone (17OHP) is higher than 6 nmol/L, and CST is considered positive for NCCAH diagnosis when the 60-minutes post-CST 17OHP serum level is above 30 nmol/L. These cut offs are mainly derived from radioimmunoassay (RIA) data. Recently, a validated enzyme-linked immunosorbent assay (ELISA) has widely replaced RIA in the measurement of serum 17OHP. This study aimed to determine the RIA and ELISA-based 17OHP cut offs at which CST should be performed.
Material and methods
We conducted a retrospective cohort study at Maccabi Healthcare Services, an Israeli Health Maintenance Organization (HMO). Data was retrieved from adult females (≥16 years) with suspected NCCAH, referred for CST during 2001–2020. Clinical indications that led to NCCAH testing were hirsutism, irregular menses, acne, alopecia, or infertility. NCCAH was defined as post-CST 17OHP serum level >30 nmol/L. Serum 17OHP levels were assayed by direct RIA (Wizard gamma counter, Perkin-Elmer) from January 2000 through March 2015, and by ELISA (IBL International, Tecan) from April 2015 to December 2020. We allocated the individuals into two groups according to the assay method used. For each group, a ROC curve was generated and optimal pre-CST 17OHP threshold with the highest sensitivity and specificity determined.
Results
Cosyntropin testing was performed in 2409 female subjects (1564 in the RIA and 845 in the ELISA groups). The mean (±SD) age was 24.1±7 years. NCCAH was diagnosed in 74 (4.7%) of the RIA group and 63 (7.5%) of the ELISA group. The mean (±SD) pre- and post-CST 17OHP levels were lower in the RIA group as compared to the ELISA group (4.1±6.4 vs. 5.9±9.0 and 9.9±15.3 vs. 12.3±17.3, respectively, $P<0.0001$). Using ROC analysis, the optimal pre-CST 17OHP cut off values predicting NCCAH were 6.05 nmol/L in the RIA group (sensitivity 93.2%, specificity 91.7%) and 8.16 nmol/L in the ELISA group (sensitivity 93.7%, specificity 92.3%). When the guideline-recommended pre-CST 17OHP cut off value of 6 nmol/L was used in the ELISA group, sensitivity was 95.2%, and specificity decreased to 84%.
Conclusions
Our study showed a significant number of unnecessary cosyntropin tests. The optimal RIA-based pre-CST 17OHP cut off was comparable with that recommended in the guidelines. However, the results suggest adopting a higher 17OHP cut off when using ELISA. Further studies that incorporate genetic data are needed.

Almost half of patients using inhaled corticosteroids have secondary adrenal insufficiency

Vishal Batheja[1], Neeru Mittal[2] & Jubbin Jagan Jacob[3]
[1]Christian Medical College & Hospital, Department of Medicine, Ludhiana, India; [2]Christian Medical College & Hospital, Department of Respiratory Medicine, Ludhiana, India; [3]Christian Medical College and Hospital, Department of Endocrinology, Ludhiana, India

Context
Secondary adrenal insufficiency (SAI) has been identified in over 22% of adults using inhaled corticosteroids (ICS).[1] This has been co-related with the total daily dose and type of ICS along with individual genetic susceptibility among the subjects using ICS.[1,2] Our recent paper suggested that 2.8% of adults with euvolaemic hyponatremia admitted to the hospital had ICS related SAI.[3]
Objective
To determine prevalence of SAI among chronic users of ICS in India along with determining the association of SAI with the type and total daily dose of ICS and baseline clinical clues to the presence of SAI.
Methods
Adult patients using ICS for over 4 weeks were included after informed consent from among patients seen in medical and respiratory clinics of a tertiary care hospital in India. Critically unwell patients, those who received oral or intravenous steroids in the past 6 months and those already having SAI were excluded. Baseline ICS dose and type were converted to fluticasone dose equivalents as per National Asthma Education Expert panel and classified as having high (>1gm/day), moderate (0.5-1gm/day) or mild(<0.5gm/day) exposure.[4]Baseline demography and presence of symptoms suggestive of SAI was recorded. An Acton Prolongatum™ Stimulation test (APST) was done on all patients to evaluate SAI.[5] A cut-off cortisol value of <18 mg/dL after 60 min of APST was used to diagnose SAI.
Results
Seventy-five patients (F43:M32) with a mean age of 54.9±15 years were included and underwent APST testing. Among them 34 (45.3%) had SAI. There was no difference in the prevalence of SAI with type or dosing of ICS (1.0±0.4 vs. 1.1±0.4gm/day p-value=0.2). Clinically patients with asthma (52.9%) had more SAI than those with chronic obstructive airway disease (23.5%) (p-value=0.04). Among symptoms those with baseline nausea had more prevalent SAI (9.7% vs.29.4%, p-value=0.03). There was a suggestion that longer use of ICS (3.3±3.5 vs 4.7±3.7 years, p-value=0.07) was associated with more SAI.
Conclusion
Among patients who are on long-term ICS around 45% have SAI, which may require appropriate replacement during stressful periods. Clinically patients with chronic asthma, those with longer use of ICS and those who have nausea may be more likely to have SAI. The dose and type of ICS was not associated with the presence of AI.

Evaluation of a tertiary centre specialist adrenal MDT: The first 900 patients

Louisa Child[1], Rebecca Sagar[2], Sheila Fraser[3], Emma Collins[3], Russell Frood[3], Andrew Scarsbrook[3] & Afroze Abbas[2]
[1]University of Leeds, School of Medicine, Leeds, United Kingdom; [2]Leeds Teaching Hospitals Trust , Leeds Centre for Endocrinology and Diabetes, Leeds, United Kingdom; [3]Leeds Teaching Hospitals Trust, Leeds, United Kingdom

Background
Adrenal incidentalomas are common amongst the general population, incidence increases with age. Radiological and biochemical assessment of all lesions >1 cm is standard practice to determine appropriate future management, as per current European guidelines. We report the experiences of a recently formalised adrenal multi-disciplinary pathway in a large UK teaching hospital, where all adrenal incidentalomas are referred and systematically assessed.
Methods
902 patients presenting with an adrenal incidentaloma discussed at a multi-disciplinary team (MDT) meeting over 2.5 years were retrospectively reviewed. Data were collected on demographics, imaging, biochemistry and where relevant diagnosis, surgical outcome and histopathology. Functional testing included overnight dexamethasone suppression tests, aldosterone, plasma renin activity and plasma metanephrines. Prism v9.3.1 was used for statistical analysis.
Results
Of the 902 patients, 47% were male. Mean age was 64 years ± 14 (SD). 865 patients had some form of functional testing, of which 45% had initial results suggestive of endocrine hypersecretion. 899 had imaging available, 82.7% had unilateral lesions with 64.1% found within the left adrenal gland. Mean lesion size 2.9 cm±2.4 (range 0.6-21 cm). Mean Hounsfield Units was 4.88±15.7. 39.8% of ONDST performed had an unsuppressed cortisol (greater than 50nmol/l). 21.2% of plasma metanephrine tests performed were elevated above the normal reference range. From the entire cohort, 5.6% were diagnosed with phaeochromocytoma, 3.7% with primary aldosteronism, 9.2% had mild autonomous cortisol secretion, 2.1% had adrenal cortical carcinoma and 0.9% had paraganglioma.

Other diagnoses include metastases, lymphoma and haemorrhage. There was an overall mortality of 5.8% over the follow-up period (1-3 years).
Conclusion
Our results demonstrate a very high proportion of patients with incidental adrenal nodules have abnormal endocrine functional testing. ONDST in particular had a high positivity rate. There are significant confounders to most of these tests, with the likelihood some results will be false positives. Therefore, multidisciplinary expertise is crucial for appropriate interpretation and determination of further assessment in every case. This systematic multi-disciplinary approach to incidental adrenal nodules has led to earlier detection of a large number of phaeochromocytomas, patients with primary aldosteronism and malignancy, who may have not otherwise been referred in our centre.

Proposition of the first histopathological classification of primary bilateral macronodular adrenal hyperplasia (pbmah) and its correlation with armc5 and kdm1a status

Florian Violon[1,2], Lucas Bouys[1,3], Anna Vaczlavik[1,3], Giannone Gaetan[1], Annabel Berthon[1], Bruno Ragazzon[1], Benoît Terris[2], Mathilde Sibony[1,2] & Jerome Bertherat[1,3]
[1]Institut Cochin, Equipe Génomique et Signalisation des Tumeurs Endocrines, Paris, France; [2]Hôpital Cochin, Service de Pathologie, Paris, France; [3]Hôpital Cochin, Service d'Endocrinologie, Paris, France

Introduction
Primary Bilateral Macronodular Adrenal Hyperplasia (PBMAH) is a rare cause of ACTH-independent Cushing syndrome. It is characterized by the development of supracentimetric nodules resulting in increased adrenal volume and weight. Its presentation is clinically, radiologically and biologically heterogeneous. Morphological descriptions of PBMAH are rare. Although the initial description highlights that multinodular hyperplastic adrenal glands are made of a majority of spongiocytic cells with some eosinophilic cell isles, later descriptions based on a few cases only, did not mention any morphological variation. The identification of inactivating pathogenic variants of *ARMC5* in 2013 and of *KDM1A* in 2021, argues for a genetic heterogeneity. This work aimed to describe the microscopic characteristics of a series of PBMAH and determine if morphological heterogeneity might correlate with the genetic profile.
Methods
35 PBMAH patients operated by adrenalectomy at Cochin Hospital between 1998 and 2021 whose genetic status was known. All slides were reviewed by two independent pathologists, without knowledge of the patients' genetics. Immunohistochemistry included DAB2, HSD3, Cyp17 and inhibin. DNA sequencing on multiple nodules from 25 of these patients was performed by Illumina NGS.
Results
Four morphological subtypes are identified: two subtypes with nodular architecture (with nodules within macronodules) referred as subtype 1 and 2, and two subtypes with few nodules: subtype 3 and 4. Subtype 1 consists of a majority of spongiocytic cells and eosinophilic cells (10–30%) that forms isles or bands. Subtype 2 has a higher proportion of eosinophilic cells ($>30\%$), mixed with spongiocytic cells. Subtype 3 is composed mostly of spongiocytic cells with less than 10% eosinophilic cells. Subtype 4 is composed of numerous ($>40\%$) oncocytic cells. Their immunohistochemical profile is also heterogeneous. NGS identifies somatic events in *ARMC5* and *KDM1A* mutated patients. The study of correlations between morphological data and genetic status showed that 14 out of the 17 patients classified in subtype 1 are harboring pathogenic variant in *ARMC5*gene whereas the subtype 2 is exclusively composed of 4 *KDM1A* mutated tissues. Subtypes 3 and 4 are seen in patients without known mutation. These correlations are statistically significant: $P < 0.0001$ (Fisher test).
Conclusion
The study of this series allowed us to propose four different morphological groups, in favor of a histopathological heterogeneity. Two of these subtypes correlated with the presence of specific germline mutations. The anatomopathological examination of PBMAH based on architectural analysis and cell quantification represents an advance in the classification of adult nodular adrenal hyperplasia.

The accuracy of adjusted unconventional indices for the assessment of selectivity and lateralization of adrenal vein sampling in the subtype diagnosis of primary aldosteronism

Martina Bollati[1], Mirko Parasiliti-Caprino[1], Fabio Bioletto[1], Filippo Ceccato[2], Chiara Lopez[1], Maria Chiara Di Carlo[1], Giacomo Voltan[2], Denis Rossato[3], Giuseppe Giraudo[4], Carla Scaroni[2], Ezio Ghigo[1] & Mauro Maccario[1]
[1]City of Health and Science University Hospital, University of Turin, Department of Medical Sciences, Endocrinology, Diabetes and Metabolism, Turin, Italy; [2]University-Hospital of Padua, Department of Medicine DIMED, Endocrinology Unit, Padua, Italy; [3]City of Health and Science University Hospital, University of Turin, Radiology Unit, Turin, Italy; [4]City of Health and Science University Hospital, University of Turin, Surgery, Turin, Italy

Objective
This study aimed to evaluate the performance of simple and clinical/imaging-corrected unconventional indices in predicting the selectivity of adrenal vein sampling (AVS) and the lateralization of aldosterone hypersecretion in patients with primary aldosteronism (PA).
Methods
Data of all consecutive patients with a proven diagnosis of PA who underwent AVS for subtype differentiation in two Italian referral centers were analyzed retrospectively. All patients with confirmed unilateral aldosterone hypersecretion underwent adrenalectomy. For the assessment of lateralization, only bilaterally selective AVS were considered.
Results
AVS was bilaterally selective in 112/144 patients. Unilateral disease was diagnosed in 60 cases (53.6%), whereas idiopathic hyperaldosteronism was diagnosed in 52 individuals (46.4%). The aldosterone index, calculated as the ratio between aldosterone in the adrenal vein and aldosterone in the peripheral blood, showed a high accuracy in predicting selectivity using a cortisol selectivity index of 1.1 as the reference standard, and a moderate accuracy when compared to a cortisol selectivity index cut-off of 2 and 3. The simple aldosterone index also demonstrated a moderate accuracy in predicting ipsilateral and contralateral aldosterone hypersecretion. The monoadrenal index, calculated as the aldosterone-to-cortisol ratio in the adrenal vein, revealed a high accuracy in predicting ipsilateral disease and a high accuracy in predicting contralateral disease, whereas the monolateral index, calculated as the aldosterone-to-cortisol ratio in the adrenal vein vs. peripheral blood, revealed moderate accuracy in predicting ipsilateral disease and high accuracy in predicting contralateral disease. Lesion-side and hypokalemia corrected ROC curves for these unconventional indices revealed a significant improvement in the prediction of ipsi/contralateral disease. For a more straightforward clinical application, we calculated the adjusted cut-offs of covariate-corrected indices in an explicit form, for all possible combinations of lesion side at imaging and presence/absence of hypokalemia, according to the Youden's criterion and using an optimized specificity. Finally, the comparative aldosterone index, calculated as the ratio between aldosterone in the dominant vs the non-dominant vein, showed a high accuracy in the assessment of lateralization.
Conclusions
In the present study, we demonstrated a satisfactory accuracy of unconventional indices in predicting selectivity and lateralization of aldosterone hypersecretion in the setting of AVS, which became even higher after correction for hypokalemia and lesion side at imaging. After an external validation, these indices may become a useful tool in interpreting AVS results for the subtype diagnosis of PA, thereby allowing the selection of patients for adrenalectomy, when standard indices cannot be performed.

Characterization of molecular pathway alterations in Cushing's Syndrome

Sharmilee Vetrivel[1], Ru Zhang[1], Ali Khan[2], Andrea Osswald[1], Martin Reincke[1], Silviu Sbieria[2] & Anna Riester[1]
[1]Medizinische Klinik und Poliklinik IV, , LMU Klinikum, Ludwig-Maximilians-University, Munich, Germany; [2]Department of Internal Medicine I, Division of Endocrinology and Diabetes, University Hospital, University of Würzburg, Würzburg, Würzburg, Germany

Context
Transcriptomic based characterization of signaling pathways in the adrenals of different subtypes of Cushing's syndrome.
Patients
For preliminary NGS analyses, a total of 27 adrenal samples were used. The cohort consisted of the following patient groups: Cortisol producing adenoma (CPA, $n=9$), primary bilateral macronodular adrenal hyperplasia (PBMAH, $n=10$). The adjacent normal adrenal tissue from pheochromocytoma patients ($n=8$) served as controls. For QPCR validation, the patient groups included: Cushing's disease (CD, $n=8$), ectopic Cushing's syndrome ($n=3$). Controls included adrenal tissues of aldosterone producing adenoma ($n=10$) and normal adrenals from patients who underwent kidney surgery ($n=10$).
Methods
Next-generation sequencing was performed in the 27 adrenal samples (Illumina HiSeq). Bioinformatic analyses was done by R to identify significantly differently expressed genes between the groups. For pathway mapping bioinformatic tools (ShinyGO and Gprofiler) were used. The significant genes related to the respective pathways were validated by real-time reverse transcription-qPCR.
Results
With reference to transcriptomic data PBMAH was found to have the most dysregulated genes compared to Controls ($n=5394$) and CPA ($n=248$). Pathway mapping using the significantly altered genes gave neuronal synaptic signalling pathways and PPARG (peroxisome proliferator-activated receptor- gamma) signalling pathway as top hits in the groups of PBMAH and CPA. Validation of the pathway genes identified PPARG (l2fc < -1.5) and its related genes - FABP4 (l2fc < -5.5), PCK1 (l2fc < -2.1), PLIN1 (l2fc < -4.1) and ADIPOQ (l2fc < -3.3) to be significantly downregulated ($P<0.005$) in CS subtypes - CPA, CD and PBMAH in comparison to the controls. The in vitro mechanistic characterization of this pathway in cortisol production using adrenal cell lines is in process.
Conclusion
This study investigated for the first time PPARG pathway, which plays a critical physiological role in lipid and glucose metabolism, in cortisol regulation and found a significant downregulation of the pathway in the adrenals of CS patients.

Salivary profiles of cortisol and cortisone in patients with primary adrenal insufficiency under replacement therapy: a pilot study

Lorenzo Tucci[1,2], Valentina Vicennati[1,2], Matteo Magagnoli[2,3], Giacomo Colombin[1,2], Kimberly Coscia[1,2], Laura Rotolo[1,2], Flaminia Fanelli[2,3], Uberto Pagotto[1,2] & Guido Di Dalmazi[1,2]
[1]S. Orsola-Malpighi Polyclinic, Bologna, Italy; [2]Alma Mater Studiorum - Università di Bologna, Bologna, Italy; [3]CRBA, Bologna, Italy

Background
Evaluation of steroid replacement therapy (SRT) in adrenal insufficiency (AI) is challenging for the lack of reliable parameters. Measurement of salivary cortisol and cortisone emerged as a non-invasive tool for AI management, however poorly investigated.
Aim
To analyse the cortisol and cortisone circadian rhythm in normal controls (NC) and patients with primary AI (PAI) under different SRTs, and to identify useful biomarkers.
Methods
We evaluated 24 NC and 30 PAI under hydrocortisone (HC) ($n=8$), cortisone acetate (CA) ($n=14$), and dual-release HC (DRHC) ($n=8$), with equivalent-HC doses of 13.2 mg/m^2, 15.8 mg/m^2, and 14.6 mg/m^2, respectively. SRT was taken at 07:00 (all patients) and between 13:00-16:00 (mean 15:13, patients under HC and CA). We collected 9 saliva samples throughout a day at 7:00 (before therapy), 7:30, 10:00, 12:30, 14:00, 16:00, 19:30, 21:00, and 23:00 for cortisol and cortisone measurement by liquid-chromatography tandem-mass spectrometry (LC-MS/MS). We performed cosinor analysis, and calculated area under the curves (AUCs) and percentual variation from NC values (V%). Due to oral contamination from drug intake, we evaluated cortisol for patients under CA and cortisone for those under HC and DRHC. Patients with PAI completed the following questionnaires: quality of life (AddiQol-30), Hospital Anxiety and Depression Scale (HADS) and Pittsburgh Sleep Quality Index (PSQI).
Results
Compared to NC, AUCs between 14:00 and 23:00 were higher in CA ($P=0.001$) and HC ($P<0.001$), while similar in DRHC ($P=0.12$). In the same period, V% was lower under DRHC (-28%) than CA (+128%; $P=0.001$) and HC (+90%; $P=0.001$). Cosinor analysis showed comparable mesor, but delayed acrophase ($P=0.002$ for HC; $P=0.026$ for DRHC; $P=0.027$ for CA) and batiphase ($P=0.002$ for HC; $P=0.023$ for DRHC; $P=0.027$ for CA), compared to NC. The number of time points with salivary steroid levels within the range derived from NC was higher in DRHC than CA ($P=0.002$) and HC ($P=0.005$). Between 07:00 and 10:00, patients with PAI showed a similar percent increase in salivary steroids among different SRT groups, which was higher than NC ($P<0.001$ for all comparisons). AddiQol-30, HADS and PSQI were comparable among PAI.
Conclusion
Salivary cortisol and cortisone showed a higher excursion in the morning (all patients) and an increased glucocorticoid exposure in the afternoon/evening (patients under HC and CA), than NC. Although DRHC provides better glucocorticoid exposure than HC and CA, significant differences with NC were observed. Salivary cortisol and cortisone levels and AUC may be useful tools for SRT management in PAI.

Progression of atherosclerosis after the menopause and the role of circulating Amyloid Beta 1-40

Irene Lambrinoudaki[1], Elena Armeni[1], Dimitrios Delialis[2], Georgios Georgiopoulos[2,3], Simon Tual-Chalot[4], Nikolaos Vlachogiannis[4], Raphael Patras[2], Evmorfia Aivalioti[2], Areti Augoulea[1], Nikolaos Tsoltos[1], Anastasia Soureti[1], Konstantinos Stellos[4] & Kimon Stamatelopoulos[2]
[1]National and Kapodistrian University of Athens, 2nd Department of Obstetrics and Gynecology, Aretaieio Hospital, Athens, Greece; [2]National and Kapodistrian University of Athens, School of Medicine, Department of Clinical Therapeutics, Athens, Greece; [3]School of Biomedical Engineering & Imaging Sciences, Rayne Institute, St. Thomas' Hospital, London, United Kingdom; [4]Biosciences Institute, Vascular Biology and Medicine Theme, Faculty of Medical Sciences, Newcastle University, Newcastle upon Tyne, United Kingdom

Background
A large body of evidence is supporting that the incidence of adverse cardiovascular events is increasing signfiicantly after the menopausal transition. Primary prevention practices continue to propose evolving algorithms, in an attempt to accurately estimate the actual female cardiovascular risk at midlife. Irrespectively of these attempts, considerable unrecognized cardiovascular disease (CVD) risk remains unexplained, beyond traditional risk factors (TRFs) . On the other hand, a growing body of evidence is suggesting the potential role of a proatherogenic peptide, thecirculating amyloid β 1-40 (Aβ1-40). This peptide may serve as a novel biomarker in CVD.
Aim
This study aimed to explore the role of plasma Aβ1-40 and its patterns of change over time in the progression of structural atherosclerosis in postmenopausal women.
Methods
This prospective study recruited a total of 152 postmenopausal women without history or symptoms of CVD, consecutive outpatients in the Menopause Clinic of Aretaieion Hospital, National and Kapodistrian University of Athens, Greece. Baseline assessment consisted of measuring anthropometric and demographic parameters, obtaining fasting blood samples, performing carotid high-resolution ultrasonography. Blood samples were used to measure Aβ1-40, by enzyme-linked immunosorbent assay. Follow-up assessment was performed after a median follow-up of 28.2 months, during which a repeat assessment of subclinical atherosclerosis through sonographical studies was performed
Results
At baseline, the sum of maximal wall thickness in all carotid sites (sumWT) as well as the values of carotid bulb intima-media thickness (cbIMT) associated independently with high Aβ1-40 ($P < 0.05$). Levels of Aβ1-40 levels appeared to increase over time, and were also associated with decreasing renal function. Accelerated progression of cbIMT and maximum carotid wall thickness and sumWT ($P < 0.05$ for all) was observed for women with a pattern of increasing or persistently high Aβ1-40 levels after adjustment for baseline Aβ1-40 levels, TRFs, and renal function ($P < 0.05$ for both).

Conclusion
The results of our study provide novel insights into a link between atherosclerosis progression in menopause and the time-related pattern of change in values of Aβ1-40. More specifically, the rate of progression of subclinical atherosclerosis was associated with persistently high Aβ1-40 levels or persistently high values, irrespective of the baseline levels. Further research is required to clarify the value of monitoring Aβ1-40 values, as a possible atherosclerosis biomarker in middle-aged women without clinically overt CVD.

Heat shock protein 60 and Endothelial function in postmenopausal women

Elena Armeni[1], Anastasia Soureti[1], Areti Augoulea[1], Asimina Chondrou[1], Demetrios Rizos[2], George Kaparos[3], Dimitrios Delialis[4], Spyros Stefos[1], Lasthenis Angelidakis[4], Alexandros Sianis[4], Aggeliki-Maria Dimopoulou[4], Andreas Alexandrou[1], Stavroula Baka[5], Leon Aravantinos[1], Kimon Stamatelopoulos[4] & Irene Lambrinoudaki[1]
[1]National and Kapodistrian University of Athens, 2nd Department of Obstetrics and Gynecology, Aretaieio Hospital, Athens, Greece; [2]National and Kapodistrian University of Athens, Hormonal Laboratory, Aretaieion Hospital, Athens, Greece; [3]National and Kapodistrian University of Athens, Biochemical Laboratory, Aretaieion Hospital, Athens, Greece; [4]National and Kapodistrian University of Athens, Department of Clinical Therapeutics, Athens, Greece; [5]National and Kapodistrian University of Athens, Biochemical Laboratory, Athens, Greece

Background
Heat shock protein 60 (HSP60), a potentially homeostatic antigen, has been shown to be involved in physiological and non-physiological conditions. Experimental data is supporting the role of HSP60 in placental and mitochondrial steroidogenesis. Under stress conditions, HSP60 are translocated into the endothelial-cell plasma membrane and the extracellular space, promoting the atherosclerotic process.
Aim
We decided to investigate the association between HSP60 and endothelial-cell function in postmenopausal women, considering the possible atherogenic effect of androgenic hormones.
Methods
This study included a total of 160 apparently healthy postmenopausal women. Exclusion criteria were treatment for hypertension or dyslipidaemia, menopause hormone therapy during the last 6 months, previously diagnosed peripheral vascular disease or cardiovascular disease. Fasting venous blood samples were obtained for biochemical, hormonal assessment and evaluation of HSP60. Sonographical assessment of flow mediated dilation (FMD) took place immediately thereafter in one session.
Results
Univariate analysis showed log-HSP60 values differed between women with FMD lower vs higher than the median 5.12% (low vs high FMD, HSP60 values: 2.01 ± 1.16 ng/ml vs 3.22 ± 1.17 ng/ml, p-value = 0.031). Multivariable analysis showed that LogHSP60 was associated with FMD (b-coefficient = 0.244, p-value = 0.031), adjusting for traditional cardiovascular risk factors. Further adjustment for HOMA-IR and testosterone or DHEAS rendered the result non-significant. In the multivariable analysis, DHEAS was associated with FMD (b-coefficient = -0.199, p-value = 0.039), adjusting for cardiovascular risk factors.
Conclusion
The results of this study indicate an association between androgens and endothelial function, independent of HSP60 molecules, in women with low insulin resistance and androgenicity. Further prospective studies are needed to explore the significance of our findings.

Adrenal lesions - the importance of a careful evaluation

Daniela Dias[1], Inês Figueiredo[2], Cristina Duarte[2], Fllipa Serra[1], Carlos Leichsenring[3], Isabel Távora[4], João Paulo Fernandes[5] & Inês Sapinho[1]
[1]Hospital CUF Descobertas, Endocrinology , Lisbon, Portugal; [2]Hospital CUF Descobertas, Internal Medicine, Lisbon, Portugal; [3]Hospital CUF Descobertas, Surgery, Lisbon, Portugal; [4]Hospital CUF Descobertas, Imagiology, Lisbon, Portugal; [5]Hospital CUF Descobertas, Hematology and Oncology, Lisbon, Portugal

Most differential diagnoses of unilateral adrenal lesions include non-functional adenoma, adrenocortical carcinoma or pheochromocytoma. Primary adrenal lymphoma(PAL) is an extremely uncommon type of primary extranodal non-Hodgkin's lymphoma(<1%). Most cases are bilateral (~75%), being unilateral PAL scarcely reported. The apparent unilateral involvement of this entity at presentation, in the CT scan/MRI may difficult the diagnosis, delaying the start of chemotherapy. We report a case of a bilateral PAL interpreted primarily as a unilateral suspicious adrenal lesion. A 68-year-old(yo) male patient presented to the emergency department with persistent fatigue for 3 months getting worse in the last 3 weeks. His past medical history included type 2 diabetes with macrovascular disease, prostate cancer at 61 yo and active smoking. Physical examination was unremarkable, except for a mild edema in the lower limbs. Laboratory investigations revealed: hemoglobin 13.1g/dL, white blood cell count 4×109/L, D-dimer 2232 ng/ml(<500), LDH 488U/L(85-227), NT-proBNP 636pg/mL(<125). A computed tomography(CT) angiogram of the chest was performed to exclude pulmonary embolism(PE)/COVID-19 infection. A lesion of 139 mm on the left adrenal gland, suggestive of a mass or hemorrhage was observed. No signs of PE were evident. The patient was hospitalized for further investigation. Hormonal evaluation revealed: ACTH 37.8 pg/mL(<46), serum cortisol 20 mg/dL, 24-hour urine cortisol levels were slightly increased with 437 mg/24h(28-213), aldosterone and total urinary metanephrines were normal, except for a slightly increased normetanephrine of 545 mg/24h(<444). An abdominal MRI confirmed a large neoformative lesion on the left adrenal gland of 140 mm. The patient underwent left adrenalectomy and nephrectomy. Histology revealed a diffuse large B-cell lymphoma, non-germinal centre B-cell. Staging 18F-FDG PET/CT scan showed intense 18F-FDG 14 mm uptake in the right adrenal gland(SUVmax 5.7). He received 6 cycles of R-CHOP(rituximab-cyclophosphamide, doxorubicin, vincristine and prednisone) chemotherapy. The follow-up 18F-FDG PET/CT scan performed at the end of the treatment revealed no evidence of tumor. Thus, this case illustrates the difficulties found in the diagnosis of PAL and draws attention to consider it as a differential diagnosis during evaluation of adrenal masses. In this case, an adrenalectomy was performed given the presence of unilateral large adrenal mass and the possibility of an adrenal carcinoma, leading to a delay in treatment initiation. Furthermore the absence of adrenal insufficiency commonly associated with bilateral adrenal lymphomas was absent. It is noteworthy that the staging 18F-FDG PET/CT scan revealed uptake in the other non-operated adrenal gland that was not evident after chemotherapy, making obvious the diagnosis of a bilateral PAL.

Presenting clinical features of Cushing's syndrome and non-classic hypercortisolism

Elisa Delle Donne[1], Chiara Parazzoli[1], Vittoria Favero[1], Iacopo Chiodini[2,3], Valentina Morelli[3] & Carmen Aresta[3]
[1]University of Milan, Department of Medical Biotechnology and Translational Medicine, Italy; [2]University of Milan, Department of Medical Biotechnology and Traslational Medicine, Italy; [3]IRCCS Istituto Auxologico Italiano, Department of Endocrine and Metabolic Diseases, Italy

Background
The Endocrine Society Guidelines recommend screening for hypercortisolism especially in patients with specific features that best discriminate Cushing's Syndrome (CS): easy bruising, facial plethora, proximal myopathy and striae. Clinical experience suggests that these features, though suggestive of hypercortisolism, are not enough sensitive. Indeed, patients with hypercortisolism frequently manifest primarily less discriminatory cortisol-related features, such as arterial hypertension, diabetes mellitus, weight gain, osteoporosis, defining a hidden form of CS, also defined as "non classic hypercortisolism" (nCH). We conducted a study to retrospectively compare the biochemical and clinical data of patients with hypercortisolism, in CS and nCH forms at their first presentation.
Methods
Fifty-eight adult patients (age 47.7 ± 16.7 years, female/male 50/8) with proven biochemical hypercortisolism referred to our hospital from 2008 to 2021 were included. In all patients we evaluated the clinical features present at their first presentation to our outpatient clinic. The subjects were divided into two groups according to the presence or absence of classic and highly specific presenting symptoms, CS and nCH groups respectively. In all patients we assessed 24-hour urinary free cortisol (UFC), cortisol after 1mg-overnight-dexamethasone (F-1mgDST), the delay between estimated clinical onset and diagnosis, the therapy undertaken, the recovery and/or persistence/recurrence of the disease.

Results
In the whole sample, hypertension was the most frequent feature present at presentation (18.2% of all presenting symptoms), followed by weight gain (15.6%) and facial plethora (13%). Classic signs of CS accounted for only 25.2% among all presenting symptoms. Twenty-eight patients were classified with CS (48.3%) and 30 with nCH (51.7%). Hypertension and weight gain were the most common features (48% and 41.4%, respectively) without difference between CS and nCH. UFC and F-1mgDST levels were higher in CS patients (625.9 ± 496.3 µg/24h, 18.2 ± 13.5 µg/dl, respectively) than in nCH patients (272.1 ± 261.6 µg/24h, 9.6 ± 7.3 µg/dl respectively, $P < 0.05$ for all comparisons). Notably, hypertension was the most frequent sign in patients with nCH (56.7%) and the second most frequent in CS (39.3%), second only to weight gain (50.0%) in the latter group. Importantly, in all hypertensive patients hypertension was non controlled or resistant or with early onset. Diagnostic delay was three-fold longer for nCH than for CS (5.4 ± 5.6 vs 1.9 ± 1.7 years, $P = 0.003$).
Conclusions
Specific signs of CS are frequently absent at clinical onset of hypercortisolism, most common finding being hypertension. It is crucial for the clinician to recognize potential non-classical features of hypercortisolism which, although non-specific, may present peculiar features and allow a correct diagnosis.

Success rate of adrenal venous sampling in iceland

Hrafnhildur Gunnarsdottir[1,2], Jon Gudmundsson[1], Gudjon Birgisson[1] & Helga Agusta Sigurjonsdottir[1]
[1]Landspitali University Hospital, Reykjavík, Iceland; [2]University of Iceland, Reykjavík, Iceland

Introduction
Primary aldosteronism is an important cause of hypertension. Adrenal venous sampling (AVS) is the gold-standard investigation to determine whether one or both adrenal glands are affected. AVS is a complicated procedure with success rate varying greatly from one hospital to another.
Aims
To investigate the success rate of AVS at Landspitali over a 10-year period and compare it to published results from other hospitals.
Methods
The results from all AVS procedures performed from 2007 throughout 2016 in Landspitali National University Hospital of Iceland were retrospectively reviewed. Landspitali is a tertiary referral center for the whole country. We collected data on serum concentrations of aldosterone and cortisol from both adrenal veins, inferior vena cava and a peripheral vein. All patients were started on synacthen (tetracosactrin) infusion of 93,75 µg/h at least one hour before the AVS. Selectivity index (SI) for each side was calculated by dividing the serum concentration of cortisol from the appropriate adrenal vein by the serum cortisol concentration from a peripheral vein. An AVS was considered successful if serum concentrations of cortisol were five times greater in the adrenal veins than in the peripheral vein, e.g. SI > 5 on both sides.
Results
During the 10-year period, 66 AVS procedures were performed at Landspitali. A total of 57 were successful, which gives a success rate of 86%. Six (9%) AVS procedures gave SI < 5 on the right side only and two (3%) gave SI < 5 on the left side only. One (2%) AVS gave SI < 5 bilaterally. Seven (11%) AVS procedures were repeated due to difficulties cannulating the right adrenal vein. All seven repetitions were successful.
Conclusions
Despite being a small nation, the success rate of AVS at Landspitali, Iceland, is fairly good (86%). The success rate is not far from published numbers from Gothenburg, Sweden, (92%) and Mayo Clinic, Rochester, USA, (96%). All the AVS procedures at Landspitali were performed by the same specialist throughout the study period, which is considered to be the key to this success.

Effects of FSH on endothelial function

Maria Santa Rocca[1], Micaela Pannella[2], Carlo Foresta[3] & Alberto Ferlin[1]
[1]University Hospital of Padova, Department of Medicine, Unit of Andrology and Reproductive Medicine, Padova, Italy; [2]IRCCS Istituto Ortopedico Rizzoli, Regenerative Therapies in Oncology, Bologna, Italy; [3]University of Padova, Department of Medicine, Padova, Italy

Follicle-stimulating hormone (FSH) is a member of the glycoprotein hormone family that plays a pivotal role in ovarian folliculogenesis and spermatogenesis. FSH receptor (FSHR) is, indeed, highly expressed in granulosa and Sertoli cells respectively. However, recent studies have detected FSHR also in extra-gonadal tissues, such as adipose tissue, bone, endometrium, placenta, endothelium, monocytes, and malignant tissues, suggesting, that the activity of this hormone may not be limited to fertility regulation. Although the role of FSH in extra-gonadal tissues is an interesting topic, the effect of FSH in endothelial tissue has been poorly studied and the findings are sometimes discordant, mainly about angiogenic effect of FSH. However, a recent study has observed an increased vascular cell adhesion molecule-1 (VCAM-1) expression in endothelial cells after FSH treatment, suggesting a role of this hormone in the development of atherosclerosis. In this study, we aimed to evaluate the effects of FSH on human umbilical cord vein endothelial cells (HUVEC) as cell model. Wound healing and tube formation assay were performed to investigate respectively cell migration and tube length in cells treated with 5, 25, 50 mUI/ml of rhFSH for 24h and shear stress assay was performed to measure Nitric Oxide (NO) production after 24h of treatment with the same doses of rhFSH. Furthermore, we used Elisa assay to quantify eNOS (endothelial Nitric Oxide Synthase) phosphorylation and Inositol Triphosphate (IP3) production, and Fluo4-probe and immunofluorescence to assess Ca^{2+} level and VE-cadherin localization, respectively. Wound-healing and tube formation assays did not highlight any significant difference, whilst NO production and Ca^{2+} level increased after stimulation with 25 and 50mUI/ml of FSH compared to controls or cells incubated with a low FSH dose (5mUI/ml). Furthermore, eNOS phosphorylation and IP3 increased after stimulation with 50 mUI/ml FSH, suggesting that FSH could exert its biological action via Pospholipase C (PLC)/Ca^{2+}/Protein Kinase C (PKC) pathway. Although NO has a protective role in cardiovascular disease, however, over production of NO could result in a damaging effect on cellular membrane. In fact, immunofluorescence assay showed an anomalous localization of VE-cadherin, an adhesion molecule that is involved in the control of vascular permeability, after stimulation with 50 mUI/ml of FSH. This is the first study showing a putative molecular signaling triggered by FSH in endothelial cells. However, further experiments *in vivo* are necessary to clarify whether perturbation of FSH, similar to the one observed in menopause or hypergonadotropic hypogonadism, may affect endothelial function.

Coagulation parameters in asymptomatic patients with adrenal incidentaloma: is mild autonomous cortisol secretion correlated with thromboembolic risk?

Marianna Minnetti, Ilaria Bonaventura, Valeria Hasenmajer, Dario De Alcubierre, Alessandra Tomaselli, Davide Ferrari, Riccardo Pofi, Alessia Cozzolino, Emilia Sbardella, Andrea Lenzi & Andrea Isidori
Sapienza, University of Rome, Department of Experimental Medicine , Italy

Background
Overt hypercortisolism is highly associated with venous thromboembolism. Patients with Cushing's syndrome (CS) typically show an alteration of the intrinsic coagulation pathway, especially an increase in factor VIII (f-VIII), and increased levels of coagulation inhibitors (i.e., antithrombin III) as a compensatory response. Mild autonomous cortisol secretion (MACS) has been variably associated with higher risk of cardiovascular events and mortality compared to patients with non-functioning adrenal adenomas (NFAA). However, dedicated studies describing coagulation status in these patients are lacking.
Aim
To describe coagulation parameters in patients with MACS compared with patients with NFAA enrolled in the ITACA study (NCT04127552)
Method
56 asymptomatic patients with adrenal incidentaloma without the classic signs or symptoms of overt hypercortisolism were prospectively enrolled. According to post-dexamethasone suppression cortisol values (post-DST), three groups were defined: NFAA (<50 nmol/L), possible MACS [MACS-1] (50 to 138 nmol/L) and MACS [MACS-2] (>138 nmol/L). Coagulation markers (fVIII, fVII, fV, fibrinogen, PT, aPTT, platelets) and coagulation inhibitors (Antitrombin III, Protein C, Protein S) were studied. Patients with an history of thrombosis were excluded.
Results
A total of 24 NFA, 22 MACS-1 and 10 MACS-2 were included in the analysis. No differences in coagulation markers and inhibitors were observed between MACS-1 and NFAA. Mean factor VIII levels were significantly increased in the MACS-2 group (167% ± 54) compared to the NFA group (129% ± 30; $P = 0.021$) and MACS-1 (122% ± 32; $P = 0.012$), respectively. Overall, a positive correlation was found between post-DST, platelets ($r = 0.214$; $P = 0.038$) and antithrombin III ($r = 0.354$: $P = 0.021$).

Conclusions
asymptomatic patients with elevated post-DST (>138 nmol/L) may show early thrombotic alterations, similar to those in patients with symptomatic CS. Coagulation parameters may help to identify patients with adrenal incidentalomas at high risk of thromboembolic events, who could benefit from anticoagulant prophylaxis prior to adrenal surgery.

Management of pheochromocytoma and hyperaldosteronism coexistence

David Veríssimo, Catarina Ivo, Vitória Duarte, Ana Cláudia Martins, Joao Silva, Luis Lopes, Dolores Passos, J Jácome Castro & Mafalda Marcelino
Portuguese Armed Forces Hospital, Endocrinology Department, Lisboa, Portugal

Introduction
Primary hyperaldosteronism (PHA) and pheochromocytoma are endocrine causes of secondary arterial hypertension. The association of hyperaldosteronism and pheochromocytoma is rare and the involved mechanisms are poorly understood. Either there is coexistence of the two diseases (pheochromocytoma with PHA) or the pheochromocytoma stimulates the production of aldosterone.
Case Report
Male, 54 years old, referred to our department for type 2 diabetes and resistant hypertension (SBP>190mmHg and DBP>110mmHg), medicated with lercanidipine 10 mg, azilsartan 40 mg, chlorthalidone 12.5 mg and nebivolol 5 mg. Laboratory evaluation showed: renin <0.2 ng/ml/h (0.2-1.6); aldosterone 26.8 ng/dL (1-16); renin/aldosterone ratio 134 (<30); K+ 3.3 mmol/L (3.5-5.5); high urinary metanephrines (metanephrine 474 µg/24h (64-302); normetanephrine 1013 µg/24h (162-527); 3-Methoxytyramine 345 µg/24h (30-434)) and a negative chromogranin A. A saline infusion test was conducted, with serum aldosterone 9.5 ng/dL after 4 hours. Therapy with spironolactone was started, with a good response (blood pressure 130/80 mmHg), suggesting the diagnosis of PHA. Abdominal CT without contrast revealed bilateral adrenal gland lesions: a single nodule in the right adrenal gland with 2 cm and spontaneous density of 23 HU; 3 nodules in the left adrenal gland with 1.4 cm (12 HU), 1.3 cm and 1.0 cm (both < 10 HU). Both 123I-MIBG and PET 18F-FDOPA scintigraphy revealed a high uptake in the right adrenal gland. The patient was submitted to a right adrenalectomy, whose histological evaluation confirmed pheochromocytoma without malignancy criteria. The presence of genetic mutations was excluded. After surgery, the patient maintained difficult-to-control high blood pressure, with normal metanephrine measurement, and a captopril test was conducted which confirmed PHA (aldosterone reduction of 3%). He was medicated with eplerenone 50 mg/day, maintaining an adequate blood pressure since then.
Discussion
The simultaneous occurrence of pheochromocytoma and PHA is rare, with only 15 cases described in the literature. In the present case, due to the bilaterality of the lesions, the surgical treatment focused on the pheochromocytoma. Although the literature describes cases in which hyperaldosteronism resolves after removal of the pheochromocytoma, in this report it persisted, suggesting the presence of a contralateral aldosterone-producing adenoma.

Behavior of metastatic paragangliomas and pheocromocytomas: experience from a single center

David Veríssimo[1], ines damasio[2], Ana Gomes[3], Joana Simões-Pereira[2], Sara Donato[2] & Valeriano Leite[2]
[1]Hospital das Forças Armadas, Serviço de Endocrinologia, Portugal; [2]Instituto Português de Oncologia de Lisboa Francisco Gentil, EPE, Serviço de Endocrinologia, Portugal; [3]Hospital de Santa Maria, CHULN, EPE, Serviço de Endocrinologia, Diabetes e Metabolismo, Portugal

Paragangliomas (PGL) and pheochromocytomas (PHEO) are rare neuroendocrine tumors with an estimated prevalence of 1:6500 and 1:2500, respectively. Although most PGL/PHEO are benign, approximately 10% of PHEOs and 15-35% of PGLs have metastatic disease, which it is main cause of death, with 6 years of median survival. Objective: To characterize the metastatic PHEOs and PGLs from a single center. Methods: Retrospective analysis of clinical records of patients with metastatic PHEO or PGL diagnosed from 2000 to 2022. Results: We identified 23 patients, 52.2% male, median age at diagnosis was 38 years (Δ8-77) and at metastasis diagnosis 40 years (Δ12-77). The median follow-up was 4 years (Δ0-17). A total of 8 PHEOs and 23 PGLs (30.4% multifocal) were identified. PGLs were located in the head and neck ($n=8$, 35%), abdomen ($n=8$, 35%) and mediastinum ($n=7$, 30%). The median tumor size was 50mm (Δ 20-160mm). The most frequent complaints were hypertension (39.1%), tachycardia (17.4%), hyperhidrosis and headache (13%); 13% were asymptomatic. A functional profile was detected in 56.5%. The majority of primary tumors ($n=19$, 82.6%) underwent surgery. Regarding germline mutations, 43.5% had a mutation in *SDHB* gene, 4.3% in the *SDHD*; in 52.2% mutations were not detected. Bone was the main site of secondary deposits ($n=17$, 73.9%), followed by lymph nodes ($n=16$, 69.2%), liver ($n=8$, 34.8%), lung ($n=6$, 26.1%) and kidneys ($n=1$, 4.3%). Multifocal metastases were identified in 13 patients (56.5%). Metastases were present at diagnosis in 6 cases (26.1%). Metastases-directed therapies were radiotherapy in 60.9% ($n=14$), ^{131}I-MIBG in 26.1% ($n=6$), surgery in 21.7% ($n=5$), chemotherapy in 21.7% ($n=5$), tyrosine kinase inhibitors (TKI) in 17.4% ($n=4$), peptide receptor radionuclide therapy (PRRT) in 17.4% ($n=4$) and chemoembolization in 8.7% ($n=2$). Multimodality approaches were used in 47.8% ($n=11$). Surgery obtained a remission rate of 80%. After radiotherapy 50% had disease progression, 30% stability, 5% partial response and 5% remission. PRRT achieved 50% of disease stability and 50% of progression. After chemotherapy 80% progressed and 20% showed partial response. All the patients progressed after ^{131}I-MIBG, TKI and chemoembolization. Median estimate survival from diagnosis was 14 years and from metastases diagnosis was 11 years, with 39.1% death rate.
Discussion
Metastases location is similar to what is described in the literature. Metastatic disease treatment is challenging due to the low response rate of approved treatments, with the surgical approach offering the best remission rate.

A single dose of Neutrophil Elastase inhibitor Elafin does not alter CBG cleavage during post-surgical stress in humans *in vivo*

Luke D Boyle[1], Mark Nixon[1], Caroline Underhill[2], Lesley A Hill[2], John G Lewis[3], Geoffrey L Hammond[2], Oliver Wiedow[4], Peter A Henriksen[1], Roland H Stimson[1] & Brian R Walker[5]
[1]The University of Edinburgh, Centre for Cardiovascular Science, Edinburgh, United Kingdom; [2]The University of British Columbia, Department of Cellular & Physiological Sciences, Vancouver, Canada; [3]Canterbury Health Laboratories, Steroid & Immunobiochemistry Laboratory, Christchurch, New Zealand; [4]University of Kiel, Department of Dermatology, Kiel, Germany; [5]Newcastle University, Faculty of Medical Sciences, Newcastle upon Tyne, United Kingdom

Introduction
Corticosteroid Binding Globulin (CBG) binds >85% of plasma cortisol and modulates free cortisol levels. Observations *in vitro* show that CBG is cleaved by neutrophil elastase (NE), a mechanism proposed to reduce CBG binding affinity and increase free cortisol availability to inflamed tissues. However, detection of cleaved CBG *in vivo* in human plasma is controversial, and any influence of NE on CBG cleavage has not been tested *in vivo*. We hypothesised that the endogenous NE inhibitor elafin reduces CBG cleavage and thus free plasma cortisol. We tested this in humans using coronary artery bypass graft (CABG) surgery as a model of acute neutrophil-mediated inflammation.
Methods
In a randomised double-blind placebo-controlled parallel group clinical trial, 35 patients undergoing CABG surgery were randomised 1:1 to intravenous elafin 200 mg or saline placebo administered after induction of anaesthesia. Blood samples were taken at baseline (time 0, skin incision) and 2, 6 and 24 hours postoperatively. We measured elafin (LC-MS); plasma elastase activity (fluorometric assay); IL-6, TNF-alpha, NE and CBG (all ELISAs); CBG binding capacity (radioligand-saturation assay); total cortisol (LC-MS) and free cortisol (isotopic dilution and ultrafiltration). Data were analysed as area under the curve from 0-24h or by two-way ANOVA.
Results
With placebo, NE increased from baseline 91.4 ± 10.0 to peak 894.4 ± 108.4 ng/ml at 2h, accompanied by increased IL-6 and TNF-alpha. Elafin infusion resulted in >1000-fold higher plasma concentrations than those of endogenous elafin, with marked reduction in elastase activity (mean $AUC_{0\text{-}24}$; 3.83 ± 1.99 vs 8.04 ± 2.97 units/mL). Plasma CBG concentrations fell >30% between 0-2h in both treatment groups, then remained unchanged to 24h; this was mirrored by reduced binding capacity, unaffected by elafin. Total cortisol rose dramatically, a fourfold increase between 2-6h in both groups. Free cortisol fraction doubled over 0-6h from 16.4 ± 0.44 to 30.7 ± 6.1 % in placebo, while elafin tended to

increase free cortisol concentration (mean difference 24.3 nM, 95% CI -1.33 to 49.9, $P=0.062$).
Discussion
The fall in plasma CBG and increase in total and free cortisol during CABG surgery is in keeping with published studies in humans during sepsis. We also noted an increase in cytokines which downregulate hepatic CBG production. However, we did not find evidence that the fall in CBG is mediated by increased cleavage by NE. Further studies are needed to assess any effects on CBG cleavage of NE inhibition in target tissues or more potently in serum.

Ang-Tie pathway in adrenocortical tumors angiogenesis

Sofia Oliveira[1], Sofia Pereira[1], Madalena M. Costa[1], Mariana P Monteiro[1] & Duarte Pignatelli[2,3,4]
[4]Abel Salazar Biomedical Sciences Institute - University of Porto, Porto, Portugal; [2]Instituto de Investigação e Inovação em Saúde (I3S) , University of Porto Portugal, Cancer , Porto, Portugal; [3]Faculdade de Medicina da Universidade do Porto - FMUP, Porto, Portugal; [4]Hospital de São João, Endocrinology, Porto, Portugal

The majority of adrenocortical tumors (ACT) are benign and hormonally non-functioning, in contrast to adrenocortical carcinomas (ACC), which are rare and usually very aggressive tumors. The differential diagnosis between these two entities is mainly based on unspecific and subjective criteria, contributing to the inaccuracy of diagnosis. Due to ACC molecular and biological heterogeneity, prognostic factors have a limited capacity to predict ACC clinical outcomes, leading to an inappropriate therapeutic strategy. Angiogenesis is a well-recognized hallmark of cancer. As a dynamic and a complex multistage mechanism, various signaling pathways regulate the growth and maintenance of blood vessels, such as the vascular endothelial growth factor (VEGF) and Ang-Tie pathways. This study aimed to evaluate the role of the VEGF and Ang-Tie pathways in ACT angiogenesis, in order to identify molecular markers that may contribute to the diagnosis and/or prognosis of ACC. The ACT studied included ACC ($n=22$), adrenocortical adenomas (ACA) with Cushing's syndrome ($n=8$) and non-functioning ACA ($n=13$). For each sample, the expression of proteins involved in angiogenesis, namely CD34, VEGF, VEGF-R2, Ang1, Ang2, Tie1 and Tie2, were analyzed by immunohistochemistry. The percentage of the stained area for each protein was quantified using a morphometric analysis tool, except for VEGF. CD34, Ang1 and Ang2 expression was found to be significantly different between benign and malignant ACT. ACC presented lower CD34 expression when compared to ACA, whereas Ang1 and Ang2 expression was higher in ACC. Despite the differences observed, none of these proteins demonstrated to be accurate biomarkers for ACT differential diagnosis. Additionally, higher Tie1 expression was observed in ACC of patients with venous invasion and shorter overall survival. As conclusion, this study demonstrated for the first time that the Ang-Tie pathway has a role in ACC angiogenesis. The higher Ang2 levels in malignant ACT could be related with higher vascular permeability, and therefore facilitating tumor dissemination. In addition, the higher Tie1 expression in ACC patients with poor prognosis may represent a possible therapeutic target for ACC.
Finding: This study was funded by the Foundation for Science and Technology (FCT) (PTDC/MEC-ONC/31384/2017).

Prognostic value of endocrine biomarkers in patients admitted to intensive care unit for COVID-19

Emanuele Varaldo[1], Alessandro Maria Berton[1], Andrea Rosata[1], Giorgia Montrucchio[2], Francesca Rumbolo[3], Nunzia Prencipe[1], Ezio Ghigo[1], Luca Brazzi[2] & Silvia Grottoli[1]
[1]University of Turin, Division of Endocrinology, Diabetes and Metabolism, Department of Medical Sciences , Italy; [2]University of Turin, Division of Anesthesia and Intensive Care 1, Department of Anesthesia, Intensive Care and Emergency; [3]University of Turin, Clinical Biochemistry Laboratory, "Città della Salute e della Scienza di Torino" University Hospital Turin

Introduction
To date, there are no clear biochemical parameters to identify early COVID-19 cases at risk of complications in the Intensive Care Unit (ICU).
Aim
To evaluate the prognostic potential of endocrine biomarkers associated with acute inflammatory conditions in ICU patients for COVID-19.
Methods
Between 1/3/2020 and 31/12/2020 we recruited 126 consecutive patients at the admission to ICU 1U, Molinette University Hospital of Turin. Within 24 hours (T1), we calculated: SAPS II (Simplified Acute Physiological Score II), SOFA (Sequential Assessment of Organ Failure) and MuLBSTA (Multinodular infiltration, hypoLymphocytosis, Bacterial co-infection, Smoking history, hyperTension and Age). At T1, at 72 hours (T3) and after 7 days (T7), we measured the plasma levels of copeptin and MR-proADM. Duration of extracorporeal membrane oxygenation (ECMO) and mechanical ventilation (MV), ICU and hospital length of stay (LOS), ICU (IM) and hospital mortality (HM) were recorded. We present the results of the first 69 patients.
Results
53 males and 16 females (median age 63) were enrolled. The ICU and hospital LOS were 13 [6.7-22.2] days and 20 [13-30] days, respectively. The median time free from MV was 1 day. The need for pronation was significantly predicted by a higher MuLBSTA classification (OR 4.01, $P=0.025$). The median duration for ECMO was 17 days. The SOFA score was higher in patients requiring ECMO ($P=0.019$) and performed better when corrected for copeptin at T1 (HR 1.25, $P=0.02$). IM and HM were 62.3% and 68.1% (median survival time 18 and 24 days), respectively. MR-proADM was higher in dying patients with increasing statistical significance over time (T1 1.3 vs 0.91 nmol/L, $P=0.028$; T7 1.77 vs 0.9 nmol/L; $P=0.0001$). The MR-proADM T7/T1 ratio was significantly higher in those who died during hospitalization ($P=0.0003$) predicting HM (HR 1.35, $P=0.025$). SAPS II class at the admission also predicted HM (HR 1.39, $P=0.013$), but correcting for MRproADM (HR 1.43, $P=0.012$) or copeptin measured at T1 improved its statistical significance (HR 1.56, $P=0.003$). Likewise, SOFA score, easier to collect in ICU, significantly predicted HM (HR 1.09, $P=0.041$), but improved its performance if corrected for MR-proADM (HR 1.12, $P=0.019$) or copeptin at T1 (HR 1.11, $P=0.018$). Neither gender, estimated glomerular filtration rate, C-reactive protein, or procalcitonin affected the previous regression analyses.
Conclusions
Endocrine biomarkers evaluated at ICU admission improve the ability of prognostic scores to predict mortality and severe adverse outcomes. The increase in MR-proADM after 7 days of hospitalization in the ICU also predicts hospital mortality.

A novel mutation in creb3l1 gene involved in vasopressin synthesis pathway in patients with hypertensive cardiovascular diseases

Sania Rauf[1,2], Abida Arshad[1], Roger Foo[3], Maleeha Akram[1], Shumaila Naz[2], Afzaal Ahmed Naseem[4], Mazhar Qayyum[1] & Syed Shakeel Raza Rizvi[1]
[1]Pir Mehr Ali Shah Arid Agriculture University Rawalpindi, Department of Zoology, Fisheries and Wildlife, Rawalpindi, Pakistan; [2]University of Wah, Wah Cantt, Pakistan, Department of Biosciences, Wah Cantt, Pakistan; [3]Genome Institute of Singapore (GIS), Singapore, Singapore, Singapore; [4]University of Lahore, Sihala Campus, Islamabad, Islamabad, Pakistan

Arginine vasopressin (AVP) is a neurohormone, which regulates blood and extracellular fluid volume and hence blood pressure (BP). AVP has its chief action in kidneys where it reduces flow of urine, increases permeability of convoluted tubules of kidneys to water and its reabsorption. It binds to receptors on sweat glands and decreases water loss by perspiration from the skin. Also, AVP binds to peripheral arteriolar receptors, causing vasoconstriction and increase in BP. The synthesis of vasopressin occurs in paraventricular and supra-optic nuclei of the hypothalamus. The mRNA encoding AVP is translated into preprohormone that is delivered into endoplasmic reticulum with concomitant signal peptide removal. The resulting prohormone is folded and delivered to Golgi apparatus where the precursor is cleaved and post-translationally modified into mature hormone. The newly synthesized neurohormone is packed in granules in Golgi complex, which move down the axons, through the stalk, to the posterior pituitary, where AVP is stored and released in response to appropriate stimuli. The main physiological stimulus for release of AVP is an increase in osmotic pressure in circulating blood. AVP causes retention of water by kidneys, which reduces plasma osmolality. The transcription factor cAMP responsive element-binding protein 3 like 1 (CREB3L1) is an important component for cellular homeostasis, particularly within cell types with high peptide secretory capabilities. CREB3L1 serves an important role in body fluid homeostasis through its transcriptional control of AVP gene. In this study, hypertensive cardiovascular patients were screened using whole exome sequencing (WES) to find possible pathogenic mutations in different genes of AVP pathway. Thirteen hypertensive cardiovascular patients from three families (3 patients in 1st from 21-48; 5 in 2nd from 43-72 and 5 patients in 3rd from 19-47 years of age) were

selected for WES. Genomic DNA was extracted (DNA Isolation Kit from QIAamp DNA mini Kit) at Department of Biosciences, University of Wah, Wah Cantt, Rawalpindi, Pakistan. DNA obtained was taken to Genome Institute of Singapore (GIS), Singapore, where final dilutions of 25µl DNA were outsourced to Proteomics Lab, Macrogen Asia Pacific, Singapore for WES. Subsequent bioinformatics analysis was performed at GIS, Singapore. The results identified a novel homozygous splice region variant (1524-1A>G) in *CREB3L1* gene in all patients. In addition, a novel heterozygous splice region variant (340-2_340-1insCCC) was also identified in *SEC63* gene in 10/13 patients. In conclusion, we report novel mutations in two genes involved in AVP synthesis pathway in our patients with hypertensive cardiovascular diseases.

Whole exome sequencing of genes involved in dysfunctional renin-angiotensin-aldosterone system in hypertensive cardiovascular patients

Sania Rauf[1,2], Abida Arshad[1], Roger Foo[3], Maleeha Akram[1], Shumaila Naz[2], Afzaal Ahmed Naseem[4], Mazhar Qayyum[1] & Syed Shakeel Raza Rizvi[1]

[1]Pir Mehr Ali Shah Arid Agriculture University Rawalpindi, Department of Zoology, Fisheries and Wildlife, Rawalpindi, Pakistan; [2]University of Wah, Wah Cantt, Pakistan, Department of Biosciences, Wah Cantt, Pakistan; [3]Genome Institute of Singapore (GIS), Singapore, Singapore, Singapore; [4]University of Lahore, Sihala Campus, Islamabad, Islamabad, Pakistan

The renin-angiotensin-aldosterone system (RAAS) is an endocrine system within the body that is essential for regulation of blood pressure (BP) and fluid balance. The system is mainly comprised of three hormones renin, angiotensin II (Ang II) and aldosterone. The RAAS pathway is initiated in the kidney with the proteolytic conversion of liver derived angiotensinogen to angiotensin I (Ang I) by renin secreted by juxtaglomerular apparatus of the nephron. Ang I is cleaved by angiotensin converting enzyme to produce Ang II, the physiologically active component of the system. Ang II acts on the adrenal cortex through its receptors, AT-1 and AT-2, to stimulate the release of aldosterone. Aldosterone is a mineralocorticoid, a steroid hormone released from the zona glomerulosa of the adrenal cortex and plays a central role in regulation of BP mainly by acting on distal tubules and collecting ducts of the nephron, increasing reabsorption of sodium and water in the kidney and secretion of potassium. Increase in water retention causes increase in the blood volume and hence BP. In this study, whole exome sequencing (WES) was used to identify pathogenic mutations in different genes of RAAS pathway, whose dysfunction may lead to hypertension and related cardiovascular diseases. Thirteen hypertensive cardiovascular patients from three families (3 patients in 1st from 21-48, 5 in 2nd from 43-72 and 5 in 3rd from 19-47 years of age) were selected for WES. Genomic DNA was extracted (DNA Isolation Kit from QIAamp DNA mini Kit) at University of Wah (UOW), Wah Cantt, Rawalpindi, Pakistan. DNA obtained was taken to Genome Institute of Singapore (GIS), Singapore, where final dilutions of 25µl DNA were outsourced to Proteomics Lab, Macrogen Asia Pacific, Singapore for WES. Subsequent bioinformatics analysis was performed at GIS, Singapore. Our results revealed pathogenic mutations in different routes of RAAS pathway; gene mutations in *DGKB* in all 13 patients, *NCOR2* in 12 patients, *ESRRA* in 10 patients, *SEC63* in 10 patients, *RYR3* in 3 patients of 2 families and *CAMKK2* in 1 patient. Novel variants were identified in *NCOR2*, *SEC63* and *CAMKK2* genes. Missense variants were found in *RYR3* and *ESSRA* genes, splice region variants in *DGKB* and *SEC63* genes and frameshift variants were identified in *NCOR2* and *CAMKK2* genes. All the variants were found to be heterozygous except *NCOR2* gene. In conclusion, our results identified non-synonymous mutations in 6 genes involved in different steps of RAAS pathway in patients with hypertensive cardiovascular diseases.

Objective

Glucocorticoid-induced adrenal insufficiency is highly prevalent, but the clinical consequences are not fully understood. Therefore, the indication of adding stress dosages of glucocorticoid during ongoing anti-inflammatory glucocorticoid treatment remains unclear. The aim of this study was to determine the impact of adrenal function on health-related quality of life (HRQoL) in patients receiving ongoing low-dose prednisolone treatment.

Methods

Cross sectional study of 181 patients treated >6 months with prednisolone for rheumatoid arthritis (RA) ($n=103$), polymyalgia rheumatica/giant cell arteritis (PMR/GCA) ($n=47$) or renal transplantation (RTx) ($n=31$). Patients received ongoing prednisolone treatment, median dose 5 mg/day (range 2.5-20 mg) and were not routinely advised to increase the dose during intercurrent illness or stress. Adrenal function was assessed by ACTH test. HRQoL was evaluated during ongoing prednisolone treatment with SF-36v2 scales *General Health* and *Vitality*, AddiQol total score (not RA patients), *Fatigue* VAS scale (PMR/GCA cohort), and self-reported hospital admissions and doctor's appointments. Analyses of the impact of stimulated P-cortisol on HRQoL controlling for underlying disease were performed in i) all patients and ii) 128 patients receiving low-dose treatment (≤5 mg/day), respectively.

Results

Adrenal insufficiency was found in 41% of patients (35% low-dose patients). Overall, *General Health*, *Vitality,* and AddiQol scores were not associated with stimulated P-cortisol. Mean total AddiQol score was 62.5 (SD 7.7). There was a trend for more medical contacts with lower stimulated P-cortisol (1.17 hospital admissions/year/-100nmol/L, CI95%:-0.05–2.23, $P=0.061$) and (1.11 doctor's appointments/year/-100nmol/L, CI95%:-0.14–2.36, $P=0.083$). In the PMR/GCA subcohort, *Fatigue* VAS score was higher with lower stimulated P-cortisol (4.8mm/-100nmol/L, CI95%:0.9–8.7, $P=0.017$) and *General Health* and *Vitality* tended to be lower (GH:-3.78 points/-100nmol/l, CI95%:-7.16–-0.40, $P=0.029$) (VT:-3.96 points/-100nmol/l, CI95% -8.38–0.45, $P=0.077$). However, low-dose patients had higher *Vitality* with lower stimulated P-cortisol (3.12/-100nmol/L, CI95%:0.17–6.07, $P=0.038$).

Conclusion

Glucocorticoid-induced adrenal insufficiency was associated with fatigue and reduced *General health* in the PMR cohort and a trend for more doctor's appointments/admissions in the whole cohort, but otherwise poorly associated with HRQoL during ongoing prednisolone treatment. Results can reflect poor HRQoL consequences of glucocorticoid-induced adrenal insufficiency during ongoing (low-dose) prednisolone treatment or insufficient sensitivity of HRQoL instruments with long recall periods rather than daily symptom monitoring during situations of stress.

Laboratory evidence of hyperaldosteronism is common in patients with kidney stones – a retrospective single-center analysis

Andrej Skoberne[1] & Mojca Jensterle Sever[2]

[1]Department of Nephrology, Ljubljana, Slovenia; [2], Department of Endocrinology, Diabetes and Metabolism, Ljubljana, Slovenia

Background

Kidney stones have been linked to chronic kidney disease and a higher probability of adverse cardiovascular events. Precise mechanisms that lead to these complications have not yet been elucidated. Most cases of kidney stones are idiopathic, related to metabolic disturbances like hypercalciuria, which often have a genetic background. There have been few reports of kidney stones associated with primary hyperaldosteronism (HA); however, the prevalence of HA in patients with kidney stones has not been fully examined.

Methods
We conducted a retrospective single-center study that included 181 patients evaluated for recurring kidney stones in whom basic laboratory tests to identify HA (plasma renin activity – PRA, plasma aldosterone concentration – PAC, and aldosterone to renin ratio – ARR) had been performed. The aim of the study was to assess the prevalence of laboratory evidence of HA (LEHA) in kidney stone patients and to identify clinical and laboratory characteristics associated with LEHA in this group of patients.
Results
The prevalence of LEHA was high. High ARR was identified in 39.8% patients, while a concurrent high PAC was identified in 21.5% ($>$ 0.41 nmol/l) and 13.8% ($>$ 0.55 nmol/l) of all patients. Arterial hypertension (AH) was identified in only about a quarter of patients with LEHA and the prevalence of LEHA was similar in patients with or without AH. Patients with LEHA and AH, particularly when associated with high PAC ($>$ 0.55 nmol/l), exhibited some characteristic features of primary HA like lower serum potassium and higher serum bicarbonate. Patients with LEHA and without AH did not exhibit these features; however, they had higher serum phosphate associated with a trend towards lower urine phosphate excretion, a feature not present in patients with LEHA and AH. Patients with LEHA and AH were also older and tended to have their first stone event at a later age, while patients with LEHA and without AH had more stone-related urological procedures. An extremely low PRA value ($<$ 0.07 μg/l/h) was present in 8.3% patients and was associated with a faster rate of decline in kidney function on follow-up.
Conclusions
Our study shows that LEHA can be common in patients with recurring kidney stones. Few of these patients present with typical features of primary HA. There are some distinct features of patients with LEHA and without AH, that could represent a separate phenotype in this population. The biological relevance of these findings is yet to be determined.

Brain Structure in a cohort of young adult patients with Autoimmune Addison's Disease

Annelies van't Westeinde[1], Nelly Padilla[1], Sara Ström[2,3], Olle Kämpe[4], Sophie Bensing[2,3] & Svetlana Lajic[1]
[1]Karolinska Institute, Women's and Children's Health, Sweden; [2]Karolinska Institute, Molecular Medicine and Surgery, Sweden; [3]Karolinska University Hospital, Endocrinology, Sweden; [4]Karolinska Institute, Medicine (Solna), Center for Molecular Medicine, Sweden

Background
Both cortisol and other adrenal hormones are well known to affect brain structure and function throughout development. Due to destruction of the adrenal cortex, patients with Autoimmune Addison's disease (AAD) lack production of adrenal hormones and therefore receive lifelong replacement of cortisol and aldosterone, and, for some female patients dehydroepiandrosterone (DHEA). However, replicating the natural rhythm of secretion is difficult, and patients are often exposed to either supra- or infra- physiological adrenal hormone levels. Such long-term hormonal disturbances might be expected to affect the brain on both a structural and functional level. Assessing brain structure in patients with AAD is relevant, as varying treatment-regimes may have detrimental effects on the brain and could lead to problems with cognitive function and mood. The present study therefore investigated grey and white matter structure of the brain in a cohort of young adult patients with AAD.
Methods
T1 and DWI Magnetic Resonance Imaging (MRI) of the brain was done on fifty-two patients with AAD and seventy healthy control participants (aged 19-43). A whole-brain exploratory approach was used to compare patients to controls on estimates of global and regional cortical thickness, surface area, cortical grey matter volume, subcortical volumes, hippocampal and amygdalae subfields (FreeSurfer), and white matter microstructure (FSL TBSS).
Results
Apart from reduced volume of the right superior parietal cortex in male patients, there were no differences in any of the estimates between patients with AAD and healthy controls, when correcting for total intracranial volume and multiple comparisons.
Conclusion
Brain structure of patients with AAD seems to be relatively unaffected at this young adult age. This finding is reassuring and suggests the brain is able to cope with disturbances in adrenal hormone levels. Follow-up studies are needed to determine if the brain of patients with AAD may be affected later in life, or by varying treatment regimes, such as immediate or slow-release hydrocortisone medication.

Cortical-sparing adrenalectomy for bilateral pheochromocytoma - is it a game worth the candle? Systematic review with meta-analysis comparing total vs partial adrenalectomy in bilateral pheochromocytoma

Karolina Zawadzka, Piotr Tylec, Piotr Małłczak, Piotr Major, Michał Pędziwiatr & Magdalena Pisarska-Adamczyk
Jagiellonian University Medical College, 2nd Department of General Surgery, Kraków, Poland

Background
Bilateral total adrenalectomy (TA), despite causing persistent adrenal insufficiency with lifetime replacement of corticosteroids, is the method of choice in patients with bilateral pheochromocytoma. Partial adrenalectomy (PA) is an alternative approach that aims to balance tumor removal while maintaining adrenal function, although the oncological completeness of the procedure is questionable.
Objective
The aim of this systematic review and meta-analysis was to compare bilateral total adrenalectomy and partial (cortical-sparing) adrenalectomy.
Methods
A bibliographical search of databases (MEDLINE, EMBASE, Scopus, Web of Science, CENTRAL) as well as registers of clinical trials (ClinicalTrials.gov, European Trials Register, WHO International Trials Registry Platform) was conducted in order to identify eligible studies. The databases and registries were searched from inception until August 14, 2021, and no language restrictions or dates were imposed. Both randomised controlled trials and observational studies comparing TA with PA in adults with bilateral pheochromocytoma were considered for inclusion in this study. The primary outcomes were the risk of pheochromocytoma recurrence and steroid dependence. The secondary outcomes of interest were: time to recurrence after surgery, development of metastatic pheochromocytoma, incidence of adrenal crisis, morbidity, overall mortality and pheochromocytoma-specific mortality.
Results
Twenty five retrospective observational studies including 1444 patients were eligible. During follow-up, every third patient after PA required steroid supplementation: RR 0.32, 95% CI: 0.26–0.38, $P < 0.00001$, $I^2=21\%$. Patients undergoing partial adrenalectomy had lower risk of developing Addisonian-like crisis: OR 0.3, 95% CI: 0.1–0.91, $P=0.03$, $I^2=0\%$. On the contrary, PA was associated with higher risk of reccurence than TA: OR 3.72, 95% CI: 1.54-8.96, $P=0.003$, $I^2=28\%$. We found no difference between PA and TA groups in the development of metastatic pheochromocytoma: OR 1.47, 95%CI: 0.48-4.44), $P=0.5$, $I^2=0\%$, overall mortality: OR 1.04, 95% CI: 0.47-2.33, $P=0.92$, $I^2=0\%$, as well as pheochromocytoma-specific mortality: OR 0.54, 95% CI: 0.08–3.72, $P=0.53$.
Conclusions
Patients undergoing partial adrenalectomy had a three-fold lower risk of developing steroid dependence and developing an adrenal crisis, but had a higher risk of recurrence. Thus, partial adrenalectomy may be worth considering in some patients with bilateral pheochromocytoma only with careful lifelong follow-up. Our findings are based on limited certainty evidence, and further well-designed, multi-center studies are required to confirm the benefits and drawbacks of both approaches.

Inflammation in Hypertensive Patients with Type 2 Diabetes on Stable Therapy with Non-dipper and Dipper Status

Lolita Matiashova & Ganna Isayeva
L T Malaya Therapy National Institute of the National Academy of Medical Sciences of Ukraine, Department of Comprehensive Risk Reduction for Chronic Non-Communicable Diseases, Kharkiv, Ukraine

Background
Hypertension has a negative effect on the cardiovascular system, but the data are limited about the connection between non-dipper hypertension and inflammation in patients with type 2 diabetes (T2D) and without.
Aim
To study the effects of dipper and non-dipper hypertension with and without type 2 diabetes on inflammatory factors.
Methods
The cross-sectional study included 97 hypertensive patients (57 men) without type 2 diabetes and 85 hypertension patients with type 2 diabetes median age 56,5 (45.00 ÷ 63.70) years old. All patients had been on stable antihypertensive and anti-hyperglycemic therapy during the last three months and had target ambulatory blood pressure at the moment of inclusion to the study. Daily blood

Table 1 The mean and standard deviation of day systolic (SBP) and diastolic (DBP) blood pressure, mm Hg in patients with type 2 diabetes (T2D) and without

	Day SBP	Day DBP	Daily SBP	Daily DPB	Night SBP	Night DBP
Dipper ($n=44$)	128.3∓15.7	76.0∓10.0	132.3∓15.4	79.14∓10.2	114.3∓16.4	65.9∓8.9
Non-Dipper ($n=53$)	128.4∓17.4	74.2∓9.4	130.0∓16.0	75.2∓8.8	123.6∓18.3	71.4∓10.6
Dipper with T2D ($n=40$)	131.8∓13.9	81.9∓8.1	134.8∓14.7	84.6∓9.2	121.1∓21.5	72.8∓11.0

pressure monitoring was done to all patients with Heaco ABPM50 monitoring. Fasting glucose (FG), blood lipids, creatinine, uric acid, high sensitive C-reactive protein (hCRP), and interleukin 1 beta (IL-1B) were measured. Physical activity was assessed using the International Physical Activity Questionnaire. Data were analyzed with SPSS IBM 19.0.

Result

According to their night blood pressure, the patients were divided into dipper ($n=84$) and non-dipper ($n=98$). The mean of day and night systolic and diastolic blood pressure according to the group presented in table 1. The mean of hCRP in dipper patients without T2D was 7.7 ∓8.4 and IL-1b 2.3 ∓ 0.5 pg/ml, non-dipper hCRP 11.4∓6.7 mg/L ($P=0.05$) and IL-1b 2.2 ∓ 0.6 pg/mL ($p>0.05$). The mean of hCRP in dipper patients with T2D was 12.2∓7.9 mg/L and IL-1b 2.3 ∓ 0.5 and non-dipper hCRP 10.2 ∓5.5 ($p>0.05$) and IL-1b 2.7 ∓ 0.7 pg/mL ($p>0.05$).

Conclusion

Non-dipper hypertension patients without type 2 diabetes could be an additional risk factor of vascular inflammation. Patients with type 2 diabetes and hypertension have a higher inflammation level, independent of dipper status; future studies are needed.

Gastric monomorphic epitheliotropic intestinal T-cell lymphoma with bilateral adrenal metastases

Eirini Kaliakatsou[1], Athina Markou[1], Labrini Papanastasiou[1], Irini Giagourta[1], Athanasia Kalantzi[1], Anastasia Dimitriadi[2], Michael Lenos[2], Theodora Kounadi[1] & Athanasios Fountas[1]
[1]'G. Gennimatas' General Hospital of Athens, Department of Endocrinology and Diabetes Center, Athens, Greece; [2]'G. Gennimatas' General Hospital of Athens, Department of Pathology, Athens, Greece

Introduction

Monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL), formerly known as type II enteropathy-associated T-cell lymphoma, is a rare and aggressive subtype of lymphoma of the gastrointestinal track typically noted in Asian or Hispanic populations. Adrenal involvement as part of MEITL is extremely rare. Herein we present a patient of Greek origin with MEITL and bilateral adrenal metastases.

Case Presentation

A 74-year-old man presented with a 2-week history of right upper quadrant abdominal pain, decreased appetite and fatigue, as well as weight loss (10 kgs in 8 months). Abdominal CT imaging revealed heterogenous bilateral adrenal lesions (maximum diameter 11 cm on the left and 10 cm on the right, respectively). On clinical examination, there were no signs of cortisol excess, no skin pigmentation, no palpable lymph nodes and the abdomen was soft. Hormonal investigations revealed primary hypocortisolism (basal cortisol: 61 nmol/L, ACTH: 189 pg/ml) and treatment with hydrocortisone was initiated; twenty-four-hour urine metanephrines were normal. Further investigations showed anemia and increased LDH (1365 IU/L, normal values: 134-279), β2-microglobulin (4.99 ng/L, normal values: 0.97-2.64) and inflammation markers (ESR, CRP and ferritin). Primary bilateral adrenal lymphomas were suspected and fine needle biopsy of the left adrenal lesion was performed. Staging CT scans showed no brain or lung metastases but gastric wall thickening and infiltration of the right kidney by the adrenal mass were noted on the abdominal scan. Gastroscopy revealed a mucosal lesion with a micronodular and ulcerated surface which was biopsied. Histology from both the adrenal and the gastric lesions was consistent with MEITL; Ki-67 was positive in approximately 80% of tumor cells. Bone marrow biopsy and aspiration did not show any signs of infiltration by the lymphoma. Treatment with high dose dexamethasone was initiated but the patient rapidly deteriorated. He developed sepsis with multi-organ failure and finally passed away before receiving combined chemotherapy.

Discussion

MEITL is a rare aggressive T-cell lymphoma arising from intestinal intraepithelial lymphocytes with a poor prognosis. Most often it involves the small bowel, particularly the jejunum and ileum, but it can also involve the colon or stomach, like our case. Involvement of the adrenal glands in patients with MEITL is extremely rare. To our knowledge, this is the second report of MEITL with bilateral adrenal metastases. Clinical experience, awareness and a multidisciplinary approach in such perplexing cases is required.

A retrospective evaluation of the utility of overnight dexamethasone suppression tests in over 500 patients evaluated for hypercortisolism

Rebecca Sagar[1], Mohamed Elsabbagh[1], Stephen Gibbons[2] & Afroze Abbas[1]
[1]Leeds Teaching Hospitals Trust, Leeds Centre for Endocrinology and Diabetes, Leeds, United Kingdom; [2]Leeds Teaching Hospitals Trust, Leeds, United Kingdom

Background

Overnight dexamethasone suppression tests (ONDST) are conducted to investigate patients with symptoms suggestive of cortisol hypersecretion or if an adrenal incidentaloma is identified. Cortisol levels of 50 nmol/l and above following ONDST may be related to autonomous cortisol secretion (ACS) and require further investigation. Determining likely presence of ACS is essential given reported associations with type 2 diabetes mellitus (T2DM), obesity, cardiovascular disease and osteoporosis. ONDST are inherently prone to interference and false positive rates are high, often resulting in clinicians conducting multiple ONDST, with associated patient and service impacts. Our study assesses the outcomes from a large UK cohort who underwent ONDST.

Methods

560 unselected patients who underwent ONDST were retrospectively examined. Data were collected on indication, demographics including body mass index (BMI), biochemical results and co-morbidities. A positive ONDST was considered any cortisol greater than or equal to 50nmol/l, further categorised into mild ACS (MACS) between 50-138nmol/l and probable ACS >138nmol/l. Statistical analysis was conducted using Prism v9.3.1.

Results

62% of the cohort were female. Mean age was 57.3 years ±17.1 (SD). Mean BMI was 30.5kg/m^2 ± 7.2. 71.6% had an adrenal lesion as the indication for the test, with a further 16.3% undergoing ONDST for clinical suspicion. 28% had an unsuppressed cortisol on ONDST (greater than or equal to 50nmol/l), of these 6.1% were greater than 138nmol/l. 48% of patients with an unsuppressed ONDST underwent repeat testing with 90.7% of results remaining unsuppressed. 47 patients with unsuppressed ONDST had an ACTH level recorded, 25.5% had an ACTH less than 5ng/l (normal range 5-47ng/l). 89.8% had a HbA1c recorded, with 31.2% having a result greater than 48mmol/mol or known T2DM. BMI did not correlate with suppressed vs unsuppressed cortisol on ONDST. Of the 157 patients with an unsuppressed cortisol, 63.7% had a potential confounder including obesity, diabetes or depression.

Conclusion

Our data demonstrates that there are high rates of unsuppressed cortisol following ONDST. Given the large numbers of patients with adrenal incidentalomas now identified and assessed, this leads to significant increased demand on endocrinology outpatient appointments. We have also shown that repeated ONDST may be unnecessary given greater than 90% remained unchanged, and the majority of patients had a potentially irreversible confounder. Therefore, we would suggest that careful further evaluation of the likelihood of MACS following a positive ONDST, through additional biochemical and clinical investigation but without a repeat ONDST, is required prior to any clinic attendance.

HIF-2α is detrimental for the functioning of the adrenal medulla

Deepika Watts[1], Nicole Bechmann[1,2], Hermine Mohr[3], Anja Krüger[1], Natalia S. Pellegata[3], Graeme Eisenhofer[1], Mirko Peitzsch[1] & Ben Wielockx[1]

[1]Institute of Clinical Chemistry and Laboratory Medicine, University Hospital Carl Gustav Carus, Medical Faculty Carl Gustav Carus, Technische Universität Dresden, , Dresden, Germany; [2]Department of Internal Medicine III, University Hospital Carl Gustav Carus, Technische Universität Dresden, Dresden, Germany; [3]Institute for Diabetes and Cancer, Helmholtz Zentrum München, Neuherberg, Germany

The adrenal gland is a crucial regulator of numerous fundamental biological processes and its hormones are essential for maintaining homeostasis in normal and stressful situations. However, the impact of hypoxia signalling on the function of the adrenal remains poorly understood. During the past years, our research group has focused on enhancing our understanding of hypoxia pathway proteins (HPPs) in the different areas of the adrenal gland. Firstly, we described a crucial role for hypoxia inducible factor-1 α (HIF-1α) during adrenal steroidogenesis (Watts *et al.*, CMLS, 2021) and secondly, we demonstrated that HIF-2α is essential for the synthesis and release of catecholamines. Briefly, HIF-2α stabilization due to loss of prolyl hydroxylase domain protein-2 (PHD2) leads to reduced phenylethanolamine N-methyltransferase (PNMT) activity and consequent epinephrine synthesis. Simultaneously, HIF-2α mediated erythropoietin (EPO) production in renal EPO producing cells (REPCs) stimulated excessive RBC formation (erythrocytosis) leading to hypoglycaemia and increased release of epinephrine from the adrenal medulla (Watts *et al.*, JMM, 2021). Recently, we generated a new set of mouse lines efficiently targeting the HPPs in chromaffin cells to further unravel the impact of HIF-2α -stabilisation during the development of medulla-related tumours. This will provide us with an excellent chance to enhance our current knowledge on potential targets for the therapeutic treatment of pheochromocytomas (PCCs) and paragangliomas (PGLs).

Characterization of angiotensin II-induced dual-specificity MAPK phosphatase gene expression changes in vascular smooth muscle cells

Janka Gém[1], Kinga Kovács[1], András Balla[1,2] & László Hunyady[1,3]
[1]Semmelweis University, Department of Physiology, Budapest, Hungary; [2]MTA-SE Laboratory of Molecular Physiology, Budapest, Hungary; [3]Institute of Enzymology, Research Centre for Natural Sciences, Budapest, Hungary

Angiotensin II (AngII) is an octapeptide hormone, which participates in physiological and pathological mechanisms. AngII exerts a number of biological effects through the type 1 angiotensin II receptor (AT1R). One of the main targets of AngII are vascular smooth muscle and its stimulation activates numerous signaling pathways that cause contraction and could also result in gene expression changes in vascular smooth muscle cells (VSMCs). Next-generation sequencing (NGS) experiments were performed to analyze the effects of AngII stimulation on gene expression in VSMCs. The experiments were conducted using a rat aortic primary isolated VSMC cell line. In our experimental set-up more than 200 genes were upregulated in response to AngII stimulation in VSMCs. The transcriptome analysis revealed the upregulation of several DUSP genes, such as *DUSP 5*, *6*, *10*, *4*, and *14*. We also investigated the kinetics of the gene-expression changes and the signaling pathways involved in AngII-mediated responses. The results of the quantitative PCR measurements also confirmed the increased expression of selected genes upon AngII stimulation. Transcription of most genes was largest two hours after AngII stimulation. Based on our results, the regulation of the studied gene expression induced by AngII is much more complex than we originally thought, due to the multiple signaling pathways that mediate them. We assume that the regulation of expression changes is probably determined by the interaction of the involved signaling cascades. Based on our data, the expression changes of the studied genes can occur through classical $G_{q/11}$ activation, which triggers Ca^{2+}-mediated mechanisms leading to epidermal growth factor receptor transactivation dependent or independent responses. During the search of the signaling pathway(s) which is/are responsible for certain gene-expression changes, we found that dasatinib, an Src-family tyrosine kinase inhibitor, was able to selectively inhibit the AngII induced gene-expression changes. We have also demonstrated that the imatinib, a selective inhibitor of Bcr-Abl kinases, was not able to achieve the similar effect as the dasatinib. Our data suggest that Src-family tyrosine kinase(s) may play an important role in AngII-induced long-term cellular responses. Our data can provide new insight into the physiology of VSMCs in response to AngII stimulation, and better understanding of the mechanism of AT1-R-mediated gene expression changes in primary VSMCs, which may lead to the development of novel types of drugs for the treatment of cardiovascular and other diseases. This work was supported by the National Research, Development and Innovation Fund (NKFI K116954, K139231, VEKOP-2.3.2-16-2016-00002 and NVKP_16-1-2016-0039).

Testosterone, hypogonadism, and heart failure: a systematic and critical review

Elena Di Lodovico[1], Paolo Facondo[1], Andrea Delbarba[2], Letizia Chiara Pezzaioli[1], Filippo Maffezzoni[2], Carlo Cappelli[1] & Alberto Ferlin[3]
[1]University of Brescia, Department of Clinical and Experimental Sciences, Brescia, Italy; [2]ASST Spedali Civili di Brescia, Unit of Endocrinology and Metabolism, Brescia, Italy; [3]UNIVERSITY OF Padova, Department of Medicine, Padova, Italy

Background
Male hypogonadism is defined by low circulating testosterone level associated with signs and symptoms of testosterone deficiency. Although the bidirectional link between hypogonadism and cardiovascular disease has been clarified recently, the association between testosterone and chronic heart failure (CHF) is more controversial.
Methods
We critically review published studies relating to testosterone, hypogonadism, and CHF and provide practical clinical information on the correct diagnosis and treatment of male hypogonadism in patients with CHF.
Results
In general, the published studies are extremely heterogeneous, they frequently have not adhered to hypogonadism guidelines, and they suffer from many intrinsic methodological inaccuracies; therefore, the data have low-quality evidence. Nevertheless, by selecting the very few studies that are methodologically robust, we show that the prevalence of testosterone deficiencies (30-50%) and symptomatic hypogonadism (15%) in men with CHF is significant. Low testosterone correlates with CHF severity, NYHA class, exercise functional capacity, and a worsened clinical prognosis and mortality. The interventional studies on testosterone treatment in men with CHF are inconclusive, but promising in suggesting beneficial effects on exercise capacity, NYHA class, metabolic health, and cardiac prognosis.
Discussion
We suggest that clinicians should measure the testosterone levels of men with CHF who have symptoms of a testosterone deficiency and/or conditions that predispose to hypogonadism, such as obesity and diabetes. These patients - if diagnosed as hypogonadal - could benefit from the short- and long-term effects of TRT, which include improvements to both the cardiological prognosis and systemic outcomes. Further studies with a strong collaboration between cardiologists and endocrinologists are warranted.

Impact of covid-19 on arterial stiffness

Nevin Sadeep, Rakesh Sahay & Neelaveni K
Osmania General Hospital, Endocrinology, Hyderabad, India

Introduction
Recently published research works have concluded that Covid-19 infection will result in endothelial dysfunction or worsen it, especially when associated with comorbidities such as diabetes mellitus. Arterial Stiffness is a manifestation of endothelial dysfunction and it can be used as a prediction parameter as well as a target for therapies aimed at ameliorating endothelial cell dysfunction.
Aims and Objectives
To compare arterial stiffness using carotid-femoral Pulse Wave Velocity (cf-PWV) between subjects with Covid-19 and controls without history of Covid-19. Further cases and controls were further subdivided into those with or without comorbidities such as Diabetes Mellitus, Systemic Hypertension, Chronic Kidney Disease, Coronary Artery Disease & Stroke.
Methodology
This study was designed as an observational, single centre, cross sectional study to be done amongst police personnel from Telangana State Police Force, India by randomly selecting subjects who were willing to give written informed consent, after excluding subjects with chronic inflammatory diseases on chronic steroid therapy and pregnant/lactating subjects. Subjects were further divided into 4 groups. Group A did not have any history of Covid-19 or comorbidities, Group B had history of prior Covid-19 infection but no previous history of comorbidities,

Group C had history of comorbidities but no previous history of Covid -19 and Group D had history of prior Covid-19 infection as well as comorbidities. Arterial stiffness was measured indirectly by measuring carotid femoral-Pulse wave velocity (cf-PWV) with a clinically validated device known as PeriScope® [Genesis Medical Systems, India].
Results
Analysis of 170 age-matched (35years to 58 years) subjects was done using GraphPad PRISM software. The mean increase in cf-PWV was 76.2 cm/s in Group-A, 126.5 cm/s in Group-B, 210.1 cm/s in Group-C & 263.9 cm/s in Group-D. Significant p-values were obtained for the differences in the increase in cf-PWV between the 4 different groups. The Arterial stiffness values of prior Covid-19 positive subjects were found to be higher than the group of subjects without prior Covid-19. The group with comorbidities without Covid-19 had a higher increase in arterial stiffness levels compared to subjects with prior Covid-19 but without other comorbidities. Subjects with history of both Covid-19 as well as comorbidities had the highest levels of arterial stiffness.
Conclusion
Arterial Stiffness levels are elevated significantly after Covid-19 infection and is an indicator of increased cardiovascular risk. Carotid Femoral Pulse wave velocity (cf-PWV) can be considered as an easy non-invasive screening tool in post-COVID patients to identify possible high-risk candidates in day-to-day practice.

P528

The role of neuropeptide Y in the pathogenesis of vasovagal syncope

Zora Lazurova[1], Ivica Lazúrová[2], Peter Mitro[3] & Marcela Popovnakova[4]
[1]University of PJ Safarik, Medical Faculty, 4th Department of Internal Medicine, Kosice, Slovakia; [2]University of PJ Safarik, Medical Faculty, 1st Department of Internal Medicine, Kosice, Slovakia; [3]University of PJ Safarik, Medical Faculty, 1st Department of Cardiology, Kosice, Slovakia; [4]Medirex Laboratory, Department of Immunology, Kosice, Slovakia

Introduction
Vasovagal syncope (VVS) is a transient loss of conscioussness due to hypoperfusion of the brain caused by vasodepressoric and/or cardioinhibitory reflex. In the pathogenesis, a dysregulation of autonomic nervous system is playing an important role. There is a growing evidence about more complex neurohumoral background of VVS. Neuropeptide Y (NPY) is hormone involved in the regulation of blood pressure with potent vasoconstriction effect. Moreover, NPY is also a cotransmitter with noradrenaline in sympathetic nervous system and is considered to be involved in sympathetic-induced vasoconstriction. Other vasoacitve hormones such as endothelin (ET-1) and angiotensin (ANG) can be implicated in pathogenesis of VVS, too.
Aim
The aim of this study was to evaluate the serum levels of NPY before and after head up tilt test (HUTT) and to compare them between patients with tilt induced VVS and group of negative individuals. Second aim was to find a correlation between NPY and other vasoactive hormones – ET-1 and ANG.
Subjects and methods
Altogether 69 subjects were included in this preliminary study (age 39 + 3,2 years; 41 females) with the history of at least one syncope. HUTT was performed in all subjects according to Italian protocol (20 minutes of passive standing followed by 15 minutes lasting phase after provocation by sublingual nitroglycerin). According to the result of HUTT, patients were divided into HUTT-positive (HUTT+) and HUTT-negative (HUTT-) group. Blood samples were collected before and immediately after HUTT. Serum levels of NPY, ET-1 and ANG were evaluated by ELISA method.
Results
HUTT was positive in 60 patients (HUT+ group), 29 subjects were negative (HUT-) . There was no significant difference in basal levels of NPY between HUTT+ and HUTT- group (36.4 + 2.4 vs 40.1 + 1.5 ng/ml, $P = 0.1$, $T = 1.5$). The stimulated levels of NPY were significantly lower in HUT+ patients when compared to HUT- (36.7 + 2.1 vs 44.4 + 3.2 ng/ml, $P = 0.028$, $T = 2.0$). Both subgroups did not differ in ET-1 and ANG levels. Stimulated NPY levels positively correlated with stimulated ET-1 ($P = 0.001$; $R2 = 0.16$) and ANG ($P = 0.04$; $R2 = 0.06$) in all subjects. When divided into HUT+ and HUT-, NPY significantly correlated only with ANG ($P = 0.004$; $R2 = 0.4$) in HUT- group, while in HUT+ patients, there was a positive correlation with ET-1 ($P = 0.0009$; $R2 = 0.23$) found.
Conclusion
The impaired release of NPY may play a role in pathogenesis of VVS. Other vasoconstrictive hormones, such as ET-1 and ANG, can be involved in pathomechanisms, too.

Characteristics of patients with life-threatening events in pheochromocytoma

Sofia-Maria Lider-Burciulescu[1], Monica Livia Gheorghiu[1,2] & Corin Badiu[1,2]
[1]C.I. Parhon National Institute of Endocrinology, Bucure|ti, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucure|ti, Romania

Introduction
Pheochromocytomas and paragangliomas (PPGLs) are rare tumors of the chromaffin tissue characterised by catecholamine excess. Cardiovascular complications, such as hypertensive crisis and catecholamine-induced cardiomyopathy, are known to be the most frequent causes of life-threatening events in PPGLs patients.
Design
We analysed records of patients diagnosed with PPGLs in one referral centre from Romania between 1976 and 2021 ($n = 106$) in order to compare demographics, symptoms, preoperative catecholamine levels, tumor diameter and outcome in patients with life-threatening events vs. patients without complications (control group).
Results
9 patients (8.4%), 8 F, 1 M presented life-threatening events before the diagnosis or during surgery for PPGL: catecholamine-induced Tako-Tsubo cardiomyopathy ($n = 3$); inverted Tako-Tsubo cardiomyopathy and pulmonary edema ($n = 1$); acute coronary syndrome and pulmonary edema ($n = 2$); pulmonary edema ($n = 1$) ; cardiac arrest and pulmonary edema ($n = 1$); pulmonary thromboembolism and feto-placental apoplexy ($n = 1$). Seven patients had the life-threatening event before the diagnosis of PPGL and two of them had the complications during surgery for PPGL. Compared to pheochromocytoma patients without life-threatening events ($n = 97$), patients with severe complications had a nonsignificantly higher mean tumor diameter (53 vs. 48 cm, $P = 0.3$), similar levels of catecholamine (median 5-6 fold ULN; $P = 0.5$), similar age at diagnosis (50 vs. 47 years; $P = 0.51$). The maximum arterial blood pressure before surgery was non-significantly higher in patients with complication (231 vs. 207 mmHg; $P = 0.1$). All patients with complications survived. Patients with Tako-Tsubo cardiomiopathy had normal cardiac function few days after the event. One patient with acute coronary syndrome and pulmonary edema but a background of other cardiac comorbidities had the ejection fraction of 40% after this event. The woman with feto-placental apoplexy had a negative outcome: her baby died in uterus and she underwent hysterectomy at 34 years old.
Conclusion
Although pheochromocytomas are rare tumors, they may induce a life-threatening complications (diagnosed in 8.4% of cases in our series). There was no specific clinical, hormonal or imaging feature that could predict a life-threatening event in patients with PPGLs.

Objective markers and new indicators in adrenal insufficiency- findings from the omni-aid study comparing hydrocortisone and prednisolone replacement therapy

Sirazum Choudhury[1,2], Thilipan Thaventhiran[1,2], Katharine Lazarus[1,2], Tricia Tan[1,2] & Karim Meeran[1,2]
[1]Imperial College London, Department of Metabolism, Digestion and Reproduction, London, United Kingdom; [2]Imperial College Healthcare NHS Trust, Department of Endocrinology, London, United Kingdom

Background
Adrenal insufficiency (AI) is a life-threatening condition if left unmanaged. Despite treatment patients can expect a life expectancy that is shortened by 12 years secondary to probable inherent over-replacement associated with oral glucocorticoid regimens. Thrice-daily hydrocortisone is the most common regimen used. Very low-dose prednisolone (2-4 mg) is an alternative with lower uptake due to the absence of evidence for its use. This study fills this literature gap.
Methods
This is a cross-sectional, observational study that recruited 20 healthy volunteers (HV), 20 AI patients on prednisolone, 20 AI patients on hydrocortisone and 9 patients on anti-inflammatory doses of steroids (mainly IV methyl-prednisolone) for other medical conditions. During stereotyped study visits, subjects provided anthropometric data, blood samples, urine samples and SF-36 data. This was used to assess bone health, cardiovascular risk, diabetic risk, immune cell profiles and subjective health between groups.

Results
There was no significant difference between groups in osteocalcin, P1NP or urinary NTX. Parathyroid hormone was significantly elevated in the hydrocortisone group compared to HV at 8.2(±3.2) vs 6.1(±2.3) pmol/L ($P=0.04$). Calcium and phosphate levels were in the reference range. The waist:hip ratio was significantly lower in HV at 0.83(±0.07) compared to the cohort on hydrocortisone and prednisolone, at 0.90(±0.09) and 0.90(±0.07) respectively ($P=0.009$). High sensitivity-CRP was 1.6(2.1) mg/L compared to 0.8(1.1) mg/L ($P=0.008$) in the hydrocortisone and HV groups respectively. Potassium levels were significantly decreased in the hydrocortisone and high dose groups; 4.0(0.4) mmol/L in both compared to 4.2(0.2)mmol/L in HV ($P=0.005$). Glycaemic markers in both AI groups demonstrated significantly lower fructosamine levels compared to healthy volunteers ($P=0.0008$). The hydrocortisone group had significantly elevated insulin, c-peptide and HOMA-%β compared to HV ($P=0.039$, $P=0.025$, $P=0.025$ respectively). There was no difference in HbA1C levels between groups. Although infection rates were comparable between groups, all steroid groups had significantly elevated neutrophils compared to HV ($P<0.0001$). Monocyte count was significantly elevated in the hydrocortisone cohort at 0.6(0.2) $x10^9$/L vs 0.4(0.2) $x10^9$/L in HV. Flow cytometry showed significant HLA-DR suppression in the monocytes in the high dose group. SF36 data showed impaired energy/fatigue scores in the prednisolone group compared to the healthy volunteers (77.3±(10.2) compared to 58.2(±21.7); $P=0.021$)
Conclusion
The data suggests that hydrocortisone causes greater steroid exposure as assessed by the markers in this study, when compared to healthy volunteers. There are no overt differences between hydrocortisone or prednisolone cohorts. Both medications should be used interchangeably in the treatment of AI.

Long-term efficacy and safety of pasireotide in patients with Cushing's disease: a monocentric experience

Ylenia Alessi[1], Maria Luisa Torre[2], Salvatore Giovinazzo[2], Giuseppe Giuffrida[2], Annalisa Giandalia[2], Rosalinda Casablanca[1], Filippo Flavio Angileri[3], Marta Ragonese[2], Francesco Ferraù[1,2] & Salvatore Cannavò[1,2]
[1]Endocrine Unit, "Gaetano Martino" University Hospital of Messina, Italy; [2]Department of Human Pathology of Childhood and Adulthood "Gaetano Barresi", University of Messina, Italy; [3]Department of Biomedical and Dental Sciences, and Morpho-Functional Imaging, University of Messina, Italy

Pasireotide is the first pituitary-directed approved therapy for Cushing's disease (CD), effective in reducing UFC >50% in about half of patients, and with a good tolerability profile but associated with a relatively high incidence of hyperglicemia. The aim of this study was to evaluate efficacy and safety of long-term treatment with pasireotide (PAS) in patients with CD. Methods: We retrospectively evaluated 17 consecutive patients (11 females) with CD treated with PAS (with a mean follow of 40.4±12.5 months), referred to and followed-up at the Endocrine Unit of the University Hospital of Messina (Italy), from 2013 to 2020. Data are expressed as mean±SD. Age at diagnosis was 34.7±13.0 yrs. Before PAS treatment: all patients underwent transnasosphenoidal pituitary adenomectomy, but surgery was not successful in 10 cases, while disease recurred in the other seven; five patients underwent also radiotherapy; seven patients were administered other medical therapies. Anthropometric, clinical, hormonal and metabolic (glucidic and lipidic profile) parameters were evaluated, along with cardiometabolic CD-related comorbidities, before PAS treatment and at last follow-up visit. Side-effects and adverse events related to treatment were also evaluated.
Results
Before PAS treatment, 47% of patients were obese, 59% were dyslipidemic, 47% had diabetes, and 53% were on antihypertensive treatment. Under PAS treatment, 76% of patients achieved a normalization or ≥50% reduction of UFCxULN from baseline. At last follow-up visit as compared to baseline: body weight, BMI, waist-to-hip ratio, waist circumference, systolic and diastolic blood pressure decreased but were not significantly different (p NS); lipid profile significantly improved (total and LDL cholesterol, p 0.007 and p 0.001 respectively); glycated hemoglobin significantly increased (p 0.02). In terms of safety profile, most common adverse events were related to hyperglycemia and to difficult-to-manage diabetes mellitus (41%), which led to treatment withdrawal in 4 cases. No patient experienced QTc interval prolongation.
Conclusion
Pasireotide is a safe and effective treatment in a significant figure of patients with CD, improving also lipid profile, while frequently causing glucose metabolism alterations which represent a cause of therapy discontinuation.

Covid-19 in patients with hypocortisolism: clinical syndrome, disease duration and glucocorticoid replacement therapy

Chiara Simeoli[1], Serafina Schettino[1], Angelica La Rocca[1], Nicola Di Paola[1], Erminio Massimo Crescenzo[1], Francesco Ciardella[1], Alessandro Mazzarella[1], Claudia Pivonello[1], Annamaria Colao[1,2] & Rosario Pivonello[1,2]
[1]Università "Federico II" di Napoli, Dipartimento di Medicina Clinica e Chirurgia, Sezione di Endocrinologia, Napoli, Italy; [2]Unesco Chair for Health Education and Sustainable Development, Federico II University, Naples, Italy

Coronavirus disease caused by SARS-CoV-2 virus (Covid-19) is associated with a variable clinical syndrome, ranging from a mild-moderate to a severe disease, progressing towards acute respiratory distress syndrome. Hypocortisolism is associated with a depletion of innate immunity and disruption of immune response, which could contribute to an increased risk of infection and development of a severe disease. Glucocorticoid (GC) replacement therapy(GCRT), especially if administered in a non-circadian fashion, may result in immunosuppression favouring infection and disease progression. Sick day rules for GCRT during infections are still largely tailored empirically. The aim of the current study was to investigate clinical syndrome and disease duration of Covid-19, and to evaluate GCRT adjustments, in a cohort of patients with hypocortisolism who developed Covid-19. The study was performed on 20 patients [12F,8M, 16-62 years(39.2±12.5), 11 adrenal insufficiency(AI), 9 congenital adrenal hyperplasia(CAH)], adequately treated with GCs[hydrocortisone equivalent doses, HC-Eq: 10-45 mg/day(27.25±10.09)]. A purpose-built questionnaire was administered by a phone-survey, aimed at assessing Covid-19 signs and symptoms, disease duration, the occurrence of adrenal crises, the need of GCRT adjustment, and intervention for Covid-19 (antibiotics, GCs, oxygen therapy, and hospitalization), as well as persistent clinical syndrome of Covid-19 after the disease cure (Long-Covid). The most frequent symptoms and signs were ageusia(75%), anosmia(70%) and fever(70%). Additional symptoms and signs were myalgia(65%), fatigue(60%), headache(50%), cough(50%), dyspnea(30%), and diarrhea(25%). The disease duration was of 11-49days(25.55±9.71) and no adrenal crises were reported. To manage hypocortisolism, according to general sick day rules, six(30%) patients doubled oral dose of GCRT for 2-28days(11±9.28) and no patients used parenteral GCs. To manage Covid-19, nine(45%) patients received antibiotics for 5-10days(7.22±2.16)[azithromycin 600 mg/daily(55.6%), cefixime 400 mg/daily(22.2%) and amoxicillin-clavulanic acid 1750/250 mg/daily(22.2%)]; four(20%) GCs for 7-17days(10.25±4.71) [methylprednisolone 4 mg/daily(25%), deflazacort 6 mg/daily(25%), betamethasone 1 mg/daily(25%) and prednisone 25 mg/daily(25%), HC-Eq. 20-100 mg/day(41.66±39.01)], but no patients required oxygen therapy or hospitalization. No fatal events were observed over the Covid-19 period. The most frequent Long-Covid symptoms and signs were fatigue(30%), anosmia(15%) and ageusia(10%). No significant differences were observed comparing females and males, as well as AI and CAH patients. In conclusion, patients with hypocortisolism, adequately treated with GCs, display a mild-moderate Covid-19 disease course, mainly characterized by ageusia, anosmia and fever, without severe complications and adrenal crises, and requiring a double dose of oral GCRT in less than one third of cases, different GCs in a minority of cases, and not requiring oxygen therapy and hospitalization, with persistent fatigue, anosmia and ageusia as the most common Long-Covid manifestations.

Renin indicates the mineralocorticoid activity of fludrocortisone: a 6-year study in primary adrenal insufficiency

Filippo Ceccato[1], Marianna Torchio[2], Irene Tizianel[2], Mattia Barbot[2], Chiara Sabbadin[2], Corrado Betterle[2] & Carla Scaroni[2]
[1]Department of Medicine, University of Padova, Padova, Italy; [2]Department of Medicine, University of Padova, Italy

Context
Fludrocortisone (FC) is the mineralocorticoid (MC) replacement treatment for patients with primary adrenal insufficiency (PAI).
Objective
To explore the dose of FC treatment and its relationship with glucocorticoid therapy, sodium, potassium, renin and clinical parameters.
Design
Longitudinal study.
Setting
Monocentric cohort.

Patients
Data of 193 patients with PAI (130 autoimmune) were collected during baseline (T0), intermediate (T1) and last follow-up visit (T2, respectively after 38 and 35 months).
Main Outcome Measure
Utility of endocrine and clinical parameters to titrate FC dose.
Results
FC dose (50-75 μg/daily) was stable in the follow-up in half patients. The MC activity of FC was dose-dependent: we observed a positive linear correlation between FC dose and sodium ($r=0.132$) and negative linear correlation between FC and potassium ($r=$-0.162) or renin ($r=$-0.131, all $P<0.01$). An overall reduction in the FC dose was observed at T2 in the group with longer follow-up (>60 months, $P<0.05$). Higher doses of FC were observed in patients with low-normal renin, especially in autoimmune PAI (86 vs 65 μg/daily, $P<0.05$). On the contrary, reduced sodium and increased potassium levels were observed in patients with high renin at T2. The number of cardiovascular events (15 in the whole cohort) was similar in patients sorted by renin levels or FC dose.
Conclusions
Renin and electrolytes are marker of MC activity: they should be routinely evaluated and used to titrate FC treatment, because FC dose can be reduced in the long-term follow-up.

Reevaluation of the 1-mg overnight low-dose dexamethasone suppression test in the diagnosis of Cushing's syndrome

Cyrine Chehaider, Ibtissem Oueslati, Amani Terzi, Meriem Yazidi & Melika Chihaoui
La Rabta University Hospital, Department of Endocrinology, Tunis, Tunisia

Introduction
The 1-mg overnight low-dose dexamethasone suppression test is used as a screening tool when Cushing's syndrome is suspected. However, the biological confirmation of this syndrome is based upon the measurement of 24-hour urinary free cortisol and low-dose dexamethasone suppression test (Liddle test). The aim of this study was to assess the performance of the 1-mg overnight low-dose dexamethasone suppression test in the diagnosis of Cushing's syndrome.
Methods
This was a retrospective study including patients admitted to our department for suspicion of Cushing syndrome between 2016 and 2021. Clinical and paraclinical data and results of 1-mg overnight low-dose dexamethasone suppression test and Liddle test were collected from medical records.
Results
Fifty-one patients (39 women and 12 men) were enrolled in this study with a mean age of 54.3 ± 15.4 years. The diagnosis Cushing's syndrome was established in 28 patients and excluded in 23 patients. The median serum cortisol level after the 1-mg test was 7.65 μg/dL in patients with Cushing's syndrome and 2.1 μg/dL in those without Cushing's syndrome ($P=0.001$). It was positively correlated with serum cortisol level after the Liddle test ($r=0.852$, $P<10^{-3}$) and ACTH level ($r=0.621$, $P=0.001$). The area under the ROC curve of serum cortisol level after the 1-mg test was 0.773. A cutoff value of 1.8 μg/dL had a sensitivity of 100% and a specificity of 26%. A cutoff value of 5 μg/dL was associated with the diagnosis of Cushing syndrome (Odds Ratio = 4.11, $P=0.016$) with a sensitivity of 64% and a specificity of 70%. A cutoff value of 9.9 μg/dL confirmed the diagnosis of Cushing's syndrome in 100% of cases.
Conclusion
With a cutoff value of 1.8 μg/dL, the 1-mg overnight low-dose dexamethasone suppression test is a reliable screening tool for Cushing's syndrome. However, a higher cutoff value for serum cortisol (9.9 μg/dL) can be used alone to confirm the diagnosis. Further studies involving larger sample sizes would be useful to confirm our findings.

Minimally invasive treatment of conn's adenoma: real world cases in tertiary oncology center

Claudia Costa[1], Sara Franco[2], Ana Paula Santos[1,3], Belarmino Gonçalves[4], Sara Gil-Santos[1], Joana Oliveira[1], Pedro Souteiro[1], Maria José Sousa[4] & Isabel Torres[1]
[1]IPOFG Porto, Endocrinology; [2]Hospital Garcia de Orta, Endocrinology; [3]Precancerous lesions and early cancer management group, RISE@CI-IPO (Health Research Network), Portuguese Oncology Institute of Porto (IPO Porto) / Porto Comprehensive Cancer Center (Porto.CCC); [4]Portuguese Oncology Institute of Porto (IPO Porto) / Porto Comprehensive Cancer Center (Porto.CCC) , Interventional Radiology

Introduction
Primary aldosteronism (PA) is a rare but underestimated cause of hypertension. PA has been associated with increased risk of malignancy through mechanisms involving up-regulation of the renin angiotensin system (RAS) promoting an enzymatic cascade influencing carcinogenesis. Recently, Microwave Ablation (MWA) has been established as an effective and safe minimal invasive treatment for Conn's Disease.
Aim
The authors present four clinical cases of successful treatment of PA with MWA in an oncological setting.
Patients and Methods
Retrospective review of patient's files.
Results
Four women (mean age 55y; 37-67) with pre-diagnosed cancer (1 papillary thyroid carcinoma, one with both gastric carcinoma and Chronic Lymphocytic Leukaemia; one colon carcinoma in context of hereditary syndrome and one breast carcinoma) were evaluated in the Endocrinology Department of IPOFG Porto, either for hypertension and/or hypokalemia and adrenal nodules compatible with adenoma on imaging studies. One patient (pt.) was already treated with spironolactone because of long-term previously diagnosed PA. Renin/aldosterone tests confirmed PA in one pt. In two other pts. the diagnosis was based on the normalization of PA and potassium after spironolactone treatment as diagnosis was made under active cancer treatment. All the 4 pts. were submitted to adrenal adenoma MWA performed by the same Interventional Radiology skilled specialist. Soon after the procedure that occurred without peri-procedure complications, blood pressure and potassium normalized. Re-evaluation of the renin/angiotensin tests out of cancer treatment revealed normal aldosterone and renin levels. After a mean follow-up of 34 months (15-54) there is no evidence of recurrence and/or adrenal insufficiency.
Conclusion
MWA seems to be a long-term effective and safe alternative for the treatment of Conn's adenomas, which is very important in the oncological setting. PA must be excluded in the evaluation of cancer patients with refractory hypertension and/or hypokalemia and adrenal incidentaloma. Orthodox evaluation of PA through traditional tests should be questioned in oncological pts. on active cancer treatment as it can interfere on test results and withdrawing of anti-hypertensive therapies may not be advised.

Glucocorticoid resistance syndrome : Case report

Yousra Settai, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC IBN ROCHD, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction
Glucocorticoid resistance syndrome is a rare disease, sporadic or familial, of autosomal dominant or recessive inheritance. It is a partial or complete inability of glucocorticoids to exert their effects on target tissues. Associated with compensatory increases in corticotropin and circulating cortisol with excessive secretion of adrenal androgens and mineralocorticoids.
Observation
A 67-year-old patient, having recently discovered diabetes started on insulin then on metformin 1g /d, hypertensive for 1 year on amlodipine 10 mg/d, with no personal or family endocrinopathy. Having presented a month before his admission tremors of the extremities, with muscular weakness, and walking disorders. All in a context of weight loss and asthenia. On examination, the patient did not present with clinical cushing syndrome The results showed a persistent hypokalaemia at 1.9mmol / l despite potassium supplementation, a hypernatremia at 147mmol / l. On the overnight 1mg-Dexamethasone suppression test, cortisol levels were high to 25.7 μg / dl. A high urinary free cortisol 1610 mg / 24 h (20-50), with ACTH at 408ng / l (5-60), the pituitary MRI did not reveal any abnormality. The bone densitometry was normal. The diagnosis of glucocorticoid resistance syndrome was retained and the patient was placed on dexamethasone 2 mg / day with a good clinical course, in particular a notable improvement in paresthesia and asthenia, and biological improvement with normalization of serum potassium. Furthermore, the patient presented with hypercalcemia due to

primary hyperparathyroidism having undergone resection of the parathyroid adenoma with good progress. The anatomo-pathology did not objectify signs of malignancy
Conclusion
Glucocorticoid resistance syndrome is a rare and often unrecognized condition. This should be considered in case of chronic asthenia associated with hypokalaemia in the context of excess cortisol without clinical cushing syndrome.

Management of persistent subclinical hypercortisolism post left adrenalectomy in a patient with primary bilateral macronodular adrenal hyperplasia with aberrant receptors

Melpomeni Moustaki[1], Kasiani Papadimitriou[1], Vasiliki Papanikolaou[1], Eleni Cherolidi[1], Maria Rigana[1], Georgios Kyriakopoulos[2], Nikolaos Kalogeris[1] & Andromahi Vryonidou[1]
[1]Korgialeneio-Benakeio Red Cross General Hospital , Department of Endocrinology, Diabetes and Metabolism, Athens, Greece; [2]Evaggelismos General Hospital, Department of Pathology, Athens, Greece

Introduction
Endogenous subclinical hypercortisolism occurs in 5-30% of patients with adrenal incidentalomas. Adrenal adenoma is the commonest cause of autonomous cortisol secretion (ACS), while primary bilateral macronodular adrenal hyperplasia (PBMAH) is rare. In both, ACS results from activation of the cAMP/PKA pathway. This may be triggered by ligands, other than ACTH, acting upon aberrant G-protein coupled receptors (GPCRs), which may also control locally produced ACTH in paracrine/autocrine fashion. In this setting, diagnosis is challenging due to intermittent hypercortisolism and fluctuations of ACTH level.
Case presentation
We present the case of a 65-year old lady with large bilateral adrenal incidentalomas and imaging features compatible with adenomas. Initial hormonal work-up revealed ACS {cortisol post low dose dexamethasone suppression test (LDDST): 13.92 mg/dl, midnight salivary cortisol: 0,8 mg/dl, ACTH = 9.2 pg/mg}. She was not Cushingoid, but had obesity, osteoporosis, hypertension and anxiety disorder. On accounts of the size of her left adrenal adenoma (4.9 x 1.9 cm), she underwent unilateral adrenalectomy. Initial histology demonstrated adrenal adenoma (Weiss score 0/10). During hormonal follow-up, she had persistent hypercortisolism with fluctuating plasma ACTH level (11.5-44.2 pg/ml). Considering the latter, we proceeded to pituitary magnetic resonance imaging, which showed a 3mm incidentaloma. At this point, we repeated LDDST with ACTH measurement: despite adequate ACTH suppression (2.2 pg/ml) cortisol was unsuppressed (6.26 mg/dl). Thus, ACS was confirmed. Imaging-wise, the size of her right adrenal adenoma increased from 4.2 x 1.6 cm to 4,8 x 2.2 over 3 years. Pathology review of the resected left adrenal revealed absence of non-neoplastic adrenal tissue and extended nodular appearance, establishing PBMAH diagnosis. Dynamic testing for aberrant receptors post dexamethasone suppression was performed, demonstrating partial response to posture (25%) and meal (26%). In the absence of overt hypercortisolism and given that PBMAH is a benign condition, we considered medical treatment as more appropriate. To control hypercortisolism, we modified hypertension regime to propranolol and valsartan with later addition of low dose of metyrapone.
Conclusions
Patients with bilateral adrenal adenomas may represent PBMAH, in which aberrant receptor expression is present in 80% of cases. The recognition of aberrant receptor-mediated hypercortisolaemia in patients with PBMAH and unilateral adenomas is important as it may lead to targeted therapies. In this context, b-blockers, angiotensin II blockers, GnRH and somatostatin analogues have been used. Additionally, steroid enzymes inhibitors were found to restore normal circadian secretion of cortisol. Nevertheless, existing data originate from small case series and larger prospective studies are needed.

Primary adrenal angiosarcoma within a hematoma

Elisabete Rodrigues[1,2], Tiago Oimenta[2,3], Jorge Pinheiro[2,4,5], Davide Carvalho[2,6] & José Manuel Lopes[2,4,5]
[1]Centro Hospitalar Universitário de S. Joao, Endocrinology, Porto, Portugal; [2]Faculty of Medicine of the University of Porto; [3]Centro Hospitalar Universitário de S. Joao, Endocrine Surgery, Porto, Portugal; [4]Centro Hospitalar Universitário de S. Joao, Pathology, Porto, Portugal; [5]IPA-TIMUP; [6]Centro Hospitalar Universitário de S. Joao, Endocrinology, Porto, Portugal

Introduction
Angiosarcomas account for < 1% of all sarcomas, and are highly agressive neoplasms whose clinical course is striking: local recurrence, metastasis, and a high mortality rate. Primary angiosarcoma of the adrenal gland was first described in 1988 by Kareti et al. and is very rare with, so far, only 51 reported cases.
Case report
A 49-year-old male, without prior malignancy, presented with a 4.9x5.9 cm right adrenal nodule and a 2.4 cm lesion at L1 both found incidentally on a chest CT. His mother died with lung cancer. Physical examination was unremarkable. Routine lab tests were within the normal range. Serum aldosterone, renin, DHEAS, cortisol post 1 mg dexametasone supression test, 24H urinary catecholamines and metanefrines were normal; 24H urinary normetanephrine slightly elevated. An abdominal MRI confimed an heterogeneous lesion 5.5x4.7x4.4 cm on the right adrenal gland with areas of possible hemorraghe. An MRI of the column revelead a 2.1x1.3x2.2 cm lesion at L1 without agressive features. No uptake was shown at MIBG scan. Right laparoscopic adrenalectomy was done. The adrenal gland (76 g and 8.2x5.8x3.4 cm) disclosed a 4.0x2.6x5.0 cm well defined mass with hemorraghic areas. On microscopic examination, the mass consisted mostly of hematoma and scattered small agregates of cytologically atypical epithelioid cells with amphophilic cytoplasm, irregular vesicular nuclei with variably prominent nucleoli and some mitoses; the cells were diffusely positive for CD31 and ERG. The features are characteristic of epihelioid angiosarcoma. After surgery, a FDG-PET scan disclosed 2 foci of uptake, one on the right thyroid lobe (SUV max 3.7) and the other at the L1 lesion (SUV max 3.2). The cervical US revealed a heterogeneous thyroid gland with characteristics of thyroiditis. Anti microssomal antibodies positive, TSH normal. A biopsy of the L1 lesion did not reveal malignancy. Because there were complete resection margins and no metastic foci were found no adjuvant chemotherapy was done. The patient has been kept under clinical and imagiological surveillance for three years with no further evidence of disease.
Discussion
Adrenal angiosarcoma is a very rare clinical entity with a propensity for local recurrence and metastasis and a median survival of 18 months. Noteworthy the prognosis is unpredictable but some times quite good as in this case.

Hypertension of adrenal origin - a never-ending story

Miruna Maria Popa[1,2], Raluca Cristina Pascu[1], Mihai Lucian Pavel[1], Elisabeta Andreea Malinici[1,2], Anca Sirbu[1,2] & Fica Simona[1,2]
[1]"Elias" Emergency University Hospital, Endocrinology, Bucharest, Romania; [2]"Carol Davila" University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania

Background
Pheochromocytomas and paragangliomas (PPGLs) are rare neuroendocrine tumors characterized by a high degree of variability and unpredictability. Coexistence of PPGLs and adrenocortical adenomas is an uncommon occurrence that can further complicate the clinical course.
Objective
We describe the diagnostic and management challenges of a patient with a history of surgically removed pheochromocytoma, presenting with symptoms of catecholamine excess, following a prolonged period of clinical remission.
Case Report
A 52 yo. female patient was admitted to our hospital for surgical cure of a left adrenal mass. She reports a history of right adrenal pheochromocytoma, excised 15 years before and resulting in clinical and biochemical remission. 15 months prior to presentation she started experiencing paroxysms of arterial hypertension, occurring every other day, accompanied by headache, palpitations, tremor, nausea and emesis. Abdominal CT showed a 3/2 cm left adrenal adenoma, while biochemical screening revealed elevated plasma normetanephrines (6x upper normal limit), along with normal metanephrines and chromogranin A. Renin-to-aldosterone ratio and cortisol diurnal variation were unaltered, but ACTH values were slightly decreased. Postoperatively, the patient was initially stable and exhibited normalized blood pressure under high-dose corticoid treatment, but on the 3rd day, as corticoid dosage was decreased, she developed an acute adrenal crisis. In spite of the initial suspicion of adrenal pheochromocytoma,

histopathological and immunohistochemical examinations described an adrenocortical adenoma. Unsurprisingly, normetanephrines failed to normalize postoperatively; metanephrines and chromogranin A also became marginally elevated and symptoms reoccurred. MRI examination of the head and neck was negative. Interestingly, the patient now also described lumbosacral warmth accompanying the paroxysms. Octreoscan was performed, but revealed no areas of high uptake. Conversely, a metabolically active sacral lesion was described on PET-CT. MRI confirmed the presence of an osteolytic lesion (1.8/1.4/1.1 cm) in that area and described an additional similar adjacent lesion. These were interpreted as possible metastases of a malignant PPGL. Neurosurgical intervention was performed and a histopathological diagnosis of grade I WHO paraganglioma was established. The patient exhibited clinical remission postoperatively, along with the decline of all tumoral markers. However, 6 months later, in spite of imagistic regression of the sacral lesions and lack of symptoms, both metanephrines and normetanephrines showed an upward tendency.

Conclusion

Long-term follow-up is mandatory in PPGLs, as clinical recurrence is possible even after prolonged periods of remission. Genetic testing can aid the diagnosis and management and should be ideally performed in all cases of recurrent/aggressive PPGLs.

Challenges and anxiety of fluctuating normal to mild/moderate elevations of urinary catecholamines and metanephrines in clinical practice

Bonnie Grant[1], Mohammadreza Emami[1], Siraj Adam[2], Edel Casey[1], Raj Tanday[1], Anna Hawkins[1], Nemanja Stojanovic[1,2], Imran Syed[2] & Khash Nikookam[1,2]

[1]Barking, Havering and Redbridge University Hospitals NHS Trust, Greater London, United Kingdom; [2]Spire London East Hospital, Greater London, United Kingdom

We present a 70-year-old female who was initially referred to the endocrinology clinic for an assessment of her type 2 diabetes mellitus. She has a complex medical history including treated hypothyroidism, mastectomy for breast cancer and ongoing yearly surveillance for an excised benign lung lesion. On further questioning she acknowledged feeling generally unwell in the days prior to her appointment and had self-presented to the emergency department with undiagnosed hypertension (blood pressure 219/110mmHg and 190/80mmHg) but no evidence of end-organ hypertensive damage. A full clinical examination did not identify either endocrinopathies or any cardiovascular abnormalities. She was commenced on amlodipine 5 mg daily and subsequently ramipril 5 mg daily. Given her severe hypertension and a negative family history for the same, urinary catecholamines and metanephrines in addition to renin/aldosterone ratio and other relevant investigations were performed to exclude secondary causes. Table 1 shows results performed on three separate occasions, each four weeks apart. She was commenced on doxazosin 1 mg twice daily while also recommended to stop ramipril; however, she was unable to tolerate this nor a switch to phenoxybenzamine 10 mg twice daily, with debilitating side effects of palpitations and dizziness. A CT adrenal with contrast showed no adrenal nodularity bilaterally suspicious of phaeochromocytomas. Further evaluation with I-123 MIBG Scintigraphy and Ga-68 DOTATATE was also negative for any MIBG or DOTATATE avid lesions. The patient continued amlodipine 5 mg daily, achieving adequate blood pressure control with a systolic range of 125-130mmHg and diastolic range of 62-75mmHg. 24-hour urinary catecholamines were repeated six months later, shown in table 2. The patient was advised to further follow up in the endocrine clinic and regular monitoring with her General Practitioner. In conclusion, this case highlights the challenges we encounter during clinical practice with fluctuating urinary catecholamines and metanephrines when other causes of hypertension have been excluded. This can cause additional anxiety over the underlying diagnosis to both the clinician and the patient.

Gender and age-matched case control study of a cohort of adrenal adenomas

Miriam Giordano Imbroll[1,2], Stefanie Agius[1,2], Sarah Craus[1,2] & Mark Gruppetta[1,2]

[1]Mater Dei Hospital, Malta; [2]University of Malta, Malta

Background

The majority of adrenal incidentalomas are benign and patients can be reassured, but a personalized and multidisciplinary approach is required when dealing with these lesions, since they might be linked with various comorbidities. The aim of our study was to carry out an in-depth analysis of the biochemical workup of adrenal incidentalomas and comparing the results with controls.

Methods

252 patients with an incidentally discovered adrenal adenoma were identified. A retrospective cross-sectional analysis of this cohort was carried out. A corresponding cohort of 252 gender and aged-matched patients (+/- 5 years) who underwent a CT scan for a similar indication and on the same day as the cases was recruited. A comparison of numerous parameters was carried out.

Results

From a total cohort of 252 patients, 55.8% were females. The mean age at diagnosis was 69 years (IQR 60-75 years). 84.1% had an overnight dexamethasone suppression test (ODST) performed, out of whom 65.1% had a cortisol post-ODST <50nmol/L. The median longest radiological diameter was 20.0mm (IQR16.0-26.0). From the patients with an adenoma, there was a statistically significant difference between those who were deceased and those alive in the following parameters: MCV ($P=0.008$), Urea ($P=0.046$), Age ($P=0.006$) and T4 ($P=0.009$). When comparing cases with controls, statistically significant different results were observed in lymphocytes ($P=0.002$), higher in cases, and total cholesterol ($P=0.036$), neutrophil-to-lymphocyte ratio (NLR) /monocyte ratio ($P=0.006$) and NLR/monocyte/platelet ratio ($P=0.001$), lower in cases. In our cohort, mortality was highest amongst the controls, compared to cases ($P=0.015$). Among all cases and controls, the following parameters were found to be significantly higher in those still alive at the end of the study: haemoglobin ($P<0.001$), lymphocytes ($P<0.001$), total cholesterol ($P=0.047$), LDL-c ($P=0.008$), Lymphocyte-monocyte ratio (LMR) ($P<0.001$) and eGFR ($P=0.003$). On the other hand, the following parameters were higher in those deceased: Neutrophils ($P=0.004$), urea ($P<0.001$), ALP ($P=0.001$), fasting blood glucose (FBG) ($P=0.008$), Age ($P<0.001$), Neutrophil-lymphocyte ratio (NLR) ($P<0.001$), Platelet-lymphocyte ratio (PLR) ($P=0.009$), Systemic immune inflammatory index (SII) ($P<0.001$), NLR/monocyte ratio ($P<0.001$), NLR/monocyte/platelet ratio ($P<0.001$) and creatinine ($P=0.002$).

Conclusion

Our cohort of adrenal adenomas did not exhibit a higher mortality rate compared to controls and some of the haematological parameters linked with increased mortality were more favourable among the adenoma cohort.

Mortality in patients with non-functional adrenal tumors: a swedish population-based national cohort study

Jekaterina Patrova[1,2], Buster Mannheimer[1,2], Jonatan D Lindh[3] & Henrik Falhammar[4,5]
[1]Karolinska Institutet, Department of Clinical Science and Education, Södersjukhuset AB, Stockholm, Sweden; [2]Södersjukhuset, Department of Internal Medicine, Stockholm, Sweden; [3]Karolinska Institutet, Division of Clinical Pharmacology, Department of Laboratory Medicine, Stockholm, Sweden; [4]Karolinska Institutet, Department of Molecular Medicine and Surgery, Stockholm, Sweden; [5]Karolinska University Hospital, Department of Endocrinology, Metabolism and Diabetes, Stockholm, Sweden

Background
It is not known if non-functional adrenal adenomas (NFAA) are associated with increased mortality.
Objective
To investigate mortality in patients with NFAA and compare with matched controls.
Design
Retrospective register-based national cohort study.
Methods
Patients diagnosed with NFAA in Sweden 2005-2019 were identified and followed until death or 2020. For each case, four age/sex/municipality-matched controls were identified. Individuals with diagnosis indicating adrenal hormonal excess or malignancy were excluded. Though, in some cases malignancy of another origin than adrenal glands was detected in conjunction with index date. Statistical analysis was made both including and excluding these cases. Main study outcomes were all-cause 1 and 5-year mortality as well as causes of death after adjustment for comorbidities and socioeconomic factors.
Results
In total, 20390 patients with NFAA and 125392 matched controls were included. Median age at diagnosis was 65 years (IQR-16) and 59.1% were women. During follow-up, 4427 (21.7%) cases and 20480 (16.3%) controls had deceased. Among all patients with NFAA both 1-year and 5-year overall mortality was higher compared to controls (OR-6.79, aOR-5.38 and OR-2.66, aOR-2.03). After eliminating controls with detected malignancy at index date, both 1-year and 5-year overall mortality was still high (OR 2.64 (2.42-2.88), aOR-1.84 (1.68-2.01) and OR 1.69 (1.61-1.77), aOR 1.18 (1.12-1.25)). While all patients with known malignancy were excluded before and at index date, mortality due to new malignancy during the follow-up period was high: 1-year mortality OR was 8.86 (7.54-10.42), aOR 8.04 (6.81-9.51) and 5-years mortality OR was 2.77 (2.55-3.01), aOR 2.43 (2.23-2.65). Moreover, 1-year mortality due to cardiovascular diseases was also increased (OR 2.02 (1.64-2.47), aOR1.33 (1.06-1.66), however 5-years mortality due to cardiovascular diseases was increased only before adjustment (OR 1.39(1.24-1.57), aOR 0.88 (0.76-1.01), the latter was adjusted for, e.g., cardiovascular disease at index date). In total 1273 (28.8%) of controls diseased due to malignancy and 1023 (23.1%) due to cardiovascular diseases.
Conclusions
Patients with NFAA have significantly higher overall mortality rate, as well as mortality due to new malignancy diagnosed during the follow-up time when compared to controls.

Whole blood transcriptomic profile of Cushing's syndrome

Roberta Armignacco[1], De Murat Daniel[1], Anne Jouinot[1], Lucas Bouys[1], Karine Perlemoine[1], Franck Letourneur[1], Lucie Adoux[1], Maria-Christina Zennaro[2,3], Jerome Bertherat[1,4] & Guillaume Assié[1,4]
[1]Université de Paris, Institut Cochin, INSERM U1016, CNRS UMR8104, Paris, France; [2]Université de Paris, PARCC, INSERM, Paris, France; [3]Assistance Publique-Hôpitaux de Paris, Hôpital Européen Georges Pompidou, Service de Génétique, Paris, France; [4]Assistance Publique-Hôpitaux de Paris, Hôpital Cochin, Service d'Endocrinologie, Center for Rare Adrenal Diseases, Paris, France

Background
Cushing's syndrome, caused by an excess of circulating glucocorticoids, is associated with high morbidity and presents high inter-individual variability. The earlier the diagnosis, the better the treatment effectiveness and the prognosis. Hormone assays, routinely used, contribute to identify Cushing's syndrome. However, no biomarker is currently available to directly quantify the biological action of glucocorticoids. Blood samples represent an easily obtainable source for profiling individuals on a molecular level. In this study, we analysed the transcriptomic profile in 59 blood samples from patients with different glucocorticoid states (overt or mild Cushing's syndrome, eucortisolism, adrenal insufficiency).
Materials and methods
Total RNA was extracted from whole blood samples collected into PAXgene tubes. Transcriptome was determined by RNA sequencing performed on NovaSeq 6000 platform (Illumina). Blood cell proportions in each sample were estimated from expression profiles by using the CIBERSORT method. Unsupervised samples classification (PCA) was used to explore the transcriptomic profiles. A preliminary differential expression analysis was performed by using a linear model-based method (Limma).
Results
Unsupervised classification showed a discrimination of overt Cushing's syndrome samples (accuracy: 0.81), presenting a specific profile compared to the other glucocorticoid states. This variability also associated with blood cell proportions, particularly with a higher neutrophils percentage. The most differentially expressed genes in the group of overt Cushing's syndrome ($n=3173$ genes, with adjusted p-value <0.001) were enriched in pathways related to immunity, particularly to neutrophils activation and activity.
Conclusions
These preliminary results show that glucocorticoid excess associates with a specific whole blood transcriptome profile. Further analyses will allow to identify a set of genes representing a specific molecular signature of glucocorticoid excess, which will take into account biological factors potentially involved, such as blood cell composition.

Adrenal incidentaloma follow-up

Catarina Ivo, Vitória Duarte, David Veríssimo, Ana Cláudia Martins, João Silva, Luís Lopes, Dolores Passos, João Jácome Castro & Mafalda Marcelino
Armed Forces Hospital - Lisbon, Endocrinology Department, Lisboa, Portugal

Introduction
About 5% of the adult population has adrenal incidentaloma(AI) and its incidence increases with age. AACE guidelines recommend image and hormonal evaluation during 5 years in non functioning AI. The european's guidelines advise against repeat evaluation in non-secretory AI that present with <4 cm and had benign features. According to recent studies, the risk of developing clinically relevant hormone secretion is $<0.3\%$, in patients with previous non-functioning lesions. The risk of progression to Cushing Syndrome in patients with autonomous cortisol secretion (ACS) is also low ($<1\%$). This study evaluated the risk of developing hypercortisolism or tumor growth in AI of patients followed in an endocrinology department.
Methods
retrospective study of patients with no functioning AI evaluated between 2014-2021 with a minimum follow-up of 3 years. ACS was defined based on post-dexamethasone cortisol value between 1,8-5 µg/d. Significant tumor growth was defined as $\geq$10mm. Dimensional stability was considered if $<$5mm variation between successive imaging exams.
Results
Included 84 patients, 42.8% ($n=36$) female with a median of age of 76(48-93) years-old. At first evaluation the mean AI dimension was $20{,}9 \pm 7{,}5$mm and 20 patients (23.8%) had bilateral tumors. After a mean follow-up of $5{,}6 \pm 1{,}5$ years, each patient was submitted to a mean of $3 \pm 1{,}1$ image exams. During follow-up, 2 patients (2.4%) developed ACS and none had been diagnosed with clinical Cushing syndrome. In 68 (81%) patients there was dimension stability, 7 had dimension reduction and 9 had increased size ($>$5mm). In only 2 patients there was a significant growth: 1 cyst and 1 tumor that has been transformed to an hemorrhagic lesion (pseudocyst) and submitted to surgery.
Conclusion
In this study 2,4% of patients developed ACS. A $\geq$10 mm growth was only verified in 2 cysts. Adrenal Cysts are rare and usually asymptomatic. AI could suffer hemorrhagic or cystic degeneration and become pseudocyst. Our data are similar to a recent meta-analysis that report no relevant changes in dimension or hormonal function during follow-up of AI.

Covid-19 lockdown negatively impacted on adherence to Denosumab therapy: incidence of non-traumatic fractures and role of telemedicine

Giulia D'Angelo[1,2], Sara De Vincentis[1,2], Daniela Domenici[1,2], Anna Ansaloni[2], Gisella Boselli[1,2], Antonino Russo[1,2], Erica Taliani[2], Vincenzo Rochira[1,2], Manuela Simoni[1,2] & Bruno Madeo[2]
[1]Unit of Endocrinology, Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Modena, Italy; [2]Unit of Endocrinology, Department of Medical Specialties, Azienda Ospedaliero-Universitaria Policlinico di Modena, Modena, Italy

Background
Adherence to anti-osteoporotic therapy is fundamental to prevent harmful consequences including fragility fractures and, in the specific case of denosumab discontinuation, of rebound fractures. Coronavirus disease (Covid-19) lockdowns have impacted on management of osteoporosis, but data about adherence to denosumab and rebound fractures during the Covid-19 pandemic are still lacking. The use of telemedicine is increasingly widespread albeit supported by little evidence so far.
Aim
To assess adherence to denosumab and incidence of non-traumatic fractures (fragility and rebound) during the lockdown year compared to the pre-Covid-19 year. Thereafter, this study aims to investigate the effectiveness of telemedicine in the management of osteoporotic patients with ongoing denosumab treatment.
Methods
Retrospective, longitudinal, single-center study on patients receiving subcutaneous denosumab therapy every 6 months. Each patient was scheduled to undergo 2 visits: one during the pre-Covid-19 period (March 2019 – March 2020) and another visit during the lockdown period (March 2020 – March 2021). Adherence was defined as being punctual (with an allowable delay of up to 4 weeks) with the injection scheduled 6 months after the previous dose. Data on new fractures, risk factors for osteoporosis and the modality of visit (telemedicine or face-to-face) were collected. *Statistical analysis*: Mann-Whitney and Chi-Square tests were used to compare continuous and categorical variables, while logistic regressions were used to detect factors associated with non-adherence/new fractures.
Results
The prevalence of non-adherent patients was significantly higher in the lockdown period (35 of 269 patients, 13.0%) than the pre-Covid-19 period (9 of 276 patients, 3.3%) ($P < 0.0001$). During the lockdown the number of new non-traumatic fractures was significantly higher than the pre-Covid-19 year ($P < 0.0001$). In particular, 10 patients out of 269 (3.7%) experienced a fragility fracture and 2 patients (0.7%) a rebound fracture during the lockdown period, whereas no patient had fragility or rebound fractures during the pre-Covid-19 period. No difference was found in the prevalence of non-adherence and new non-traumatic fractures comparing patients evaluated with tele-medicine to those evaluated with face-to-face visit.
Conclusions
Non-adherent patients and new non-traumatic fractures (including rebound fractures) were more prevalent during the lockdown period in comparison to the pre-Covid-19 period, regardless of the modality of medical evaluation. Tele-medicine seems to be an alternative strategy to standard face-to-face visits, in guaranteeing the continuity of follow-up in osteoporotic patients and short-term compliance to Denosumab

Application of Calcium to Phosphorus (Ca/P) ratio in the diagnosis of pseudohypoparathyroidism: Another piece in the puzzle of diagnosis of Ca-P metabolism disorders

Sara De Vincentis[1,2,3], Giulia Brigante[1,2], Giulia Del Sindaco[4,5], Antonio Moretti[1], Angela Pagnano[4,5], Lucia Zirilli[2], Vincenzo Rochira[1,2], Manuela Simoni[1,2], Giovanna Mantovani[4,5] & Bruno Madeo[2]
[1]Unit of Endocrinology, Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena , Modena, Italy; [2]Unit of Endocrinology, Department of Medical Specialties, Azienda Ospedaliero-Universitaria Policlinico di Modena , Modena, Italy; [3]Clinical and Experimental Medicine PhD Program, University of Modena and Reggio Emilia, , Modena, Italy; [4]Department of Clinical Sciences and Community Health, University of Milan, Milan, Milan, Italy; [5]Endocrinology Unit, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Milan, Italy

Introduction
The serum calcium/phosphorus (Ca/P) ratio has been proposed to identify patients with primary hyperparathyroidism and chronic hypoparathyroidism (HPT) from healthy subjects. However, other disorders of the Ca-P metabolism might present similar biochemical profile of HPT, such as pseudohypoparathyroidism (PHP), for which the use of Ca/P can be useful.
Aim
To test the performance of Ca/P ratio in the diagnosis of PHP in comparison to healthy subjects and to HPT patients for differential diagnosis.
Methods
A retrospective, observational study was carried out, including 60 PHP patients and 60 HPT patients compared to 120 controls. Serum Ca, P, creatinine, parathyroid hormone (PTH) and albumin, and creatinine were collected. Serum Ca and P were expressed in mg/dL. The diagnostic performance was evaluated by receiver operating characteristic (ROC) curve, sensitivity, specificity and accuracy.
Results
The Ca/P ratio was significantly lower in PHP and HPT patients, compared to controls ($P < 0.0001$). At ROC curve analysis, the cut-off of 2.32 (1.78 if serum Ca and P measured in mmol/L) for Ca/P ratio was able to identify both PHP and HPT patients among the entire cohort (sensitivity and specificity: 76%). Selecting patients with Ca/P ratio below 2.32, no valid cut-off of Ca/P was found to discriminate PHP from HPT patients; in this case, serum PTH above 53.0 pg/mL was defined for the identification of PHP patients (sensitivity and specificity: 100%). The index (Ca/P x PTH) above 150 pg/mL identified PHP patients from controls (sensitivity 84.7%; specificity 87.4%), whereas (Ca/P x PTH) below 44 pg/mL identified HPT patients from controls (sensitivity 88.9%; specificity 90.8%).
Conclusions
This study further validates the serum Ca/P ratio below 2.32 (1.78 SI) as a highly accurate tool to identify PHP and HPT patients, but it is not reliable to differentiate these two conditions. The index (Ca/P x PTH) is excellent to specifically recognize PHP or HPT from healthy subjects. Thanks to its extraordinary simplicity and the favorable cost-effectiveness, serum Ca and P should be equally considered as first-line examinations to calculate their ratio that can be easily applied to screen/rule out disorders of Ca-P metabolism, especially in asymptomatic patients.

Calcifediol 0.266 mg supplementation in adult population with 25(OH) D deficiency: 4 months results

Esteban Jódar[1,2], Pedro Guerra López[3], Noelia Vega-Gil[4], Blanca Sánchez Santiago[4], Iñaki Zorrilla Martínez[5], Mario Jiménez-Mercado[5], Aintzane García-Bea[6], Araitz Landeta Manzano[6], Cristina Campo Hoyos[6] & Jesús Frías Iniesta[3,7]
[1]Hospital Universitario Quirón Salud Madrid, Madrid, Spain; [2]Universidad Europea, Madrid, Spain; [3]Pharmacology Department, Universidad Autónoma de Madrid, Madrid, Spain; [4]Valdecilla Clinical Trials Unit, Hospital Universitario Marqués de Valdecilla, Santander, Spain; [5]Clinical Trials Unit, IIS BIOARABA, OSI Araba, Vitoria, Spain; [6]Faes Farma, Medical Affairs; [7]Clinical Pharmacology Service, Hospital Universitario La Paz, Madrid, Spain

Introduction
Prevalence of vitamin D deficiency is relatively high worldwide, it is associated with poor skeletal health and has recently been related to other extra-skeletal diseases, probably due to its immunomodulatory effects. Detection and treatment of asymptomatic hypovitaminosis D in healthy adult population is especially relevant to attempt to optimize the overall functioning of the human body.
Objectives
To assess the percentage of adult healthy population with vitamin D deficiency (25(OH)D < 20 ng/ml) who achieved plasmatic levels within optimal range (20-

60 ng/ml) after a four-month treatment with calcifediol 0.266 mg soft capsules, with monthly or biweekly treatment schedules.
Methods
Multicentre, phase I clinical trial. Volunteers (18-55 years) with vitamin D deficiency were assigned to receive calcifediol 0.266 mg for 4 months according to baseline levels: severe deficiency (25(OH)D $<$ 10 ng/ml) was supplemented biweekly, while mild-moderate deficiency (25(OH)D 10-19.99 ng/ml) was treated monthly. Subsequently, subjects within the optimal range were randomly allocated to monthly treatment (placebo or calcifediol 0.266 mg), for 5 additional months.
Results
79 subjects (65% female, mean age 31.2 years) are included in this analysis; 9% with severe vitamin D deficiency and 91% with mild-moderate vitamin D deficiency. Average baseline 25(OH)D levels (14.02 ng/ml; $n=77$, 2 subjects excluded due to protocol deviations), increased up to 20.53 ng/ml and to 27.56 ng/ml at months 1 and 4. In the biweekly treatment group, 25(OH)D levels increased by 17.05 ng/ml (month 1) and 33.05 ng/ml (month 4), whereas with monthly treatment 25(OH)D levels increased by 5.78 ng/ml and 12.18 ng/ml, respectively. 79% of subjects achieved optimal 25(OH)D levels at month 4 (100% in the biweekly group, 78% with the monthly treatment). The analysed bone metabolism parameters in all subjects (calcium, PTH, albumin, phosphate, alkaline phosphatase) showed no significant changes throughout the study. Calcium and PTH baseline levels were 9.38 $\pm$ 0.40 mg/dL and 51.36 $\pm$ 18.53 pg/ml, remaining unaltered at month 4 (9.57 $\pm$ 0.40 mg/dL and 50.40 $\pm$ 22.38 pg/ml, respectively). In terms of safety, no patient reached 25(OH)D toxic levels. No serious adverse events were reported.
Conclusions
Monthly calcifediol 0.266 mg is an effective and safe treatment for vitamin D deficiency in the overall population. Moreover, and bearing in mind the sample size limitations, biweekly calcifediol 0.266 mg showed to be a safe and effective treatment for vitamin D severe deficiency in the target population and without clinically relevant variation in bone metabolism parameters.

Psychometric evaluation of the hypoparathyroidism symptom diary using data from two clinical trials

Lauren Nelson[1], Steven Ing[2], Mishaela Rubin[3], Jia Ma[1], Susan Martin[4], Rohini Sen[5] & Olulade Ayodele[5]
[1]RTI Health Solutions, Research Triangle Park, United States; [2]Ohio State University Wexner Medical Center, Columbus, United States; [3]Vagelos College of Physicians and Surgeons, Columbia University, New York, United States; [4]RTI Health Solutions, Ann Arbor, United States; [5]Takeda Pharmaceuticals USA, Inc, Lexington, United States

The Hypoparathyroidism Symptom Diary (HypoPT-SD) was developed for the daily assessment of key symptoms and impact of HypoPT as reported by patients with chronic HypoPT and includes 13-items: a 7-item Symptom subscale, 4-item Impact subscale, and single-item anxiety and depression scores. The current analysis was undertaken to confirm test-retest reliability and construct validity of HypoPT SD Symptom subscale scores using data collected during two open-label, single-arm studies of patients with chronic HypoPT treated with recombinant human parathyroid hormone (1-84) (52-week study: NCT03364738; 36-month study: NCT02910466). Test-retest reliability was determined by computing intraclass correlation coefficients (ICC) using data from two test administrations. Validity was evaluated by performing cross-sectional correlational analyses between HypoPT-SD Symptom subscale and other conceptually linked patient-reported outcome (PRO) tools. ANOVA was used to compare HypoPT-SD scores across severity groups defined by existing PRO tools to confirm the known-groups validity of the HypoPT-SD Symptom subscale. The psychometric study population included 22 patients from the 52-week study (81% women; mean $\pm$ SD age, 50$\pm$11.4 years; mean $\pm$ SD duration of HypoPT, 10.3$\pm$10.2 years) and 38 patients from the 36-month study (79% women; aged 52$\pm$12.4 years; duration of HypoPT, 18.9$\pm$12.0 years). In both studies, symptom-related item scores were generally low (eg, less severe), showed limited variability at baseline and end of treatment, most inter-item correlations exceeded 0.50, and internal consistency reliability was satisfactory ($>$0.82). ICCs were 0.67 ($n=22$) and 0.82 ($n=26$) for all patients in the 52-week and 36-month studies, respectively, and 0.92 ($n=10$) for stable patients (based on the Patient Global Impression–Severity [PGI S]) in the 52-week study and corroborated the test-retest reliability of HypoPT SD Symptom subscale. Patterns of correlations between HypoPT-SD Symptom scores and validated PRO tools (FACT-Cog [baseline], FACIT-F total score, RAND-36 physical health composite, PGI-S, and EuroQoL-visual analog scale [baseline]) were moderate to strong and supported convergent validity expectations. Mean HypoPT SD Symptom scores differed significantly across severity groups defined by PGI-S (52-week study) and RAND-36 general health perceptions (36-month study), demonstrating the known-groups validity of HypoPT SD Symptom scores. Limitations include differences in HypoPT SD recall periods (24 hours vs 7 days) in the two studies and lack of severe HypoPT symptoms in patients at baseline, which restricted the range of possible change in scores. These results provide confirmation of the reliability and validity of the disease-specific HypoPT-SD and lay the psychometric groundwork for use of HypoPT-SD in future clinical trials of adults with HypoPT.

Context
In patients with hypoparathyroidism refractory to conventional treatment, recombinant human (rh)PTH(1-84) or rhPTH(1-34) can be used as second-line therapy and effectively control hypocalcaemia. However, whether rhPTH replacement therapy is safe in the long term is unclear. Our objective was to assess bone effects of long-term therapy of chronic hypoparathyroidism with rhPTH(1-34).
Methods
We conducted a monocenter retrospective cross-sectional study at a tertiary university hospital in France. Eligible patients were adults with chronic hypoparathyroidism receiving rhPTH(1-34) therapy uninterruptedly for more than 24 months, who underwent a two-phase whole-body technetium-99m methyldiphosphonate scintigraphy. Clinical and biochemical data were collected retrospectively, covering the period of exposure to rhPTH(1-34) from its initiation until the date of the bone scintigraphy. Images were analyzed blindly by two experts using a visual grading to calculate a total composite score of the bone scan.
Results
17 patients (13 women) were studied, with a median age of 42 [29;58] years. Median treatment duration was 55 [33;68] months and mean daily dose of rhPTH(1-34) was 37.5 [22.1;40] µg. Pathological bone uptake appearing like so-called "super bone scan" was detected in 10 (59%) patients, despite adequate calcemic control (median calcaemia over the study 2.10 [2.04;2.28] mmol/L). Patients with hypermetabolic bone scan received higher daily doses of rhPTH(1-34) compared with patients normal scan (21.0 vs 39.3 mg/day, $P=0.0380$). There was no difference in reported osteoarticular pain, in total and albumin-adjusted

calcium concentration, in phosphate concentration, in calcium-phosphate product and in 24-hour urinary calcium excretion between the two groups. Patients with pathological bone scan compared with those with normal scan had higher osteocalcin (29.2 vs 232 ng/ml, $P=0.0012$), alkaline phosphatase (81 vs 112 UI/L, $P=0.0094$) and crosslaps (0.67 vs 3.83 ng/ml, $P=0.0198$). The total composite score correlated with osteocalcin ($r_s=0.79$, $P=0.0002$), alkaline phosphatase ($r_s=0.83$, $P=0.0001$), with crosslaps ($r_s=0.51$, $P=0.045$) and tended to correlate with mean daily rhPTH(1-34) dose ($r_s=0.44$, $P=0.0769$). Osteocalcin concentration $\geq$ 87 ng/ml predicted a pathological bone uptake with 100% sensitivity and 85.7% specificity.

Discussion

Abnormally increased metabolic activity of the bone may occur under long-term PTH(1-34) therapy despite adequate calcaemic control, possibly due to the pharmacokinetics of this treatment. Bone scintigraphy can be useful in detecting iatrogenic hyperparathyroidism in patients receiving rhPTH(1–34) or rhPTH(1–84). Increased osteocalcin concentrations reliably predict bone cell over-stimulation and should be used as biochemical marker for dose adjustment or treatment interruption.

Vertebral Fractures at hospitalization predict impaired respiratory function at follow-up of COVID-19 survivors

Luigi Di Filippo[1], Nicola Compagnone[2], Stefano Frara[1], Agnese Allora[1], Mauro Doga[1], Patrizia Rovere-Querini[2], George Cremona[3] & Andrea Giustina[1]

[1]San Raffaele Vita-Salute University and IRCCS San Raffaele Hospital, Institute of Endocrine and Metabolic Sciences, Milan, Italy; [2]San Raffaele Vita-Salute University and IRCCS San Raffaele Hospital, Division of Transplantation, Immunology and Infectious Diseases, Milan, Italy; [3]IRCCS San Raffaele Scientific Hospital, Unit of Respiratory Medicine, Milan, Italy

Morphometric-Vertebral Fractures (VFs), which were widely demonstrated to reduce overall-survival and respiratory function in the general population, have been recently reported to be highly prevalent in COVID-19 patients. Emerging data show negative respiratory sequelae at long-term follow-up in COVID-19 survivors. The aim of this study is to evaluate the VFs influence on respiratory function of COVID-19 survivors. We included COVID-19 patients admitted at San Raffaele-Hospital and re-evaluated at the San Raffaele-Outpatient Follow-Up Clinic. Lateral chest-X-rays on admission in emergency-department were obtained and pulmonary function tests (PFTs) were performed at six-months of follow-up. VFs were detected using a qualitative and semiquantitative assessment and PFTs were obtained by Jaeger-MasterScreen-AnalyzerUnit. Fifty patients were included in the study. Median age was 66 years, and 33 (66%) patients were males. VFs were detected in 16 (32%) patients. No differences between fractured and non-fractured groups regarding age, sex and comorbidities were observed. A Radiological-Assessment-of-Lung-Edema (RALE) score, assessing the severity of pulmonary opacities, was available for 30 patients with a median value of 5.5. Although no differences were observed in RALE score between VFs + and VFs- patients (5 vs 6, $P=0.69$), those with VFs were characterized by a significant lower SpO2/FiO2 ratio, higher CRP levels, and required hospitalization more frequently (100% vs 73%, $P=0.04$). No differences were found regarding ICU-admission. At follow-up, patients with VFs were characterized by significant lower Forced-Vital-Capacity (FVC; 2.9 vs 3.6 L, $P=0.006$; 85% vs 110% predicted, $P=0.001$), Forced-Expiratory Volume-1st-second (FEV1; 2.2 vs 2.8 L, $P=0.005$; 92% vs 110%; $P=0.001$). Moreover, a lower diffusing-capacity-for-carbon-monoxide (DLCOSB; 5.83 vs 6.98 mmol/min/kpa, $P=0.036$, 59% vs 86.3%, $P=0.043$) as well as Total Lung-Capacity (TLC; 4.9 vs 6.1 L, $P=0.027$; 84% vs 98%; $P=0.04$) were found in patients with VFs compared to those without. In linear regression analyses, the Spine-deformity-index (SDI) was significantly correlated negatively with FVC% ($P=0.02$) and positively with FEV1/FVC ($P=0.01$), and negative trends with FEV1% and DLCOSB% were observed ($P=0.12$, $P=0.12$, respectively). VFs found on hospital admission appear to be independent predictors of medium term impaired respiratory-function of COVID-19 survivors which may significantly influence their recovery. Therefore, our findings suggest that a VFs assessment at baseline may help in identifying patients needing a more intensive respiratory follow-up after discharge. Patients showing persistent respiratory symptoms and functional impairment without evidence of pulmonary disease may benefit from VFs assessment in order to preventing the vicious-circle of further fractures and respiratory deterioration.

Denosumab vs. zoledronic acid treatment in post-menopausal breast cancer: a 2-year prospective observational study

Kristian Buch-Larsen, Djordje Marina & Peter Schwarz

Rigshospitalet, Endocrinology, København, Denmark

Adjuvant treatment for post-menopausal women with early breast cancer (BC) includes aromatase inhibitors (AI), known to decrease bone mineral density (BMD). In this study, we investigate whether denosumab is a valid second option for patients unable to receive standard adjuvant i.v. zoledronic acid (ZA). In total, 212 patients have been evaluated after they did not receive ZA. Of those 194 were included. After evaluation by an endocrinologist, all patients were offered ZA as their first choice and 15% accepted ($N=29$). The remaining 85% were offered denosumab ($N=165$). All patients were followed prospectively with blood tests up to 24 months. DXA scans were performed at baseline and 24 months. No difference was observed between the two treatment groups at baseline, with regard to anthropometry and standard biochemistry. Markers of bone turnover (p-PINP, p-CTX, p-bone-specific alkaline phosphatase and p-osteocalcin) all showed significant suppression compared to baseline and remained suppressed throughout the 2 years. BMD showed small and significant increases at the spine (0.024 g/cm^2) and total hip (0.019 g/cm^2) in the denosumab group but no change at the femoral neck(-0.011g/cm^2). In the ZA group, we observed no significant change at the spine (0.015 g/cm^2) and total hip (-0.001 g/cm^2) and a small significant decrease at the femoral neck (-0.037 g/cm^2). However, when we compared BMD change between the treatment groups, we found no significant difference.

Conclusions

Our data indicate that for BC patients in AI treatment who refused or were not able to receive ZA treatment, denosumab might be recommended as a second choice. Regarding markers of bone turnover and BMD denosumab is equal to ZA.

Summary

Women with early breast cancer receiving anti-estrogen treatment are at risk of developing osteoporosis. We followed 194 women receiving zoledronic acid (ZA) or denosumab for up to 2 years. We find that with regard to bone protection, denosumab is a viable alternative to ZA and might be recommended as a second choice.

Relative incidence and demographics of hip fractures among subjects over the age of 50 from the Ethiopian ethnic minority in Israel: A preliminary survey from the Israel National Trauma Registry (INTR) database between 2011-2020

Karen Tordjman[1,2], Vanessa Rouach[1,2], Moran Bodas[3], Adi Givon[3], Anat Jaffe[4], Inbal Goldshtein[5,6] & Yona Greenman[1,2]

[1]Tel Aviv Sourasky Medical Center, Institute of Endocrinology, Metabolism, and Hypertension, Tel Aviv, Israel; [2]Tel Aviv University, Sackler faculty of Medicine, Medicine, Tel Aviv, Israel; [3]Gertner Institute, Sheba Medical Center, Israel National Center for Trauma and Emergency Medicine Research, Israel; [4]Hillel Yaffe Medical Center, Endocrinology and Diabetes Unit, Hadera, Israel; [5]Maccabi Healthcare Services, Maccabitech Institute for Research and Innovation, Israel; [6]Tel Aviv University, Sackler Faculty of Medicine, Public Health and Epidemiology, Israel

Background

Among the various ethnicities in the Israeli mosaic, the Ethiopian community is the most recently settled, with an immigration that started less than 40 years ago. Largely young, this 160,000-member community comprises nonetheless about 25,000 persons 50 years or older, virtually all born in Ethiopia. Despite this growing aging population, there is no knowledge regarding osteoporotic fractures in this unique East African ethnic group, not even from data originating from Ethiopia. Two isolated reports, from Ethiopia and from Israel, presented conflicting data regarding bone mineral density in this ethnic group. This study aimed to generate some preliminary data regarding the incidence of hip fractures, as a proxy for osteoporosis, in Ethiopian-born Israelis age 50 and over, between 2011-2020.

Methods
The INTR database contains reports on all injuries recorded in 21 of the 26 trauma centers in Israel. Hip fractures are the only osteoporotic fractures included in the database, as surgery within 48 hours is a nationally monitored medical quality index. Hip fracture data were retrieved from the registry, stratified by gender and age, and compared to those of the Israeli population of other ethnicity.
Results
Ethiopian-born subjects 50 yr and older comprised 0.6% of the INTR reports, while their representation in this age group in Israel was 1.24% ($P<0.0001$). The INTR included 966 reports on Ethiopian-born subjects in this age category, 3.9% of this stratum in the Ethiopian community, while it included reports on 7.4% of people of this age group of different ethnicity ($P<0.0001$). Between 2011-2020, there were 194 hip fractures among Ethiopian-born subjects age 50 or older, 20.1% of all reports for this group. While hip fractures represented 32.3% of injuries reported for other people in this age group, $P<0.0001$. Among Ethiopian-born subjects who suffered a hip fracture, 81/194 (41.8%) were men, compared to 16175/48130 (33.6%) among people of other origin ($P<0.05$). Additionally, 81/194 (41.75%) of these fractures occurred in Ehtiopian-born over the age of 85, while the corresponding figure was only 17303/48130 (35.95%) in people of different ethnicity, $P=0.02$.
Conclusions
Older Ethiopian-born Israelis, particularly women, appear to be less prone to hip fractures than the rest of the population. Additionally, hip fractures appear to occur more in the very old Ethiopian-born than in other ethnic groups, possibly suggesting less osteoporosis. Hip fracture being only a proxy for osteoporosis, a study linking all fragility fracture data with BMD is planned to further examine this question.

Is the concomitant presence of osteoporosis captured by the diagnosis of sarcopenia? A cross-sectional study of 262 women with a fragility fracture of the hip

Marco Di Monaco[1], Carlotta Castiglioni[1], Francesca Bardesono[1], Margherita Freiburger[1], Edoardo Milano[1] & Giuseppe Massazza[2]
[1]Fondazione Opera San Camillo, Osteoporosis Research Center, TORINO, Italy; [2]Division of Physical and Rehabilitation Medicine, Department of Surgical Sciences, TORINO, Italy

Background
Several lines of evidence support the view that sarcopenia and osteoporosis are strictly connected. However, the capability of the updated sarcopenia definition to capture the concomitant presence of osteoporosis has been scarcely investigated.
Aim
To assess the association between sarcopenia defined according to the revised criteria from the European Working Group on Sarcopenia in Older People (EWGSOP2) and osteoporosis in women with a fragility fracture of the hip.
Methods
We focused on women who were consecutively admitted to our ward for subacute rehabilitation following a fragility fracture of the hip. A scan by dual-energy x-ray absorptiometry (DXA) was performed to assess body composition. A Jamar dynamometer was used to measure handgrip strength. Sarcopenia was diagnosed with both handgrip strength $<$ 16kg and appendicular lean mass (aLM) $<$ 15kg. Osteoporosis was identified with femoral bone mineral density lower than 2.5 standard deviations below the mean of the young reference population.
Results
We studied 262 of 290 women. Osteoporosis was found in 189 of the 262 women (72%; 95% CI from 67% to 78%) whereas sarcopenia in 147 of the 262 (56%; 95% CI from 50% to 62%). The unadjusted odds ratio to have osteoporosis for a sarcopenic woman was 2.93 (95% CI from 1.69 to 5.19, $P<0.001$). After adjustment for age, time interval between fracture and DXA scan and body fat percentage the odds ratio was 2.30 (95% CI from 1.27 to 4.14; $P=0.006$). The significant association between sarcopenia and osteoporosis persisted after substituting body mass index for body fat percentage among the potential confounders.
Conclusions
We show that the diagnosis of sarcopenia according to the EWGSOP2 criteria can successfully capture the concomitant presence of osteoporosis in women with hip fracture. The updated definition of sarcopenia can help clinicians to focus on the damages of both the components of the muscle-bone unit, thus emerging as a promising tool to investigate osteosarcopenia in older people. Our findings need confirmation by robust prospective studies.

Tumor-induced osteomalacia - case report

Eva Rusu[1], Andreea Peica[1], Tudor Gliga[1], Oana Stanoiu-Pinzariu[2] & Carmen Georgescu[1,2]
[1]Clinical County Emergency Hospital Cluj-Napoca, Endocrinology Department, Cluj-Napoca, Romania; [2]"Iuliu Hatieganu" University of Medicine and Pharmacy, Cluj-Napoca, Romania

Introduction
Tumor-induced osteomalacia is a rare paraneoplastic syndrome characterized by the presence of phosphaturic hormone-secreting mesenchymal tumors - fibroblast growth factor 23 (FGF-23), which causes hypophosphatemia and osteomalacia. These tumors are small, frequently infiltrate the surrounding tissues and are located in the connective or bone tissue. Usually, these tumors are benign, but malignant tumors have also been reported.
Case report
We present the case of a 39-year-old female with persistent diffuse osteomuscular pain, progressive generalized muscle weakness and the impossibility of standing and walking for about five years. She underwent multiple medical examinations - neurologic, orthopedic and rheumatologic assessments, but did not identify any disorders to explain her symptoms. Laboratory testing showed severe hypophosphatemia (0.9 mg/dl), increased urinary phosphate excretion, increased alkaline phosphatase (320 U/l), normal renal function and elevated FGF-23 (551 kRU/l). Radiographic imaging revealed multiple, old, nontraumatic pelvic and rib fractures, evolved with vicious consolidation. SPECT CT with ^{99m}Tc-Tektrotyde demonstrated increased uptake of the radiotracer in the right supraspinatus muscle. MRI of the right shoulder confirmed a 5 cm intramuscular tumor of the supraspinatus muscle. Surgery was performed with resection of the tumor. Postoperatively, we observed progressive normalization of phosphate levels within a few days and FGF23 decreased significantly, but without normalization 48 hours or 1 month after surgery, raising the suspicion of incomplete resection. Histopathological examination and immunohistochemical profile confirmed the presence of phosphaturic mesenchymal tumor (PMT) with a predominantly hemangiomatous component, showing positive expression of CD34, CD56, CD68, SMA, vimentin and Ki-67 $<$ 5%. The resected margins showed tumor infiltration of the adipose tissue and skeletal muscle. The clinical outcome of the patient was favorable, with progressive and significant improvement of symptoms (regression of osteomuscular pain and gait abnormalities) and normalization of serum phosphate level and FGF-23 level at the upper limit of normal values. Given the histopathological result and failure of normalization of FGF-23 additional follow-up is necessary for detection of tumor recurrence.
Conclusion
Tumor-induced osteomalacia is a rare, frequently undiagnosed or misdiagnosed disease. The diagnosis is a real challenge because of the nonspecific symptoms that can delay detection of the disease. A stepwise approach, combining functional and anatomical imaging is necessary to identify the tumor. Surgery is the only curable option and should be performed whenever is possible.
Keywords
Tumor-induced osteomalacia, FGF-23, paraneoplastic syndrome, hypophosphatemia

In case of acute pancreatitis; think of hyperparathyroidism! A case report

Ali Halouache[1], Benhamdane Ahlame[2], Errahali Yassine[1], Chakdoufi Sanae[1], Isouani Jad[1] & Guerboub Anas[1]

[1]Hopital Militaire d'Instruction Mohammed V, Endocrinology, and Metabolic Diseases, Rabat, Morocco; [2]Hopital Militaire d'Instruction Mohammed V, Gastro Entérology , Rabat, Morocco

Introduction
The revelation of primary hyperparathyroidism by acute pancreatitis is an exceptional situation
Case report
We report the case of a 73 years old patient, hypertensive, having the antecedent of an ischemic cardiopathy complicated by cardiac insufficiency and atrial fibrillation, admitted to the emergency for an abdominal pain evolving since 10 days, associated with vomiting, the initial biological assessment showed lipasemia at 2543IU/l, kidney failure and malignant hypercalcemia at 142mg/l. The etiological work-up showed primary hyperparathyroidism with double localizations, the patient benefited from a Para thyroidectomy with a good clinic biological evolution.
Discussion
Hypercalcemia is a rare cause of acute pancreatitis, even more so if it is secondary to primary hyperparathyroidism, its prevalence varies, according to studies, from 1.5 to 5% [1]. Authors suggest that this association is not coincidental, and several pathophysiological explanations have been proposed, but none has been experimentally proven to date. the highest prevalence of acute pancreatitis in patients with hyperparathyroidism has been observed in those with hypercalcemia [2], and the hypercalcemia-acute pancreatitis link is currently well established. For Prinz and his team [3], acute pancreatitis is the consequence of a deposit of lithiasis secondary to an accumulation of calcium in the gastric juice. The second explanation is that of intra-pancreatic trypsinogen activation, which is widely accepted as the lever leading from acinar cell injury to acute pancreatitis [4]. Recently, the role of a genetic substrate has been suggested; mutations in the SPINK1 and CFTR genes have been detected in hyper parathyroid patients who developed acute pancreatitis[5].
Conclusion
The association hyperparathyroidism - acute pancreatitis was most often explained by the link of hypercalcemia, most of the above theories have not presented scientific evidence, and the current challenge is to seek a direct link between these two pathologies, the genetic theory remains an option, but its role is not clear.

Lower than recommended doses of cinacalcet are effective and well tolerated in the control of hypercalcaemia of primary hyperparathyroidism

Nyein Nge Nge[1] & Mohamed Malik[2]
[1]Hull University Teaching Hospital NHS Trust, General Internal Medicine, Hull, United Kingdom; [2]Scunthorpe General Hospital , Endocrinology Department, Scunthorpe, United Kingdom

Background
The treatment goal in primary hyperparathyroidism (PHPT) is the achievement of biochemical control and prevention of target organ complications. Parathyroidectomy is the current recommended intervention to cure the disease. However, Cinacalcet is an alternative medical treatment for subgroup of patients in whom surgery is deemed inappropriate, those with recurrent disease, and as bridging therapy for delayed operation particularly in recent COVID pandemic. Current recommended starting dose of Cinacalcet is 60 mg/day, with up titration to a maximum dose of 360 mg/day in divided doses. It is not yet known whether a lower dose of cinacalcet can be effective in controlling hypercalcemia, with the advantage of better tolerability and reduced cost.
Objective
To assess efficacy of Cinacalcet in unselected medically managed patients with PHTH, and to explore minimal effective dose of Cinacalcet required to control hypercalcemia in ordinary clinical practice.
Methods
We conducted a retrospective study including all patients with PHPT who had initiated treatment with cinacalcet at the Endocrinology department over a period of three years. We evaluated pre-treatment baseline biochemical data and subsequent variations at 3rd, 6th and 12thmonth after cinacalcet treatment. As well we assessed effective Cinacalcet dose, treatment side effects, and rate of treatment discontinuation.
Results
Total 66 patients with PHTH (49 women and 17 men, aged 53-97 years) were included. Average baseline serum calcium was 2.95mmol/L (95%confidence interval [CI], 2.92 to 2.98), serum PTH of 17.58 ± 6.514pg/ml, and serum phosphate of 0.83mmol/L (95%CI, 0.80 to 0.86). Following three months of Cinacalcet, serum calcium reduced to average of 2.60mmol/L (95%CI, 2.54 to 2.66) and serum phosphate was up to 0.95mmol/L (95%CI, 0.90 to 1.0). Subsequent measurements at 6- and 12-months' points were consistent with trend towards eucalcaemia, normalising serum phosphate and stabilising serum PTH level. Sixty seven percent of studied population required Cincalcet dose of 60 mg/day to maintain biochemical eucalcaemia, and further 20% have achieved the desired effects at a dose of 30 mg/day. Among the 66 patients studied, only one discontinued cinacalcet due to intractable GI side effect and one missed follow-up.
Conclusion
Lower than recommended dose of Cinacalcet is effective and well tolerated to control hypercalcaemia of primary hyperparathyroidism. This observation is of clinical significance when the factors of long-term treatment compliance, and targeted elderly population with multiple comorbidities and polypharmacy, are considered. Furthermore, the observation makes Cinacalcet an attractive cost-effective treatment when compared to surgery, and the cost of managing acute and chronic complications of hypercalcaemia.

Long-term complications of permanent hypoparathyroidism: prevalence and associated factors

Faten Cherchir[1], Ibtissem Oueslati[1], Meriem Yazidi[1] & Melika Chihaoui[1]
[1]La Rabta University Hospital, Department of Endocrinology, Tunis, Tunisia

Introduction
Patients with permanent hypoparathyroidism receiving conventional treatment have increased risk of subcapsular cataracts, basal ganglia calcifications, urolithiasis and renal insufficiency. The aim of this study was to assess the prevalence and the interfering factors of these complications in patients with permanent hypoparathyroidism.
Methods
We conducted a cross-sectional study including 53 patients with permanent hyperparathyroidism. Biochemical parameters, ophthalmological examination, brain computed tomography scan and renal ultrasound were performed to all patients.
Results
There were 41 (77%) women and 12 (23%) men with a mean age of 52.7 ± 16.5 years. Post-surgical HPT was the most frequent etiology of hypoparathyroidism (64%). Posterior subscapular cataract was diagnosed in 62% of cases. Age ($P < 10^{-3}$), disease duration ($P = 0.02$) and hypomagnesemia ($P = 0.014$) were positively associated with cataracts. Basal ganglia calcifications were found in 53% of cases. Brain CT-scan showed bilateral intracerebral calcifications located in the central gray nuclei (71%) or diffuse symmetric calcifications (29%). Patients with intracranial calcifications presented with headache, amnesic disorders, psychotic symptoms and seizures in 82, 71, 14 and 14% of cases, respectively. Younger age of onset of hypoparathyroidism ($P = 0.037$), disease duration ($P = 0.014$), nonsurgical etiologies ($P = 0.015$), poor adherence to treatment ($P < 10^{-3}$), hypomagnesemia ($P = 0.001$) and PTH level < 10 pg/ml ($P = 0.022$) were significantly associated with brain calcifications. Urolithiasis and renal insufficiency were found in 13 and 17% of cases, respectively. Creatinine clearance was negatively correlated with disease duration ($r = -0.338$, $P = 0.013$). Patients with urolithiasis had lower PTH level and received higher calcium salt doses ($P = 0.033$) than those who had no renal calcifications. However, sex, smoking, body mass index, calcemia, phosphatemia, phosphocalcic product, TSH and 25-OH-vitamin D did not significantly interfere with none of these complications.
Conclusion
Patients with permanent hypoparathyroidism are exceedingly exposed to neurological, visual and renal impairment because of phosphocalcic disorders and extra-skeletal calcifications. The disease duration, PTH and magnesium levels seem to be the most interfering factors.

Assessment of quality of life in patients with hypoparathyroidism receiving conventional treatment: a case-control study

Faten Cherchir, Ibtissem Oueslati, Meriem Yazidi & Melika Chihaoui
La Rabta University Hospital, Department Of Endocrinology, Tunis, Tunisia

Introduction
Patients with permanent hypoparathyroidism suffer from multiple complaints and are exposed to long-term complications that compromise their well-being. The aim of our study was to assess the quality of life in patients with permanent hypoparathyroidism receiving conventional vitaminocalcic therapy.
Methods
We conducted a cross-sectional case-control study including 53 patients with permanent hypoparathyroidism and 53 age-sex-body mass index matched controls. Clinical and biochemical parameters were collected. Quality of life was assessed in all participants using the Short Form 36 Health Survey (SF-36).
Results
Among patients with hypoparathyroidism, there were 41 (77 %) women and 12 (23 %) men with a mean age of 52.7 ± 16.5 years. Neck surgery was the most common etiology of hypoparathyroidism ($n=34$, 64 %). In comparison with age-sex-body mass index matched controls, hypoparathyroid patients had significantly lower scores in all eight domains of SF-36 ($P < 10^{-3}$). Patients with postsurgical hypoparathyroidism scored worse than those with non-surgical etiologies in all domains, but significance was reached only in bodily pain score ($P=0.01$). All SF-36 scores were negatively correlated with the age. However, Sex, smoking, duration of the disease, adherence to treatment and body mass index did not significantly interfere with SF-36 scores. Hypoparathyroid patients in whom PTH level < 10 pg/ml scored worse in all SF-36 domains compared with those who had PTH level > 10 pg/ml, without reaching significance. Magnesium level was positively correlated with SF-36 scores. No significant correlations were found between SF-36 scores and biological parameters such as calcemia, phosphatemia, phosphocalcic product, TSH, 25 OH vitamin D, 24 hours calciuria, and creatinine clearance.
Conclusion
Compared with matched controls, patients with permanent hypoparathyroidism, especially post-surgical ones, suffer from a major impairment of quality of life, suggesting that conventional treatment, even if it's well conducted, fails to restore well-being.

Bone mineral density, trabecular bone score and vertebral fractures in acromegalic patients

Madalina Sorohan[1,2], Ramona Dobre[3], Ionela Baciu[2,3], Simona Galoiu[1,2,2], Roxana Dusceac[1,2], Dan Niculescu[1,2], Andra Caragheorgheopol[1], Carmen Iordachescu[1] & Catalina Poiana[1,2]
[1]CI Parhon National Institute of Endocrinology, Pituitary Pathology and Neuroendocrinology, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [3]CI Parhon National Institute of Endocrinology, Bucharest, Romania

Background
Acromegaly is characterized by increased prevalence of fragility vertebral fractures. Nonetheless, there are no clear recommendations for prevention of acromegalic osteopathy. Both bone mineral density (BMD) and trabecular bone score (TBS) lack clear evidence as prognostic factors for vertebral fractures (VF).
Material and Methods
We performed an observational study on 31 acromegalic patients recruited prospectively. They were tested for alkaline phosphatase, 25 hydroxyvitamin D, parathormone, osteocalcin, the C-terminal telopeptide of type I collagen and total procollagen type 1 amino-terminal propeptide. Imaging techniques used were dual x-ray absorptiometry (DXA), TBS and antero-posterior and lateral x-ray scans of the dorsolumbar spine.
Results
They were characterized by normal BMD, partially degraded bone on TBS, 32.33% had VF on dorsolumbar x-ray and hypogonadism was present in 71% of subjects. Hypogonadal acromegaly subjects had significantly lower TBS (1.232 ± 0.123 vs. 1.343 ± 0.146, $P=0.040$) but higher T ($P=0.029$) and Z scores ($P=0.004$) at the femoral neck compared to eugonadal patients. Acromegalic patients with VF had significantly lower BMD at the femoral neck (0.901 ± 0.137 vs. 1.013 ± 0.131 g/cm^2, $P=0.037$) and hip (0.883 ± 0.109 vs. 1.036 ± 0.121, $P=0.002$) and T score at the lumbar spine [-2.7 (IQR: -3.4- -0.6) vs. -1.2 (IQR: -1.9-0.1), $P=0.047$] compared to those without VF but with no differences in terms of TBS values.
Conclusion
Vertebral fractures in acromegaly patients associate with low BMD but not with TBS. However, TBS is significantly lower in these patients in the presence of hypogonadism. The use of BMD might still prove to be useful in the evaluation of acromegalic osteopathy.

Phosphate-mediated inhibition of calcium-sensing receptor expressed endogenously in the thyroidal TT cell-line

Khaleda Alghamdi[1,2], Hee-Chang Mun[3], Arthur Conigrave[4] & Donald Ward[5]
[1]The University of Manchester, Faculty of Biology, Medicine and Health, Manchester, United Kingdom; [2]King Abdulaziz University , Department of Pharmacology and Toxicology, Jeddah, Saudi Arabia; [3]The University of Sydney, School of Life & Environmental Sciences, Sydney, Australia; [3]The University of Sydney, School of Life & Environmental Sciences, Sydney, Australia; [5]The University of Manchester, Faculty of Biology, Medicine and Health, Manchester, United Kingdom

The calcium-sensing receptor (CaR) is the key controller of parathyroid hormone (PTH) secretion and extracellular calcium homeostasis. Hyperphosphataemia increases PTH secretion and is associated with secondary hyperparathyroidism (SHPT). We reported recently that inorganic phosphate (Pi), and sulphate, can attenuate CaR activity directly (in CaR-transfected HEK-293 cells) and Pi can increase PTH secretion rapidly from human and murine parathyroid cells. To investigate this further, here we used a thyroid parafollicular C-cell model, TT cells, which express CaR endogenously. TT cells, which exhibit CaR-induced calcitonin (CT) secretion, were assayed by epifluorescence intracellular Ca^{2+} imaging and CT assay (with a gastrin-releasing peptide (GRP)-induced CT control). When co-stimulated with the CaR-activating calcimimetic R568 (1μM) and spermine (1mM), TT cells exhibited classic CaR-induced $Ca^{2+}{}_i$ mobilisation, which the $G_{q/11}$-specific inhibitor YM-254890 largely abolished (-93 ± 8%). Similar CaR-induced responses were also inhibited by increasing the buffer Pi concentration from 0.8 mm (physiological) to a pathophysiological 2 mm (-33 ± 4%; $P<0.001$). In contrast, raising Pi concentration was without effect on carbachol-induced $Ca^{2+}{}_i$ mobilisation (acting via muscarinic receptors). Finally, 1.2 mm sulphate (high) elicited a similar CaR inhibition as for Pi (-28 ± 16%; $P<0.05$; vs physiological 0.3 mm sulphate). Similar inhibitory effects were seen when the anions were used in combination; 2mM Pi (high) & 0.3mM sulphate (normal) elicited a 15 ± 12% reduction in CaR-induced $Ca^{2+}{}_i$ mobilisation, while 2mM sulphate (high) & 0.8mM Pi (normal) produced a 19 ± 3% inhibition ($P<0.05$). Regarding CT secretion, we observed time-dependent release that was stimulated maximally 15-20 fold by increasing Ca^{2+} concentration from 0.5–3.0mM (EC_{50} ~1.5 mm). Inorganic Pi (0.8-3.0 mm) inhibited CT release in a non-competitive manner, with 3mM Pi almost abolishing CT release at all $Ca^{2+}{}_o$ concentrations tested. Even raising Pi concentration from 0.8-1.4 mm (representing the physiological range) elicited a striking 50% reduction in CT release. In contrast, 2mM Pi had no effect on 1μM GRP-stimulated CT release. Sulphate was also a non-competitive inhibitor of CT release but was less potent than Pi. These results further support the idea that the CaR is a mineral sensor, at which Pi acts directly as a non-competitive antagonist to limit CaR-induced reductions in PTH secretion. Further, Pi may also limit CaR-induced CT secretion when its serum concentration is raised. Together, our studies provide important new information regarding the physiological control of PTH and CT secretion, and, the pathophysiology of SHPT.

Bleeding assessment in 195 patients with osteogenesis imperfecta

Koert Gooijer, Gabriëla Heidsieck, Arjan Harsevoort, Danielle Bout, Guus Janus & Anton Franken
Isala Zwolle, Zwolle, Netherlands

Background
Osteogenesis Imperfecta (OI) is commonly defined as 'brittle bones' disease, but there are also more characteristics like blue sclerae, hearing loss, dental problems, ligamentous laxity and a short stature. Easy bruising is also a very common feature and there are multiple case reports on haemorrhagic events in OI. Larger population studies on bleeding tendency in OI are very sparse, while other connective tissue disorders with easy bruising have much more relevant research. This paper reviews the clinical aspects of bleeding in bruising in OI based on the self-bleeding assessment tool (BAT) questionnaire among a large cohort of OI patients. The emphasis of this study will be a first translation to clinical consequences of bleeding due to surgery, tooth extraction, menstrual and obstetrical bleeding and to present therapeutic considerations relevant to bleeding in OI.
Methods
This explorative study was conducted at the national expert center for adults with OI in the Netherlands. The self-BAT was digitally distributed among 354 adults with different clinically confirmed types of OI.
Results
195/354 patients with OI types 1,3 and 4 were included. Self-BAT scores were increased in 37-44%.
Conclusion
Bleeding tendency seem to be a relevant feature in OI patients. This study should be a wakeup call for all clinicians treating OI patients for assessing bleeding tendency and taking the right interventions to reduce haemorrhagic symptoms and improve quality of life.

The international x-linked hypophosphataemia (xlh) registry: overview of the dataset

Sandro Giannini[1], Jonathan Liu[2], Angela Williams[2] & Sue Wood[2]
[1]University of Padova, Department of Medicine, Padova, Italy; [2]Kyowa Kirin International Marlow Office, United Kingdom

Background
X-Linked Hypophosphataemia (XLH) is a rare, progressive, hereditary phosphate wasting disorder characterised by a pathological increase in fibroblast growth factor 23 concentration/activity. Despite XLH being increasingly recognised as a chronic progressive disease, there are few data documenting its natural history or impact of treatment. The International XLH Registry will collect data to characterise burden of disease, disease progression and long-term outcomes. It aims to describe effectiveness and safety of treatments used to manage XLH and their value in certain subpopulations.
Methods
The International XLH Registry (NCT03193476) was initiated August 2017, aims to recruit 1,200 children and adults with XLH, and will run for 10 years. This is a multicentre, non-interventional registry, capturing treatment details and clinical outcomes in patients with XLH who are followed for as long as informed consent/assent and regulatory permissions are maintained. Only data collected during standard routine examinations are recorded, no specific examinations/data entries are mandated. Parameters collected at baseline included demographics, medical history, treatment history, and clinical presentation data. The conduct of the International XLH Registry is overseen by 17 Steering Committee expert physicians representing the region.
Results
As of 31 December 2021, 1,043 subjects diagnosed with XLH were enrolled from 88 hospital sites in 19 countries. The geographic distribution of subjects is as follows: Belgium $n=29$, Bulgaria $n=7$, Czech Republic $n=8$, Denmark $n=23$, France $n=267$, Germany $n=79$, Hungary $n=11$, Ireland $n=5$, Israel $n=21$, Italy $n=88$, The Netherlands $n=26$, Norway $n=23$, Portugal $n=9$, Slovakia $n=5$, Slovenia $n=3$, Spain $n=55$, Sweden $n=43$, Switzerland $n=17$, and the UK $n=324$. A further 30 sites are still to enrol patients (including in Austria and Latvia). Overall, 400 adults (18–29y, $n=116$; 30–39y, $n=81$; 40–49y, $n=95$; 50–59y, $n=58$; $\geq$60y, $n=50$) and 620 paediatric subjects ($<$5y, $n=138$; 5–12y, $n=321$; 13–17y, $n=161$) have been enrolled (date of birth unavailable, $n=23$). The majority of the enrolled subjects are female (648 (62.1%)), with 372 male (35.7%) and 23 for whom sex was not reported (2.2%).
Conclusions
This Registry forms the largest dataset of XLH subjects worldwide to date. Patients have been recruited from a wide geographical region, and baseline demographics are consistent with a hereditary X-linked dominant disease. Information collected during the 10-year Registry duration will generate real-world evidence to help inform clinical practice throughout the EMEA region and beyond.

Male osteoporosis, a still overlooked and undermanaged issue: an identikit of patients seeking bone health evaluation at a tertiary academic medical centre

Sara De Vincentis[1,2], Antonino Russo[1,2], Erica Taliani[2], Anna Ansaloni[2], Daniela Domenici[1,2], Bruno Madeo[2] & Vincenzo Rochira[1,2]
[1]Unit of Endocrinology, Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Modena, Italy; [2]Unit of Endocrinology, Department of Medical Specialties, Azienda Ospedaliero-Universitaria Policlinico of Modena, Modena, Italy

Background
Male osteoporosis is undermanaged. The characteristics of men referring to health care system for bone evaluation remain partially unknown.
Aim
To characterize from real-life data male patients seeking the first bone health evaluation at a tertiary academic medical center, referral for both andrological and bone diseases, over a 13-year observation period.
Methods
Retrospective, cross-sectional study, including adult men referring to our Center from 2007 to 2020 for bone health evaluation. Reasons for referral, risk factors for osteoporosis and comorbidities were investigated. Osteoporosis and osteopenia were defined considering DXA outcomes, according to WHO and ISCD criteria, and history of fragility fractures.
Results
A total of 455 men (age 62.5 $\pm$ 15.1years) were included: 42 aged 18–40 years, 57 aged 40–50, 79 aged 50–60, 109 aged 60–70, 122 aged 70–80, and 46 aged $>$80. Overall, 125 patients (27.4%) were already followed by endocrinologists due to endocrinological/andrological diseases known to increase fracture risk (94 men) or not (31 men); general practitioners and other specialists asked for bone evaluation for 226 (49.6%) and 101 (22.1%) men. DXA has been already performed for 354 patients. Prevalence of osteoporosis, osteopenia, and low bone mineral density for age were 25.9%, 26.4% and 13.2%, respectively. Fractures were the most frequent reasons for referral. At least one fragility fracture has already occurred in 213 patients (46.8%), with higher prevalence in non-endocrinological than endocrinological patients (56% *vs* 24%, $P<0.001$). Sites of fracture were lumbar spine (128 patients,60%), femoral neck alone or in combination with other sites (50 patients, 23.4%). A total of 344 patients (76%) was already known to be affected by one or more comorbidities associated to bone loss, with higher prevalence in fractured patients compared to non-fractured ($P=0.036$). Among fractured patients, 49 of them (23%) have never been treated with any anti-osteoporotic therapy, including calcium and vitamin D supplementation.
Conclusions
Male osteoporosis presents with a high rate of fragility fractures (about 50%) among men referring to a tertiary academic medical center. The high prevalence of comorbidities associated to bone loss suggests that secondary forms of osteoporosis prevails in men, and they should be carefully investigated to identify patients at increased fracture risk. Most of fractured patients have not been previously evaluated by a clinician with expertise in bone diseases or properly treated, suggesting that awareness for male osteoporosis needs to be reinforced in primary healthcare setting in order to prevent fractures. This disease remains still overlooked and unaddressed.

Extended treatment with recombinant human parathyroid hormone (1-84) in adult patients with chronic hypoparathyroidism: a phase 4 study

Mishaela Rubin[1], Natalie Cusano[2], Shaoming Yin[3], Elena Tokareva[3], Olulade Ayodele[3] & Richard D. Finkelman[3]
[1]Columbia University Vagelos College of Physicians and Surgeons, New York, United States; [2]Lenox Hill Hospital, New York, United States; [3]Takeda Pharmaceuticals USA, Inc., Lexington, United States

In Europe, rhPTH(1-84) is an approved adjunctive treatment for adults with chronic hypoparathyroidism that cannot be adequately controlled with conventional therapy. Here we present data from the longest rhPTH(1-84)-treated study cohort of patients with hypoparathyroidism. In a single-centre, single-arm, phase 4 study (NCT02910466), long-term rhPTH(1-84) treatment (25, 50, 75, or 100 μg/day subcutaneously) was evaluated in adults with chronic hypoparathyroidism who maintained uninterrupted rhPTH(1-84) treatment from the HEXT study (NCT01199614). Doses were adjusted based on albumin-corrected serum calcium and 24-hour urinary calcium excretion to achieve target serum calcium within 2.00–2.25 mmol/l. Baseline was defined as last available value before first dose in the current study. End of treatment (EOT) was the day after last rhPTH(1-84) dose for each patient, including those who did not complete the study. Data are summarized as mean ± SD. Thirty-nine patients enrolled (age, 51.9 ± 12.22 years; 79.5% female; duration of hypoparathyroidism, 18.6 ± 12.00 years). Mean length of exposure from first rhPTH(1-84) dose was 10.8 ± 3.50 years. In the current study, 36 patients received ≥ 1 rhPTH(1-84) dose, and mean duration of participation was 30.3 ± 5.79 months. Mean albumin-corrected serum calcium was 1.94 ± 0.222 mmol/l at baseline ($n = 33$), 2.08 ± 0.304 mmol/l at month 30 ($n = 23$), and 2.07 ± 0.266 mmol/l at EOT ($n = 36$). Phosphate values were 1.25 ± 0.230 mmol/l at baseline ($n = 33$), 1.30 ± 0.241 mmol/l at month 30 ($n = 23$), and 1.31 ± 0.220 mmol/l at EOT ($n = 36$). Calcium-phosphate product levels were 2.53 ± 0.475 $mmol^2/l^2$ at baseline ($n = 33$), 2.78 ± 0.421 $mmol^2/l^2$ at month 30 ($n = 23$), and 2.82 ± 0.373 $mmol^2/l^2$ at EOT ($n = 36$). Mean 24-hour urinary calcium levels were 5.52 ± 3.243 mmol/24 hours at baseline ($n = 35$), 7.47 ± 5.170 mmol/24 hours at month 30 ($n = 18$), and 6.60 ± 3.818 mmol/24 hours at EOT ($n = 35$). Mean prescribed supplemental calcium and active vitamin D decreased from 1313.8 ± 1404.46 mg/day and 0.17 ± 0.320 μg/day, respectively, at baseline ($n = 36$) to 1180.9 ± 1065.50 mg/day and 0.12 ± 0.327 μg/day at month 30 ($n = 23$), and 1076.0 ± 832.48 mg/day and 0.11 ± 0.313 μg/day at EOT ($n = 36$). No clinically relevant changes in bone mineral density occurred between baseline and EOT. Treatment-emergent adverse events (TEAEs) were reported in 36 (92.3%) patients; the most common were anxiety (41.0%), hypocalcaemia (28.2%), and depression (20.5%). Four TEAEs were considered by study investigators to be treatment related (upper limb fracture, hypercalcaemia, renal disorder, ureterolithiasis). Study limitations are small sample size, single-arm design, and lack of pre-treatment baseline data. Among patients with chronic hypoparathyroidism previously treated with rhPTH(1-84), improvements in biochemical efficacy parameters were maintained over a mean of 30 months of additional treatment. No new or unexpected safety signals emerged.

Impact of chronic hypoparathyroidism on symptom severity and interference with life as reported by patients treated with recombinant human parathyroid hormone (1-84), rhpth(1-84)

Bart L. Clarke[1], Nandini Hadker[2], Amod Athavale[2], Irana Kolev[3] & Olulade Ayodele[3]
[1]Mayo Clinic, Rochester, United States; [2]Trinity Partners LLC, Waltham, United States; [3]Takeda Pharmaceuticals USA, Inc., Lexington, United States

Chronic hypoparathyroidism is a rare mineral homeostasis disorder managed by conventional therapy (oral calcium and active vitamin D), alone or with adjunctive rhPTH(1-84). Chronic hypoparathyroidism is associated with considerable symptom burden, which can interfere with daily living. We report results from a web-based, cross-sectional survey conducted among adults with chronic hypoparathyroidism. The objectives were to quantify the impact on overall life interference of (1) time from diagnosis to rhPTH(1-84) initiation and (2) rhPTH(1-84) treatment vs conventional therapy. Overall life interference of hypoparathyroidism was patient self-reported upon considering all aspects of their condition using a 7-point rating scale (1 = none to 7 = very significant interference). Hypoparathyroidism-associated symptom severity was assessed through the disease-specific, patient-reported Hypoparathyroidism Symptom Diary. The study included 90 patients treated with rhPTH(1-84) (mean ± SD age, 54.5 ± 11.3 years; 83% female) and 57 patients treated but not adequately controlled with conventional therapy (mean ± SD age, 50.0 ± 11.7 years; 93% female). Among rhPTH(1-84)-treated patients, time from hypoparathyroidism diagnosis to rhPTH(1-84) initiation was ≤ 12 months, > 12–≤ 48 months, and > 48 months in 28%, 38%, and 34% of patients, respectively. Initiation of rhPTH(1-84) > 48 months after diagnosis was associated with higher overall life interference compared with initiation ≤ 12 months after diagnosis ($P < 0.001$ for the unadjusted and $P = 0.02$ for multivariable regression analysis adjusted for potential confounders). The life interference mean ± SE score was 2.0 ± 0.54 points higher (unadjusted) and 0.8 ± 0.34 points higher (multivariable regression) for patients who initiated rhPTH(1-84) > 48 months vs ≤ 12 months after diagnosis. Self-reported severity of hypoparathyroidism was rated as no symptoms, mild, moderate, and severe in 42%, 49%, 8%, and 1% of patients treated with rhPTH(1-84), respectively, and in 11%, 37%, 49%, and 3% of patients treated with conventional therapy. Treatment with rhPTH(1-84) was associated with lower overall hypoparathyroidism-related life interference compared with conventional therapy that did not adequately control hypoparathyroidism ($P < 0.001$ for both unadjusted and adjusted multivariable regression analyses). Mean ± SE life interference score for rhPTH(1-84)-treated patients was 1.5 ± 0.33 points lower (unadjusted) and 1.1 ± 0.29 points lower (multivariable regression) vs patients treated with conventional therapy. A strength of this study is the multivariable analysis adjusting for potential confounders; limitations include cross-sectional study design, inaccessibility of patient characteristics before treatment initiation, and recall bias. In a real-world setting, rhPTH(1-84) initiation > 48 months after hypoparathyroidism diagnosis was associated with greater overall life interference vs rhPTH(1-84) initiation ≤ 12 months after diagnosis. Compared with conventional therapy, rhPTH(1-84) treatment was associated with lower overall life interference after adjusting for confounding variables.

Novel variant of the casr gene c.2192g > A in a clinical case of chronic hypocalcemic hypoparathyroidism

Blerta Papadopoulou[1], Olga Kosmopoulou[1], Taujan Georgiana[1], Felicia Baleanu[1], Mihaela Rosu[1], Iconaru Laura[1], Karmali Rafik[1], Isabelle Vandernoot[2] & Guillaume Smits[2]
[1]CHU Brugmann, Endocrinology, Brussels, Belgium; [2]Hospital Erasme, Genetics, Brussels, Belgium

A 65 year old patient who was hospitalised for a reactive arthritis of the knee due to Rickettsia infection, presented an asymptomatic persistant chronic hypocalcemia and hyperphosphoremia. In her medical history, we noted a hypertension treated with amlodipine and bisoprolol, syndrome of sleep apnoea, acquired lumbar spinal canal stenosis and sequelae of poliomyelitis acquired at 10 years of age in Congo, her place of origin. According to her blood test results, total calcium levels were low between 1,9 to 2,1 mmol/l (normal ranges 2,15–2,50), phosphorus levels high between 1,61 to 1,81 mmol/l (normal ranges 0,81–1,45), albumine levels normal between 34 to 42 g/l (normal ranges 34–48), parathormone levels abnormaly normal between 17 to 55 ng/l (normal ranges 15–65), 25OH-vitamine-D levels low to normal between 22 to 44 mg/l (normal ranges 30–60). Urinairy calcium excretion between 0,022 to 0,081 mol/mol creat (normal range <0,700). Renal function was normal with creatinine levels between 0,40 to 0,75 mg/dl (normal range 0,55–0,96). The diagnosis of hypoparathyroidism was evoked with suspicion of an activating mutation of the calcium-sensing receptor (CaSR) gene. We performed a citrate infusion test to provoke more pronounced hypocalcemia by administrating intravenously a continuous perfusion of 100 ml solution of dextrose 2.45 g, sodium citrate 2.2 g and citric citrate 0.7 g, for 30 minutes. The subsequent measures of total calcium, ionised calcium and parathormone every 10 minutes from T0 to T30 min, showed no increase of parathormone levels in response to provoked hypocalcemia. The genetic analysis didn't identify any mutation but identified a novel variant c.2192G > A (p.Cys731Tyr) of the CaSR gene. This variant has not been described in the literature before and results from the In-Silico analysis are contradictory, benign for Polyphen and pathogenic for MutationTaster and SIFT. A genetic family study could have helped us to better interpret this result, but unfortunately the patient lives alone in Belgium since 2015 and all her family

lives in Africa. Thus, the pathogenic nature of this novel variant of CaSR gene remains unknown for the time being and the variant is classified as class III.

Atherothrombotic risk in subjects with parathyroid disorders: cross-sectional study

Anda Mihaela Naciu[1], Gaia Tabacco[1], Francesco Piccirillo[2], Michele Mattia Viscusi[2], Alfonso Maria Di Tommaso[1], Giulia Sterpetti[1], Andrea Palermo[1] & Annunziata Nusca[2]
[1]Fondazione Policlinico Universitario Campus Bio-Medico, Unit of Metabolic bone and thyroid diseases, Rome, Italy; [2]Fondazione Policlinico Universitario Campus Bio-Medico, Unit of Cardiac Sciences, Rome, Italy

Background
Clinical and molecular findings have shown that parathyroid hormone (PTH) affects the heart and vasculature through downstream actions of G protein-coupled receptors in the myocardium and endothelial cells. Furthermore, the endothelium is a recognised target tissue of PTH and there is an increasing body of evidence that PTH affects functional and structural properties of arteries. Patients with chronic post-surgical hypoparathyroidism (hypoPT) have higher incidences of hypertension, arterial stiffness and increased risk of mortality.
Purpose
To assess endothelial and other atherosclerotic predictors in subjects affected by hypoPT in comparison with primary hyperparathyroidism (PHPT) and controls.
Methods
In a monocentric, cross-sectional study we enrolled hypoPT patients treated with calcium and calcitriol, PHPT subjects and age-matched controls. All patients underwent a biochemical examination including calcium-phosphorus metabolism, inflammation markers. Moreover, we evaluated brachial artery endothelial function (flow-mediated dilation-FMD), common carotid intima-media thickness (ccIMT), diastolic function and global strain measures with ultrasound.
Results
These are the preliminary results of this project that included 49 subjects (20 hypoPT, 18 PHPT and 11 controls) of 150 expected. All study groups presented similar BMI, TSH and kidney function. HypoPT patients had significantly lower PTH and calcium levels ($P<0.001$) and higher phosphorus levels ($P<0.001$) than PHPT and controls. HypoPT had higher inflammation markers (erythrocyte sedimentation rate) levels than PHPT and controls (34.5 ± 17.2 vs 27.6 ± 10.9 vs 15.0 ± 9.6 ml/h,$P=0.020$). All study groups presented no significant differences in basal brachial artery diameter, FMD and diastolic function. HypoPT showed higher global strain value than PHPT subjects (-19.6 ± 3 vs $17.6\pm2.5P=0.042$), while compared to controls presented similar values. HypoPT showed lower ccIMT than PHPT subjects and higher values than controls (10.0 ± 2.2 vs 11.2 ± 2.4 vs 7.6 ± 2.1 mm,$P=0.002$).
Conclusion
Up to now, our findings suggest that hypoPT has an increased atherothrombotic risk and needs adequate cardiovascular evaluation. We believe that further comprehensive studies are needed.

Tumour induced osteomalacia: 2 years treatment with burosumab

Ludovica Aliberti, Margherita Pontrelli, Martina Verrienti, Irene Gagliardi, Maria Chiara Zatelli & Maria Rosaria Ambrosio
University of Ferrara, Section of Endocrinology and Internal Medicine, Department of Medical Sciences, University of Ferrara, Ferrara, Italy

Introduction
Tumor-induced osteomalacia (TIO) is a paraneoplastic syndrome due to an overproduction of fibroblast growth factor 23 (FGF23) by small and benign mesenchimal tumors. FGF23 increase causes hypophosphatemia, osteomalacia and muscle weakness. TIO is usually cured by tumour resection, but neoplasms may be unidentifiable/unresectable or the patient may refuse surgery. In these cases, medical treatment with high doses of oral phosphate and calcitriol is mandatory, even though it is usually insufficient to restore normal phosphate levels and is associated with low compliance. Burosumab is a human monoclonal antibody against FGF23 employed to treat X-linked hypophosphatemia(XLH), recently approved for TIO in USA. Maximum dose of Burosumab in XLH is 90 mg/2 weeks but there are no data on clinical efficacy and safety concerning the use of Burosumab in TIO
Case report
A 65 years old male presented to our attention for multiple non traumatic fractures (femoral neck, ribs, pelvic bone) and low bone mineral density. He was forced to use crutches because of pain and limb weakness, determining low personal autonomy and mobility. Biochemical evaluation showed hypophosphatemia (1.1 mg/dl), normal calcium and PTH, high ALP (514 U/l) and CTX (0.864 ng/ml), normal creatinine and low tubular phosphate reabsorption (80%), whereas c-FGF23 was elevated. After excluding drug-induced and genetic osteomalacia/-hypophosphatemia, a 68GaPET was performed, identifying a lesion at the I right rib as cause of TIO. The patient refused surgery, therefore Burosumab therapy was started (initial dose 0.3 mg/Kg, gradually increasing to 60 mg/2 weeks). After 2 years of treatment, biochemical evaluation showed phosphoremia normalization and ALP reduction (138U/l). Patient clinical symptoms improved: Brief Pain Inventory (BPI) scores decreased, indicating reduced pain severity (from 1 to 0,5pt) and pain interference (from 3 to 0,6pt) as well as reduced fatigue (Brief Fatigue Inventory from 35 to 6pt). Sit-To-Stand Test and 6-minute Walking Test also improved (from 14.83s and 372 m to 11.08s and 430 m respectively). No side effects nor tumour progression were reported during follow-up

Table 1

	Basal	2 years of treatment	Reference Range
Phosphoremia	1.1 mg/dl	2.8 mg/dl	2.5-4.5 mg/dl
Calcium	9.8 mg/dl	9.7 mg/dl	8.5-10.5 mg/dl
ALP	514 U/l	138 U/l	30-120 U/l
CTX	0.864 ng/ml	0.55 ng/ml	0,115 - 0,748 ng/ml
1,25(OH) 2vitamin D	180 pmol/l	63 pmol/l	36,5 - 216,2 pmol/l
Bone ALP	138 mg/l	72.7 mg/l	3-20,2 mg/l
TmP/GFR	0.85 mg/dL	1.53 mg/dl	2.47-4.18 mg/dl
TRP%	80%	97%	85-95%

Conclusions
Our experience supports efficacy and safety of the use of Burosumab every 2 weeks in TIO

DOI: 10.1530/endoabs.81.P288

Hypercalcemia with positive calcium-sensing receptor (casr) autoantibodies

Romain Vankemmel[1], Hippolyte Dupuis[1], Pierre-Loup Herman[1], Nicole Fabien[2] & Marie-Christine Vantyghem[1,3,4]
[1]CHU Lille, Department of Endocrinology, Diabetology and Metabolism, Lille, France; [2]CHU Lyon, HCL-GH Sud, Department of Immunology, Pierre-Bénite Cedex, France; [3]Univ Lille, European Genomic Institute for Diabetes, Lille, France; [4]Inserm, Translational Research for Diabetes, UMR-1190, Lille, France

CaSR-autoantibodies may cause auto-immune hypercalcemia through either simple blocking or biased properties. The phenotype of this rare disease is most often acquired hypocalciuric hypercalcemia (AAH) (*Minanbres JCEM 2020, Makita JCI insight 2022*), but sometimes hyperparathyroidism (*Pelletier-Morel Intern Med 2008*), in elderly. Gender, auto-immune context is variable. Blood calcium may fluctuate, and acute exacerbations may be successfully treated with

prednisolone and/or calcimimetics. We present two cases of CaSR-antibodies-associated hypercalcemia with a different phenotype
Case#1
A 80-year-old women (BMI 29) had a history of cured endometrial cancer, auto-immune, thyroiditis and sclerodermic-like syndrome (Sjögren and Raynaud syndrome with severe hypertension, increased level of anti-nuclear centromeric autoantibodies ($1/512^{th}$)). In 2002, detectable CaSR-antibodies with normal calcemia (97 mg/l), hypocalciuria (78 mg/24 h), mild 25-OHvitamin D deficiency (21 pg/ml), normal PTH level (36 pg/ml) and moderate CD4 and B lymphopenia was disclosed in a systematic autoimmune screening, after an episode of oral candidosis, without identified pathogenic variant of the *AIRE* gene. In 2015, she was operated from breast carcinoma. In 2022, blood calcium level was increased (107 mg/l), with normal phosphatemia (37 mg/l), low 25-OH-vitamin D (25 ng/ml) and persistent anti-CASR and anti-nuclear autoantibodies. No parathyroid hypertrophy was identified on US examination.
Case#2
A 70-year-old lady, BMI 30, with a history of cured endometrioid uterine adenocarcinoma was referred for recurrence of hypercalcemia 12 years after a left upper parathyroidectomy with total thyroidectomy for a typical biological hyperparathyroidism profile with hypercalciuria and osteopenia, associated to multinodular goiter without thyroid antibodies. Morphological parathyroid investigations were discordant, but after surgery, blood calcium dropped from 119 to 95 mg/l and remained so until 2019, where a profile of hyperparathyroid-ism reappeared with the presence of renal lithiasis. There was no excess of 25 or 1-25-OHvitamin D. Calciuria, PTH and CaSR-antibodies levels were increased, without other positive auto-antibodies. The NGS study of the *MEN1, HRPT2, CASR, AP2S1, GNA11* and *GCM2* genes was negative. Morphological investigations remained discordant.
Conclusion
The presence of CaSR-autoantibodies in these 2 elderly female cases of hypercalcemia: without overt parathyroid adenoma, suggest an auto-immune component to this hypercalcemia. Case#1 had an asymptomatic profile of AAH in an autoimmune context with long-term preexisting CaSR-antibodies. Case#2 had a profile of hyperparathyroidism without autoimmune context except for CaSR-antibodies. Both had a neoplastic history. Measurement of CaSR-autoantibodies in atypical cases of hypercalcemia with discordant morphological investigations could help to orientate diagnosis towards an autoimmune cause and a medical treatment. The functionality of CaSR-antibodies may explain the different phenotypes.

Utility of intraoperative parathyroid hormone monitoring to predict success of parathyroidectomy for primary hyperparathyroidism

Ana Rita Elvas, Andreia Fernandes, Joana Couto, Raquel G. Martins, Jacinta Santos, Teresa Martins & Fernando Rodrigues
Portuguese Oncology Institute of Coimbra, Department of Endocrinology, Coimbra, Portugal

Introduction
Parathyroidectomy is the only curative treatment for primary hyperparathyroid-ism (pHPT) and has been traditionally performed through bilateral neck exploration (BNE). However, with the use of intraoperative parathyroid hormone (IOPTH) assay along with preoperative localization exams, minimally invasive surgery can be performed with good surgical success rate.
Aim
To evaluate the usefulness of IOPTH assay in guiding adequate parathyr-oidectomy in patients with pHPT.
Materials and Methods
We retrospectively analysed the case records of patients who underwent parathyroidectomy for pHPT between 2003 and 2021 at our hospital. IOPTH monitoring was employed as an intraoperative tool to guide the surgical procedure. Blood samples were collected at pre-incision time and then 10–15 minutes after parathyroid gland excision. Successful surgery was defined as a drop of 50% or more in the IOPTH level, otherwise, BNE was performed. These results were compared to alternative strategies for IOPTH monitoring, including a 60% decline and reduction to parathormone (PTH) reference range values.
Results
A total of 99 patients were included. Post-excision PTH levels dropped $>50\%$ in 80 (80.8%) patients. 3 of 19 patients (15.8%) whose outcomes failed to reach curative criteria had confirmed multiglandular disease. Intraoperative PTH monitoring using our criteria showed a 91.7% sensitivity, 80% specificity and 89.9% accuracy. True positive among them were 77 (77.8%%), true negative 12 (12.1%), false positive 3 (3.0%) and false negative 7 (7.1%). If a normal PTH value was required as a criterion for cure, unnecessary BNE would have been performed in 32 patients (32.3%) and in 12 patients (12.1%) if a 60% decline was applied, compared with just 8 patients (8.1%) when using the previous criteria.
Conclusion
IOPTH in adjunct with other localizing studies was helpful for carrying out successful parathyroidectomy. The use of IOPTH had good sensibility in predicting cure for most of the patients with pHPT undergoing minimally invasive parathyroidectomy. The use of other criteria, such as 60% decline and normal PTH value 10–15 minutes after excision, was associated with higher rates of conversion to unnecessary BNE.

Vitamin d status and bone health in adolescents and young adults with congenital adrenal hyperplasia

Ruta Navardauskaite[1,2], Kristina Semeniene[1], Neringa Umaraite[1], Emile Rudminaite[1], Aurika Vanckaviciene[3] & Rasa Verkauskiene[4]
[1], Lithuanian University of Health Sciences, Medical Academy, Department of Endocrinology, Kaunas, Lithuania; [2], Coordinating center for rare and undiagnosed diseases Lithuanian University of Health Sciences hospital Kauno Klinikos, Kaunas, Lithuania; [3], Lithuanian University of Health Sciences, Medical Academy, Department of Nursing, Kaunas, Lithuania; [4]Lithuanian University of Health Sciences, Medical Academy, Institute of Endocrinology, Kaunas, Lithuania

Background
Data on the effects of long term glucocorticoid (GC) treatment on bone mineral density (BMD) in patients with congenital adrenal hyperplasia (CAH) are controversial.
Objectives
To evaluate BMD and vitamin D status in adolescents and young adults with CAH in comparison with healthy controls.
Methods
32 patients with classical CAH (13 males; mean of age 26.0 ± 7.1 years (14.0–37.3) were compared to 32 healthy controls matched by age, gender, and Tanner stage of pubertal development. Body composition was evaluated in all subjects with DXA (Hologic Inc., Bedford, MA, USA).
Results
Mean vitamin D level was 50.1 in patients and 55.5 nmol/l in controls, $P = 0.35$. Eighteen (56.25%) patients and thirteen (40%) controls had vitamin D deficiency ($P = 0.21$). Vitamin D levels were inversely associated with age ($r = -0.29$, $P = 0.04$) and body mass index ($r = -0.282$, $P = 0.045$) in all subjects. Mean whole body and lumbar BMD Z-scores were similar in CAH and control groups (-0.57 ± 0.96 vs. -0.29 ± 0.9, $P = 0.27$, and -0.97 ± 1.0 vs. -0.6 ± 0.8, $P = 0.15$, respectively). In 12.5% ($n = 4$) of patients and 18.75% ($n = 6$) controls whole body BMD z-score was between -2 and -1 standard deviation (SD), $P = 0.5$ Whole body BMD z-score < -2 SD was found in 12.5% ($n = 4$) of patients and 0% controls, $P = 0.04$. There was no history of bone fractures in neither of study groups. In the CAH group, vitamin D levels and BMD Z-scores did not correlate with GC cumulative doses, 17-hydroxyprogesterone or testosterone (T) levels. Adjustment for T levels did not change the results.
Conclusions
Patients with CAH are at risk for the development of osteoporosis. In our study, BMD Z-score and vitamin D were not related to cumulative GC doses and markers of disease control.

Parathyroidectomy decreases serum monocyte chemoattractant protein-1, and increases vitamin d metabolites in patients with primary hyperparathyroidism

Lingqiong Meng[1], chi su[2], Sue A Shapses[1], Stanley Z Trooskin[3] & Xiangbing Wang[4]

[1]Rutgers University, Nutritional Science, New Brunswick, United States; [2]Rutgers University, Graduate School of Biomedical Science, New Brunswick, United States; [3]Rutgers University-Robert Wood Johnson Medical School, General Surgery, Departments of Medicine and Surgery, New Brunswick, United States; [4]Rutgers University-Robert Wood Johnson Medical School, Division of Endocrinology, Department of Medicine

Background
Primary hyperparathyroidism (PHPT) is a common endocrine disorder accompanied by high cytokines and low total 25-hydroxyvitamin D [25(OH)D]. An inflammatory cytokine, monocyte chemoattractant protein-1 (MCP-1), is found to be higher in people with elevated parathyroid hormone (PTH), unlike other cytokines (1). Also, a rise in MCP-1 in response to high PTH is associated with bone loss (2). Parathyroidectomy (PTX) is the only cure for patients with PHPT. Whether the decline in PTH due to PTX leads to a decrease in MCP-1 and its effect on vitamin D metabolites remains unclear.
Objective
To investigate the effect of PTX on serum MCP-1 and vitamin D metabolites in patients with PHPT.
Methods
Patients with PHPT who underwent minimally invasive PTX were included. Serum samples were collected before and 3-month after surgery. Serum levels of calcium, PTH, vitamin D binding protein (DBP), total and free 25(OH)D, MCP-1, and C-reactive protein (CRP) were measured. Correlation coefficients and multiple linear regression models were used to assess relationships among PTH, vitamin D metabolites and cytokines.
Results
In 25 PHPT patients (age: 61 ± 11 years old; BMI: 31.0 ± 5.6 kg/m^2), levels of serum PTH and calcium were decreased (PTH: 118.6 ± 42.4 to 44.7 ± 25.2 pg/ml; Ca: 11.0 ± 0.6 to 9.6 ± 0.4 mg/dL; $P < 0.001$) to normal after PTX. Meanwhile, both total and free 25(OH)D were significantly increased (28.1 ± 10.2 to 37.9 ± 11.2 ng/ml; 4.9 ± 2.1 to 8.1 ± 3.8 pg/ml; $P < 0.001$), together with elevated DBP ($P < 0.001$) after surgery. The level of MCP-1 declined by 20% ($P < 0.001$), while CRP remained relatively stable after PTX. The PTH was negatively correlated with total and free 25(OH)D, and DBP ($P < 0.01$), however, positively correlated with MCP-1 ($P < 0.01$). The CRP (but not MCP-1) was found to be negatively correlated with both total and free 25(OH)D ($P < 0.01$).
Conclusion
These data show that the decline of PTH due to PTX down-regulates serum MCP-1, but not CRP. Also, PTX normalizes PTH and Ca level, and leads to an increase in DBP, total and free 25(OH)D, which appears to be independent of MCP-1. The role of MCP-1 on PTH, total and free 25(OH)D and bone in patients with PHPT remains unclear and further studies are needed.

Bone mineral density (bmd) of ultra-distal radius: are we ignoring a valuable information?

Yair Schwarz[1,2], Inbal Goldshtein[3], Yehudit Eden Friedman[1,2], Naama Peltz-Sinvani[1,2], Michal Brodavka[4], David Kowal[1], Iris Vered[1,2] & Liana Tripto-Shkolnik[1,2]
[1]Sheba Medical Center, Division of Endocrinology, Diabetes and Metabolism, Ramat Gan, Israel; [2]Tel Aviv University, Sackler Faculty of Medicine, Tel Aviv-Yafo, Israel; [3]Maccabi Health Care Services, Maccabitech Institute of Research and Innovation, Israel; [4]Sheba Medical Center, Rheumatology Unit, Ramat Gan, Israel

Background
BMD measurement of a non-dominant arm is not routinely performed during dual-X-ray-absorptiometry (DXA) test. While 1/3 radius measurement is recommended under certain circumstances, ultra-distal compartment is not used for osteoporosis diagnosis or fracture risk assessment.
Aim
To evaluate the correlation of ultra-distal radius (UDR) BMD to prevalent fractures, fracture risk predicted by FRAX and diagnosis of osteoporosis by traditional sites.
Methods
Women who underwent a routine DXA (including non-dominant forearm in all patients) in a tertiary medical center were included in a retrospective cross-sectional study. Risk factors relevant to FRAX calculation were assessed via a self-administered questionnaire. Spearman correlation of UDR BMD to 10-year risks of major osteoporotic and hip fractures (assessed by FRAX) was explored. The possible added value of UDR BMD in explaining prevalent osteoporotic fractures was assessed using a multivariable regression model incorporating age and traditional osteoporosis diagnosis.
Results
The study included 1,245 women with a median age of 66 (IQR 59-73), of whom 298 (24%) had UDR T-score $\leq$ -2.5 and 154 (12%) reported prior fractures. UDR BMD was significantly negatively correlated with FRAX risk score for hip and major osteoporotic fractures ($R =$ -0.5 and $R =$ -0.41 respectively; $P < 0.001$). UDR T-score $\leq$ -2.5 was associated with higher fracture prevalence (19% vs 10%; $P < 0.001$), and remained significant after adjusting for traditional BMD and age (OR 1.49, 1.01-2.19;$P = 0.043$).
Conclusions
UDR BMD correlates both with prior fractures and with predicted fracture risks and might pose added value over traditional DXA sites.

Internal Clinic - Endocrinology and Metabolism, Prague, Czech Republic

Introduction
Familial and hereditary forms of primary hyperparathyroidism (PHPT) represent a small minority of all patients with PHPT (5 – 10%). The surgical approach is different in such cases than in sporadic PHPT. Hereditary PHPT may be syndromic (multiple endocrine neoplasia: MEN – type 1, 2A or 4 and others) or nonsyndromic (familial isolated PHPT). The aim of the study was to identify and describe hereditary and familial forms of PHPT in patients referred to parathyroid surgery in our centre at University Hospital Motol Prague.
Patients and Methods
370 patients underwent parathyroidectomy for PHPT from January 2020 until December 2021. Familial PHPT was defined as the occurrence of PHPT at least in two first-degree relatives. Genetic testing was recommended in patients I) with familial PHPT, II) with PHPT onset $\leq$ 40 years of age, III) with recurrent disease, IV) with clinical presentation of MEN1 (PHPT and/or pituitary adenoma and/or gastroenteropancreatic neuroendocrine tumor). A total of 45 patients (33 female, 14 male) underwent genetic testing. The median age of PHPT diagnosis was 36 (range 15 - 62). 6 patients who were recommended for genetic testing did not participate. Genetic analysis was performed by next-generation sequencing of DNA obtained from peripheral blood. We sequenced the all exons and UTR regions of these genes: *AIP, AIRE, AP2S1, CaSR, CDC73, CDKN1A, CDKN1B, CDKN2B, CDKN2C, GATA3, GCM1, GCM2, GNA11, MEN1, PTH, RET, STX16.*
Results
We identified 11 different germline causal mutations in the MEN1 gene in 12 patients (2 patients were siblings): NM_130799.2:p.Pro32Arg; Asp70ProfsTer51; Ile85SerfsTer33; Asp123 MetfsTer31; Gln209Ter; Gln258Ter; Thr210Serfs-Ter13; Gln450His; Trp471Ter, c.1049+1G >C (change in mRNA restriction) and the loss of the entire MEN1 allele in one patients. Moreover we found a mutation in RET gene: NM_020975.4:p.Cys611Tyr. A variant of uncertain significance was identified in 5 patients.

Conclusion
Hereditary and familial forms of PHPT were found in 16 (4%) of all patients who underwent parathyroidectomy for PHPT in our centre. There may exist undiagnosed hereditary PHPT among those who have not been genetically tested. Germline mutations were detected in 13 patients (12 in MEN 1, 1 in RET – MEN 2A). Familial PHPT without detected germline mutation was found in 3 patients. 2 of them had variant of uncertain significance and further familial segregation study will be provided. 18Fluoro-choline PET/CT is a useful localization technique in patients with primary hyperparathyroidism

Laura Pierotti[1], Elisa Dinoi[1], Laura Mazoni[1], Matteo Apicella[1], Gabriele Materazzi[2], Luigi De Napoli[2], Stefano Bola[3], Alessio Faranda[1], Duccio Volterrani[3], Claudio Marcocci[1] & Filomena Cetani[1]
[1]Clinical and Experimental Medicine, University of Pisa, Endocrinology, Pisa, Italy; [2]Molecular Pathology and Critical Area, University of Pisa, Department of Surgical, Pisa, Italy; [3]Translational Research and New Tecnologies in Medicine, University of Pisa, Nuclear Medicine, Pisa, Italy

Primary hyperparathyroidism (PHPT) is a common endocrine disease mainly caused by a single parathyroid adenoma. Although the localization of the parathyroid adenoma is not a surgical criterion for parathyroidectomy (PTX), this is known to increase the cure rate and reduce the complication rate. Neck ultrasound and MIBI-scintigraphy are the first-line techniques to detect hyperfunctioning parathyroid tissue, however, they have some limitations including the operator-dependent sensitivity and limited utility in case of a deep-laying or ectopic parathyroid. Recently, it has been shown that parathyroid adenomatous cells are capable of capturing choline, making this molecule a potential tracer in parathyroid. The aim of our study was to evaluate the utility of ^{18}Fluoro-choline PET/CT in 43 patients with PHPT candidate for PTX with negative or inconclusive results on conventional imaging. All patients underwent neck ultrasound performed by an expert physician, double tracing MIBI SPECT/CT and ^{18}F-choline PET/CT. The latter both examinations were perfomed at the same site. Neck ultrasound was negative in 23/43 (53%) and inconclusive in 20/43 (47%) patients. MIBI SPECT/CT was negative in 36/43 (84%) and inconclusive in 7/43 (16%) patients. PET/CT was positive in 30/43 (70%), inconclusive in 3/43 (7%) and negative in 10/43 (23%) patients. Thirty-three patients underwent PTX, 22 mini-invasive approach, 11 open cervicotomy (1 for recurrence of parathyroid cancer, 1 for suspected parathyroid malignancy, 2 for multinodular goiter, 1 for concomitant thyroid malignancy, 4 for negative uptake and 2 for bilateral PET/CT uptake). The intraoperative PTH assay was performed in 29 cases and in all but one (96,5%) demonstrated a reduction greater than 50% of PTH levels from the highest basal value. The histology showed parathyroid adenoma in 28 (84%), parathyroid cancer in 2 (6%), papillary thyroid cancer in one and white cervicotomy in two cases. Of note, the two patients with bilateral uptake had the excision of only one pathological gland since at surgical exploration there was no evidence of other enlarged parathyroid gland. Conversely, one patient with only one abnormal uptake at PET/CT had the removal of two enlarged parathyroid glands that were both adenomas. Thus, 26 of 29 parathyroid lesions were true-positive and 3 were false-positive uptake. Overall, per-lesion sensitivity of ^{18}F-choline PET/CT was 81%, the positive predictive value was 90% and the accuracy was 75% for all parathyroid lesions. In conclusion, ^{18} F-coline PET/TC demonstrated a good diagnostic performance and it might be considered as a valid alternative in patients with negative/inconclusive conventional imaging.

Risk factors for renal calcifications and determinants of hypercalciuria in patients with chronic, post-surgical hypoparathyroidism

Laura Mazoni[1], Antonio Matrone[1], Matteo Apicella[1], Paolo Piaggi[2], Federica Saponaro[1], Simona Borsari[1], Elena Pardi[1], Bianca Cosci[1], Isabella Biagioni[1], Piercarlo Rossi[3], Federica Pacciardi[3], Alessandra Scionti[3], Rossella Elisei[1], Claudio Marcocci[1] & Filomena Cetani[4]
[1]University Hospital of Pisa, Department of Clinical and Experimental Medicine, Pisa, Italy; [2]University of Pisa, Department of Information Engineering,, Pisa, Italy; [3]University Hospital of Pisa, Diagnostic and Interventional Radiology Unit, Pisa, Italy; [4]University Hospital of Pisa, Endocrine Unit 2, Pisa,

Conventional therapy with oral calcium supplements and activated vitamin D is the most diffuse and available therapy for chronic hypoparathyroidism (HypoPT). This treatment does not replace the lack of PTH and is associated with renal complications. We report the results of a case control study with a prospective design which included 178 adult patients with differentiated thyroid cancer treated with total thyroidectomy with a follow-up longer that 3 years after surgery: 89 with PoHypoPT treated with conventional therapy and 89 without PoHypoPT, matched for age and sex. Both groups were balanced for gender, age, time since thyroidectomy, supplementation with cholecalciferol, dose of levothyroxine and dietary calcium intake. Half of the patients were stable on treatment with calcitriol alone, 45% with calcitriol and calcium carbonate, and 4 with calcium carbonate alone. All patients underwent biochemical tests and renal ultrasound. Twenty-fou- hour urinary calcium, creatinine, sodium, potassium, chloride, sulfate, uric acid, phosphate, oxalate, citrate, volume and Ph were measured. The biochemical control of patients with PoHypoPT was satisfactory, but only one-third of patients was at target according to ESE guidelines. Patients with PoHypoPT, compared with those without PoHypoPT, had significantly lower alb-Ca and PTH and increased serum phosphate, calcium-phosphate product, and 24-h urinary calcium, but there was no difference in estimated GFR. Renal calcifications were detected in 26 (29.2%) patients with PoHypoPT and in 11(12.4%) without. We found a positive association between renal calcification and age ($P=0.03$) and plasma PTH ($P=0.01$), but no association with hypercalciuria or other urinary parameters. The median 24-h urinary calcium was significantly higher in patients with PoHypoPT than in those without (248 vs 162 mg, $P< 0.01$) Urinary calcium in patients with PoHypoPT was positively associated with serum calcium ($P <0.001$), urinary magnesium ($P <0.001$), and urinary volume ($P= 0.003$), and negatively associated with serum albumin ($P = 0.025$), urinary oxalate ($P <0.001$) and creatinine ($P= 0.008$). Our study confirms that conventional therapy in patients with chronic PoHypoPT is suboptimal. 24-h urinary calcium and the rate of renal calcification are higher in patients with chronic PoHypoPT compared with controls. We found no significant difference in renal function (eGFR) between patients with chronic PoHypoPT compared with controls. We found no association between renal calcification and hypercalciuria and/or other urinary stone risk factors. Further prospective studies including a large number of patients would be necessary to better define the risk factor for renal calcifications in patients with PoHypoPT

Phenotype characterization of a PHEX non canonical splice-site mutation in a family affected by X linked hypophosphatemic rickets and efficacy of one-year Burosumab treatment in adult patients

Rosa Di Fraia, Lucia Digitale Selvaggio, Francesca Allosso & Daniela Pasquali
University of Campania L. Vanvitelli, Advanced Medical and Surgical Sciences, Napoli, Italy

X-linked hypophosphatemic rickets (XLH) is associated with mutations in *PHEX*, upregulation of FGF23, leading to hypophosphatemia, abnormal bone development and short stature. H-MAB to FGF23, Burosumab, is the new therapy for XLH. Among *PHEX* mutations, c.1586+6T >C, partially destroying the splice-site, is presumably associated to a mild phenotype not described so far. We describe two siblings bearing the *PHEX* c.1586+6T >C variant. **Case 1:** A 52y men, 152 cm tall (-3.4SDS), father of two pediatric patients, was referred after testing positive for same PHEX mutation found in the proband. Family history of a similar condition was negative, except for his sister. At 47y, after investigation on his affected daughters, an orthopedic consultation concluded for active rickets. He presented impaired mobility, district arthrosis, tibia vara, hypodisplasia of tooth enamel, and bilateral perceptive hearing loss. Six minutes walking test(6 MWT) showed reduced functional capacity. IQOLA-SF-36 showed poor QOL. X-ray found diffuse spondylarthrosis, coxosclerosis, dysmorphism of proximal femoral epiphyses and curvature of the diaphysis. The MOC-DEXA compatible

by gender and age. **Case 2:** A 47y woman, 143 cm tall (-3.34SDS). At 29y underwent surgery on right foot scaphoid bone and was diagnosed tibia vara. At 45y an orthopedic consultation concluded for active rickets. She showed skeletal malformations, waddling gait, diffuse polyarthrosis, hypodisplasia tooth enamel, and perceptive deep. 6 MWT showed reduced functional capacity. IQOLA-SF-36 showed poor QOL. They started conventional supplementation with active vitamin D, phosphate was added to calcitriol and suspended before Burosumab. Both patients started Burosumab (1 mg/Kg/die), after approval of the compassionate use since December 2020. Results: At start, **case 1:** showed: Ca 9.2 mg/dl, P 1.9 mg/dl, ALP 62U, PTH 31 pg/ml, vitD 44.1 ng/ml, Cau/24h 83 mg/24h, Pu/24h 512 mg/24h, after 1y of Burosumab, Ca 10,3 mg/dl, P 3,47 mg/dl PTH 63,5 pg/ml, 25OHVitD 7 ng/ml, Cau/24h 44 mg/24h, Pu/24h 86 mg/24. P increased of 46%, Pu/24h decreased of 84%. **Case 2:** showed Ca 9.2 mg/dl, P 1.9 mg/dl, ALP 62U/l, PTH 31 pg/ml, vit D 44.1 ng/ml, Cau/24h 83 mg/24h, Pu/24h 512 mg/24h, and after 12 months of Burosumab Ca 9,4 mg/dl, P 2,06 mg/dl, ALP 35U/l, PTH 33,6 pg/ml, 25OHVitD 10,6 ng/ml, Cau/24h 155 mg/24h, Pu/24h 75 mg/24h, P increased of 8%, Pu/24h decreased of 85%. After 1y of Burosumab they performed a IQOLA SF-36, and WOMAC showing a progressive and statistically significant improvement of physical, psychological condition. At 6 MWT the distance covered was significantly increased.

Conclusions

XLH due to c.1586+6T >C in PHEX is associated to a mild phenotype. Our data underline the importance of Burosumab treatment, capable to reduce a substantial disease burden also in adults.

Evaluation of pth deprivation effects on spatial memory in a rat model of chronic post-surgical Hypoparathyroidism

Federica Saponaro[1], Francesca Ronca[1], Cristina Dettori[1], Sabina Frascarelli[1], Giulia Di Buono[1], Silvia Giacomelli[1], Grazia Chiellini[1], Marco Scalese[2], Filomena Cetani[3], Claudio Marcocci[3] & Riccardo Zucchi[1]
[1]Biochemistry Institute, Department of Pathology, University of Pisa, Pisa, Italy; [2]Institute of Clinical Physiology, National Council of Research, Pisa, Italy; [3]Endocrinology Unit, University Hospital of Pisa, Pisa, Italy

Introduction

Hypoparathyroidism (HypoPT) is a rare endocrine disease which is characterized by hypocalcaemia and undetectable or inappropriately low serum parathyroid hormone (PTH). Post-surgical HypoPT (PS-HypoPT) is the most common cause, caused by accidental parathyroid removal/injury during neck surgery. Conventional therapy with calcium and vitamin D analogues does not restore calcium homeostasis and patients with chronic PS-HypoPT complain with several complications. From a neuropsychological standpoint, patients with PS-HypoPT present cognitive and affective symptoms: the more plausible pathophysiological mechanism resides in a direct effect of PTH in the central nervous system (CNS), but these mechanisms are still not completely elucidated. The aim of this study was to evaluate the effects of PTH deprivation on CNS in an animal model (rat) of post-surgical hypoparathyroidism, by a cognitive/behavioural assessment approach.

Methods

A rat model (Sprague Dawley) of PS-HypoPT was obtained by the surgical removal of parathyroids at 5 weeks of age and treated with gluconate calcium 1% in drinking water to maintain normocalcemia. An experimental group of 15 PS-HypoPT rats and 15 healthy Sprague Dawley controls (WT) underwent biochemical testing (serum calcium) and behavioural testing namely Morris Water Maze – MWM-to assess spatial learning and memory at 9 weeks of age.

Results

PS-HypoPT animals treated with standard calcium therapy and controls did not statistically differ in serum calcium levels (11.5 ± 0.5 vs 11.2 ± 0.2, $P<0.001$) and body weight (320 ± 20 vs 335 ± 20 gr). At MWM, during the training test PS-HypoPT animals displayed a significantly worse performance compared to controls, as suggested by a higher escape latency parameter (1° day 23.8 ± 11.9 vs 14.6 ± 9.3 sec,$P=0.02$; 2° day 13.3 ± 11.6 vs 8.7 ± 4.7 sec,$P=0.02$; 3° day 14.5 ± 7.9 vs 11.01 ± 8.4 sec$P=0.01$). Both groups improved their results from the firs to the last day of training (escape latency PHPT 23.8 ± 11.9 vs 9.2 ± 4.5 sec $P<0.001$; WT 14.6 ± 9.3 vs 5.5 ± 0.6 sec $P<0.001$), even if PS-HypoPT group had a higher improvement compared to WT (multivariate analysis$P=0.04$) . In the last day at the probe test, PS-HypoPT group and WT did not differ for the principal parameter escape latency and for secondary parameters, namely time in platform zone, entrance in the platform zone, total distance and platform crossings.

Conclusions

Animal model of HypoPT shows an impairment in spatial learning and memory compared to WT; training could ameliorate this condition. Further studies are ongoing evaluating other cognitive functions in such a model and could help to understand the physiopathological bases of neuropsychological symptom in patients with HypoPT.

Impact of body composition on skeletal health in subjects with Klinefelter's syndrome: a cross sectional study

Flaminia Carrone[1], Walter Vena[1], Andrea Delbarba[2], Letizia Chiara Pezzaioli[2], Paolo Facondo[2], Carlo Cappelli[2], Alessandro Pizzocaro[1], Gherardo Mazziotti[1,3], Andrea Gerardo Lania[1,3] & Alberto Ferlin[4]
[1]Endocrinology, Diabetology and Andrology Unit, IRCCS Humanitas Research Hospital, via Manzoni 56, 20089 Rozzano, Milan, Italy; [2]Unit of Endocrinology and Metabolism, Department of Clinical and Experimental Sciences, University Hospital of Brescia; [3]Department of Biomedical Sciences, Humanitas University, Via Rita Levi Montalcini 4, 20090 Pieve Emanuele, Milan, Italy; [4]University of Padova, Department of Medicine, Unit of Andrology and Reproductive Medicine

Background

There is growing awareness of skeletal impairment in individuals with Klinefelter syndrome (KS), involving both quantitative and qualitative alteration of the bone as well as an increased prevalence of vertebral fractures (VFs). Beyond hypogonadism, considerable evidence suggests that other factors may be responsible for the skeletal fragility observed in these patients. Abnormal body composition is a common finding in KS subjects, characterized by an unfavourable muscle/fat ratio with an increase in total and abdominal fat mass, but evidence of its relationship with bone health is scant.

Purpose

Based on the emerging evidence of a close relationship between bone and soft tissues with possible detrimental effect of body fat distribution on bone metabolism, we aimed at assessing the impact of body composition parameters on bone health in terms of bone mineral density (BMD), microarchitecture, and radiological VFs in adult subjects with KS.

Methods

Seventy-three adult males with KS were consecutively enrolled by two Endocrinology and Andrology Units (IRCCS Humanitas Research Hospital in Milan and ASST Spedali Civili in Brescia). Whole body dual-energy X-Ray Absorptiometry (DXA) was performed to assess lumbar spine, femoral neck and total hip BMD, trabecular Bone Score (TBS) and body composition. Prevalence of VFs was assessed by quantitative morphometry on lateral spine X-rays.

Results

Low BMD was observed in 16 patients (23%). No significant differences were found in body mass index (BMI) and several body composition parameters between KS subjects with normal and low BMD. Degraded TBS was found in 16 patients (26%) with a prevalence which resulted significantly higher in individuals with higher BMI ($P=0.001$), fat body mass (FBM) ($P<0.001$), visceral adipose tissue (VAT) ($P<0.001$) and/or fat mass index ($P<0.001$). VFs were detected in 14 patients (19%), without significant associations with BMD ($P=0.983$) and TBS ($P=0.371$). However, subjects with VFs had significantly higher percentage of truncal/leg fat ratio ($P=0.011$) as compared to those without VFs.

Conclusion

This study provides a first evidence that abdominal adiposity might be a determinant of VFs in KS patients, consistent with the working hypothesis that alterations in body composition could negatively affect bone health in this clinical setting. The value of TBS in predicting fractures in KS without possible interference of body composition remains to be clarified in future longitudinal studies.

Parathyroid carcinomas (PCas) are rare endocrine malignant neoplasia characterized by an abnormal PTH secretion and, consequently, severe and uncontrolled hypercalcemia. Clinically, the preoperative diagnosis can be misleading, because PCas share some molecular and clinical similarities with benign lesions and are often indolent. The histological diagnosis of carcinoma is achieved based on the presence of mitotic nuclear figures, capsular invasion, parenchyma infiltration, vascular invasion and, less frequently, distant metastasis. Moreover, there is no molecular biomarker that could support PCas diagnosis. LncRNAs are an important class of epigenetic regulators involved in both physiological processes and cancer development. Preliminary evidence suggested that lncRNAs could act as accurate prognostic and diagnostic biomarkers. Recently, we identified a long non-coding RNAs (lncRNAs) signature able to distinguish PCas from benign parathyroid adenomas (PAds) and normal parathyroid glands. Particularly, the lncRNA BCYRN1/BC200 emerged as an interesting candidate biomarker for the diagnosis of PCas. In gastric, colorectal and breast cancers BC200 expression is dramatically increased and positively correlates with distant metastasis, tumor size and clinical stage. We previously reported that BC200 is overexpressed in PCas tissues harboring *CDC73* gene inactivating mutations. Here, we found that BC200 is also upregulated in metastatic PCas ($n=4$) compared to the non-metastatic ($n=9$) parathyroid carcinomas. Then, we tested the hypothesis that circulating BC200 expression may provide a clinical and non-invasive biomarker to distinguish PCas from PAds. To this end, we analyzed circulating BC200 expression levels in serum samples from patients affected with PCas ($n=4$) and PAds ($n=22$) through digital PCR. All samples were collected prior parathyroidectomy. Our results show that BC200 counts are higher in the serum of patients affected with PCas compared to those detected in serum of patients harboring PAds. Moreover, serological BC200 counts positively correlate with circulating PTH and total calcium levels and age at diagnosis in PAds. Lastly, we analyzed circulating BC200 expression in the serum of 3 PCa patients before and after parathyroidectomy. BC200 counts are reduced in all 3 postoperative PCas serum samples compared to the preoperative specimens, suggesting its potential use also as a useful non-invasive biomarker in the clinical follow-up of PCa patients. These findings extend the knowledge on BC200 in parathyroid tumors, supporting its role as a novel tissue and circulating biomarker for PCas diagnosis.

Assessment of the cardiovascular system in patients with primary hyperparathyroidism, including the role of aldosterone

Izabela Karwacka[1], Sonia Kaniuka-Jakubowska[1], Krzysztof Sworczak[2], Izabela Pisowodzka[2] & Marcin Fijałkowski[2]
[1]Medical University of Gdańsk, Department of Endocrinology and Internal Diseases, Gdańsk, Poland; [2]Medical University of Gdańsk, 1st Department of Cardiology, Gdańsk, Poland

Typical symptomatology of primary hyperparathyroidism (PNP) includes bone lesions and renal dysfunction in the form of recurrent nephrolithiasis but the symptoms of hypercalcemia may mimic other conditions, including cardiovascular diseases. The exact frequency of cardiac symptoms is not known. The study included 45 adult patients diagnosed with PNP, over 18 years of age, who were qualified for ptx. Laboratory tests included the determination of serum PTH, Ca, Pi and cardiac ECHO assessment of the heart, 24-hour recording of blood pressure using the Holter method and 24-hour Holter electrocardiography – the procedures were performed before the surgical treatment, and then as follow-up tests one month and six months after ptx; the follow-up ECHO assessment was performed 6 months after ptx. After ptx, the expected significant decrease in PTH concentration was achieved in all patients and the levels of Ca and Pi normalized ($P < 0.001$). The study group included 25 patients with hypertension (HT) (56%). Statistical significance was not achieved both in terms of BP change and the dipper/non-dipper parameters. The relationship between PTH and mean SBP and DBP was statistically significant. Patients were divided into two groups: patients with HT (25) and patients with normal BP (20) before ptx. After surgery, improvement in HT control was observed in 23 patients (92%); in this group it was found: BP normalization in 8 patients (35% in the improvement group), discontinuation or reduction of the amount of antihypertensive drugs in 13 patients (56% in the improvement group), achievement of the correct reduction of BP at night (non-dipper → dipper) in 14 patients (61% from the improvement group). In the analysis of ECG parameters before ptx and after surgery, a statistically significant change occurred in the QTc interval ($P < 0.001$). Among patients with SVBPs and VPBs before ptx, statistically significant improvement in SVBPs after ptx was observed. The QTc interval variable correlated with PTH and Ca before ptx. In ECHO, the IVS, LVEDD and LFEV did not differ statistically significantly between the tests before and after the procedure, whereas the parameters of RWT, LVM and LVMI differed statistically significantly – before the surgery they were significantly higher than after the surgery. The GLS value was significantly decreased in 27 (60%) patients after ptx. To conclude, the patients with PNP have a higher risk of cardiovascular diseases, observing the improvement of cardiological parameters after successful surgery.

Patients' adherence and satisfaction from daily vs monthly vitamin D supplementation: results from a dedicated bone clinic

pnina rotman pikielny, Liat Barzilai-Yosef, Erez Ramaty, Sofia Braginski Shapira & osnat Tell-Lebanon
Meir Medical Center, Institute of Endocrinology, Diabetes and Metabolism, Affiliated with the Sackler Faculty of Medicine, Tel Aviv University Kfar Sava, Israel

Background
Vitamin D supplementation is an integral component of treating patients with osteoporosis/osteopenia. Data have shown that monthly vitamin D supplementation is not inferior to daily regarding target vitamin D levels. Moreover, it has been argued that monthly supplementation might increase adherence. Patients' adherence and satisfaction with daily versus monthly vitamin D supplementation have been hardly investigated. The current study evaluated osteopenic/osteoporotic patients' adherence and satisfaction from vitamin D supplementation after switching from monthly to daily (MtD) dosing and vice versa (DtM).
Methods
Ambulatory osteopenic/osteoporotic patients visiting the endocrine clinic at a tertiary medical center were asked to switch their vitamin D supplementation from MtD and vice versa. Total monthly dose remained unchanged. Patients answered questionnaires regarding socio-demographic and medical status, compliance with vitamin D dosing (Morisky Adherence Scale 8; MMAS-8), satisfaction with vitamin D regimen and physical functional status (OPAQ-15) at baseline and 6 months after switching. Each group was compared to its baseline characteristics and to the parallel group.
Results
Among 72 ambulatory patients recruited (mean age 71.5 ± 7.4, 91.7% female), 52 (72.2%) were switched from DtM treatment and 20 (27.7%) from MtD. 84.7% were taking anti-osteoporosis medications, 51.4% had a prior osteoporotic fracture and 76.5% were taking calcium supplementation. Baseline vitamin D level was 86.1 ± 17.2 nmol/l. Both groups expressed good baseline compliance (mean 98.1%) with vitamin D regimen (MMAS-8 score ≥ 8). Baseline satisfaction with vitamin D regimen was good: 74% and 77.7% from DtM and MtD dosing, respectively. Baseline physical status was good in 63.9% and moderate in 33.3%. After switching, satisfaction level, adherence to vitamin D

regimen, vitamin D level and functional capacity were not different compared to baseline. Yet, 68.8% of MtD and 52% of DtM patients wanted to remain on the current regimen. Among patients who experienced both regimens, 56.1% preferred daily and 43.9% preferred monthly.

Conclusion

Patients with osteopenia/osteoporosis had good adherence to monthly and to daily vitamin D regimens and expressed high level of satisfaction with them. All parameters remained stable after switching regimens. Most MtD patients preferred the new regimen. Additional large-scale studies are needed to evaluate the effects of various dosing regimens on patients' satisfaction and adherence.

Systematic literature review of the renal and cardiovascular complications associated with chronic hypoparathyroidism

Olulade Ayodele[1], Felicia Castriota[2], Sheetal Sharma[3], Meenu Verma[3] & Elvira Gosmanova[4]

[1]Takeda Pharmaceuticals USA, Inc., Lexington, United States; [2]Takeda Pharmaceuticals USA, Inc., Cambridge, United States; [3]Parexel International, Mohali, India; [4]Albany Medical College, Albany, United States

Despite conventional treatment with oral calcium and active vitamin D, patients with chronic hypoparathyroidism (cHypoPT) can remain not adequately controlled (NAC) and have abnormal biochemistry, disease complications, or symptoms impacting quality of life. A systematic literature review (SLR) was conducted to evaluate the clinical burden for patients with cHypoPT, with an emphasis on patients with NAC disease. This abstract focuses on data related to renal and cardiovascular complications. Key biomedical databases (MEDLINE, EMBASE, MEDLINE In-Process, Cochrane Controlled Register of Trials and Cochrane Database of Systematic Reviews) were searched for pertinent studies from database inception to June 2020. Abstracts from 6 relevant congresses held from January 2017–June 2020 were searched to identify studies not published as full-text journal articles. Publication bibliographies were reviewed to identify additional sources. Eligible studies included adults with cHypoPT and were published in English, with no restrictions on study design or comparator. NAC patients were identified via ≥ 1 of the following: abnormal biochemistry, renal impairment, persistent symptoms affecting quality of life, and study-specific NAC definitions. Results were described per Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines. Forty-nine studies from 91 publications were included in the SLR. Of these, 21 and 7 publications addressed renal and cardiovascular complications, respectively. Compared with the general population, patients with cHypoPT were at increased risk of renal insufficiency, renal failure, nephrocalcinosis, and nephrolithiasis. Nephrolithiasis and nephrocalcinosis were the most commonly reported renal disorders, with incidence ranging from 1.9%–48% in patients with cHypoPT. Impaired renal function and risk of renal diseases were positively related to cHypoPT duration. In one study, rates of renal disorders were significantly higher in patients with NAC vs adequately controlled (AC) cHypoPT ($P<0.01$). Patients with cHypoPT were at risk of cardiovascular outcomes including cardiomyopathy, congestive heart failure, ischaemic heart disease, and arrhythmia. Patients with cHypoPT had increased risk of both incident cardiovascular conditions and a composite cardiovascular endpoint compared with patients without cHypoPT (all $P<0.05$). Longer disease duration was associated with increased risk of cardiovascular complications, independent of disturbances in calcium-phosphate homeostasis. In one study, patients with NAC disease had significantly higher rates of cardiovascular disorders compared with patients who were AC, especially for cardiac artery calcification and QT prolongation. cHypoPT is associated with increased risk of renal and cardiovascular complications. Based on limited published data, patients with NAC disease may experience a higher clinical disease burden than patients whose cHypoPT is controlled.

Weakening of short- and long-term verbal memory in patients with PHPT, evaluated by a neuropsychological approach

Federica Saponaro[1], Gaspare Alfi[2], Filomena Cetani[3], Antonio Matrone[3], Laura Mazoni[3], Matteo Apicella[3], Elisa Lai[2], Marco Laurino[2], Angelo Gemignani[2] & Claudio Marcocci[3]

[1]Biochemistry Institute, Department of Pathology, University of Pisa, Pisa, Italy; [2]Department of Pathology, University of Pisa, Pisa, Italy; [3]Endocrinology Unit, University Hospital of Pisa, Pisa, Italy

Introduction and aims

Primary Hyperparathyroidism (PHPT) is a common endocrine disease associated with hypercalcemia and elevated or inappropriately normal serum levels of PTH. Among PHPT manifestations, neuropsychological symptoms have been described, including depression, anxiety, loss of memory, impaired cognition, with a wide range (3-50%) depending on the study population. Neuropsychological/ccognitive symptoms in patients with PHPT have been evaluated as part of quality of life (QoL) assessment, mainly using validated self-administered questionnaires, such as 36-Item Short Form Health Survey (SF-36), WHO-5 Well-being Index Survey (WHO-5), which lack specificity. This study aims to evaluate cognitive functions of patients with PHPT compared to a control population, using a standardized neuropsychological approach.

Methods

Observational, monocentric study on patients with PHPT and controls, in whom a standardized neuropsychological assessment, focused on attentive functions and memory abilities was performed by a trained psychologist.

Results

Patients ($n=19$) presented a mild PHPT, and mean age 53.8 ± 11.45 years). Control population ($n=24$, mean age was 51.8 ± 10.87 years) was enrolled among patients with differentiated thyroid cancer in remission (or without residual disease), without Hypoparathyroidism and in good control under levothyroxine therapy, who were followed by Endocrine Unit (University Hospital of Pisa). Patients with PHPT had significantly worse performance at Digit Span Forward (mean score 5.41 ± 0.81 – 6.17 ± 1.64; P-value <0.05) test that provides a measure of verbal short-term memory span and Story Recall Test that provides a measure of auditory-verbal long – term memory. Regarding Story Recall Test the worse performance was confirmed both in immediate (mean score 4.54 ± 1.40 – 5.72 ± 1.46 P-value <0.05) and delayed recall (4.37 ± 1.30 – 5.44 ± 1.51; P-value <0.05).

Conclusions

Patients with PHPT might present a weakening in verbal short – and long – term memory. Further studies are ongoing to evaluate other cognitive functions and to correlate cognitive testing with biochemical parameters.

[1]Humanitas Research Hospital, Endocrinology, Diabetology and Andrology Unit, Rozzano (MI), Italy; [2]Hunmanitas University, Department of Biomedical Sciences, Pieve Emanuele (MI), Italy; [3]ASST Spedali Civili di Brescia, Medical Oncology Unit, Brescia, Italy; [4]Humanitas Research Hospital, Cancer Center, Rozzano (MI), Italy; [5]University of Brescia, Department of Medical and Surgical Specialties, Radiological Sciences and Public Health, Italy; [6]ASST Spedali Civili di Brescia, Radiology Unit, Brescia, Italy; [7]Humanitas Research Hospital, Department of Radiology, Rozzano (MI), Italy

Background

Skeletal fragility is an important clinical issue in women with early-stage breast cancer and men with non-metastatic prostate cancer under hormonal hormone deprivation therapies (HDTs). Vertebral fractures (VFs) have been reported in a remarkable number of subjects exposed to HDT especially when the diagnosis of fractures is performed by a radiological and morphometric approach. Notably, prediction of fractures in this clinical setting is a challenge and determinants of fractures are still largely unknown. Current international guidelines rely on bone mineral density (BMD) and the WHO Fracture Risk Assessment Tool (FRAX) to identify cancer survivors at high risk of fractures to be treated in primary prevention, but their reliability in this setting of secondary osteoporosis seems to be inaccurate. In this study, reflecting the real-life clinical practice, we investigated the diagnostic performance of FRAX algorithm and BMD in identifying breast and prostate cancer survivors developing VFs during HDTs.

Methods
This cross-sectional study included 527 consecutive subjects (429 females with breast cancer, 98 males with prostate cancer; median age 61 years) at two referral centers in Italy. At study entry, all participants had been under HDTs for at least 6 months and none received bone-active drugs. Prevalence of VFs was assessed by a morphometric approach, in relationship with FRAX score, body mass index (BMI), BMD, age, duration and type of HDTs.
Results
VFs were found in 140 subjects (26.6%) with spine deformity index was significantly associated with duration of HDTs (rho 0.38; $P<0.001$). The prevalence of VFs was significantly higher in males with prostate cancer than females with breast cancer (45.9% vs. 22.1%; $P<0.001$). In females with breast cancer, VFs were significantly associated with FRAX score for major fractures [OR 1.07; $P<0.001$] after correction for age ($P=0.853$) and BMD ($P=0.097$). The best cut-off of FRAX score for major fractures for identifying subjects with VFs was 6.35%, with sensitivity and specificity of 62.0% and 61.9%, respectively. In males with prostate cancer, VFs were significantly and independently associated with BMI $\geq$ 25 Kg/m^2 (OR 11.86; $P<0.001$), BMD T-score below -1.0 SD (OR 7.89; $P=0.001$) and GnRHa plus abiraterone treatment (OR 20.28; $P=0.002$), after correction for age ($P=0.111$) and FRAX score for major fractures ($P=0.199$).
Conclusions
FRAX and BMD could be useful for predicting VFs in subjects undergoing HDTs, but the thresholds are lower than those applied in primary osteoporosis. Notably, high BMI is a determinant of VFs in males under HDT.

Effects on bone mineral density and bone markers of the sequential treatment with teriparatide followed by zoledronic acid in patients with severe fractured osteoporosis: retrospective real-life data

Giorgia Dito[1], Chiara Degradi[2], Gregorio Guabello[3], Matteo Longhi[3] & Sabrina Corbetta[4]
[1]Endocrinology and Diabetology Service, IRCCS Istituto Ortopedico Galeazzi, Milan, Italy; [2]Endocrinology and Diabetology Service, IRCCS Istituto Ortopedico Galeazzi, Department of Pathophysiology and Organ Transplantation, University of Milan, Milan, Italy; [3]Rheumatology Unit, IRCCS Istituto Ortopedico Galeazzi, Milan, Italy; [4]Endocrinology and Diabetology Service, IRCCS Istituto Ortopedico Galeazzi, Department of Biomedical, Surgical and Dental Sciences, University of Milan, Milan, Italy

Osteoporosis is a chronic condition requiring long-term treatment; sequential treatment regimens with different agents represents an option aimed to increase bone mineral density (BMD) and then to maintain it. The loss of BMD occurring after withdrawal of teriparatide (TPT) can be prevented by bisphosphonates (BPs). Among BPs, data about the efficacy of zoledronic acid (ZOL) after TPT treatment are scanty. Here, we contribute to this topic providing data derived from the real-life setting of the third level centre Istituto Ortopedico Galeazzi in Milan. Twenty-two severe osteoporotic fractured patients [4 males, 18 postmenopausal females; aged 74.4 (65.8, 78.9) years, median, IQ range; BMI 26.1 $\pm$ 4.5 kg/m^2, mean $\pm$ SD] were treated with subcutaneous daily 20 microg TPT (according the Italian AIFA 79 note) for 24 months followed by two intravenous infusions of 5 mg ZOL, the first one at $<$ 6 months from TPT withdrawal, the second one 12 months from the first infusion. Eight patients were smokers; 7 patients were treated with chronic steroid therapy ($>$5 mg prednisone daily). Clinical and biochemical parameters were collected in all patients. BMD at lumbar and femur sites were measured by dual x-ray absorptiometry and recorded as T-scores. All patients experienced at least one vertebral fracture (3.0, 2.0-2.3). Mean lumbar T-score [-3.09 $\pm$ 1.18] increased after TPT treatment (-2.45 $\pm$ 1.33,$P=0.002$ by ANOVA) and the increase was consolidated by ZOL treatment (-2.17 $\pm$ 1.35,$P=0.0002$ vs basal condition by ANOVA). Mean lumbar T-score increase was 21% of the basal T-score after TPT and further 11% after TPT+ZOL. Median neck T-score [-2.70 (-3.30, -2.08)] was not affected by TPT [-2.50 (-3.00, -1.88)] as well as by TPT+ZOL treatment [-2.50 (-3.20, -1.78);$P=0.157$ by ANOVA]. Median total hip T-score [-2.40 (-2.90, -1.56)] increased after TPT+ZOL treatment [-1.75 (-2.48, -1.28);$P=0.049$ by ANOVA]. Any patient experienced incident fractures during TPT treatment, while 1 patient reported a femur fracture and one patient a non-vertebral non-femur fracture during ZOL treatment. During the sequential TPT+ZOL treatment serum calcium and phosphate levels did not show significant changes, while plasma PTH levels decreased during TPT and increased during ZOL treatment. Serum total ALP and β-CTX levels increased during TPT and decreases during ZOL treatment. Serum 25hydroxyvitamin D were constantly $>$20 ng/ml in all patients. In conclusion, our data from real-life management of severe osteoporotic patients showed that the sequential treatment TPT+ZOL is effective in increasing and maintaining lumbar and hip BMDs.

Impact of underlying disease on long-term skeletal outcome after lung transplantation

Giorgia Grassi[1], Iacopo Chiodini[1], Elisa Cairoli[2], Letizia Corinna Morlacchi[3], Valeria Rossetti[3], Lorenzo Rosso[4], Ilaria Righi[5], Mario Nosotti[4], Maura Arosio[1], Francesco Blasi[4] & Cristina Eller Vainicher[6]
[1]University of Milan, Department of Clinical Sciences and Community Health, Milan, Italy; [2]Istituto Auxologico Italiano, IRCCS, Unit for Bone Metabolism Diseases and Diabetes & Lab of Endocrine and Metabolic Research, Milan, Italy; [3]Fondazione IRCCS Ca' Granda -Ospedale Maggiore Policlinico, Respiratory Unit & Cystic Fibrosis Adult Center, Milan, Italy; [4]University of Milan, Department of Pathophysiology and Transplantation, Italy; [5]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Thoracic Surgery and Lung Transplant Unit, Milan, Italy; [6]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Unit of Endocrinology, Milan, Italy

Background
fragility fractures (FX) occur frequently after lung transplantation (TX), with a higher rate (15-20%) in the first two years, which decreases subsequently. Patients affected from cystic fibrosis (CF) seem to have a lower FX risk in the first two years after TX as compared with those affected with other lung diseases (nCF). The aim of our study is to evaluate and compare the long-term skeletal outcome in CF and nCF patients after TX.
Methods
we evaluated the FX rate and the trend in bone mineral density (BMD) after the first two years post-TX in 67 patients (36 CF, 31 nCF). The mean follow-up duration was 5.4 (4-8) years and 37.3% patients (15% CF e 51.6% nCF,$P=0.023$) was taking bisphosphonates.
Results
2/67 patients (3%), both with TX rejection, had FX (1 FC 28 years old with hip FX and 1 nFC 65 years old with wrist FX). Lumbar spine (LS) BMD remained stable in both groups (-1.3 $\pm$ 1.1 vs -1.1 $\pm$ 1.1,$P=0.081$) and (-1.5 $\pm$ 1.0 vs -1.4 $\pm$ 1.1,$P=0.485$, CF and nCF respectively). Femoral neck (FN) and total hip (TH) BMD improved in CF group (-1.8 $\pm$ 1.0 vs -1.6 $\pm$ 0.9,$P=0.036$; -1.6 $\pm$ 0.9 vs -1.4 $\pm$ 0.8,$P=0.001$; respectively, FN, TH), conversely, FN worsened significantly and TH remained stable in nCF group (-1.7 $\pm$ 0.8 vs -1.9 $\pm$ 0.6,$P=0.018$; -1.3 $\pm$ 0.7 vs -1.3 $\pm$ 0.7,$P=0.666$; FN and TH respectively), in spite of a higher percentage of nCF patients taking bisphosphonates. The nCF disease was significantly associated with a worsening in both FN (OR 30.3$P=0.017$, 95%CI 1.8-500) and LS BMD (OR 11.5$P=0.027$, 95%CI 1.3-100) regardless of ongoing bisphosphonates therapy, cumulative glucocorticoids dose, age, TX rejection, spine deformity index.
Conclusions
our study confirms a low FX rate after the first two years post-TX. Also the long-term data suggest that the skeletal outcome after TX is more favourable in CF patients.

The impact of age on quality of life and frailty outcomes after parathyroidectomy in patients with primary hyperparathyroidism

Theodosios S. Papavramidis[1], Panagiotis Anagnostis[2], Ioannis Pliakos[1], Georgios Tzikos[1], Angeliki Chorti[1], Kalliopi Kotsa[3] & Antonios Michalopoulos[1]
[1]1st Propedeutic Department of Surgery, AHEPA University Hospital, Aristotle University of Thessaloniki, Thessaloniki, Greece; [2]Aristotle

University of Thessaloniki, Unit of Reproductive Endocrinology, 1st Department of Obstetrics and Gynecology, Medical School, Thessaloniki, Greece; [3]Division of Endocrinology and Metabolism and Diabetes Center, First Department of Internal Medicine, Medical School, Aristotle University of Thessaloniki, Thessaloniki, Greece

Objective
Parathyroidectomy (PTx) improves quality of life (QoL) in patients with primary hyperparathyroidism (PHPT). Whether this effect is modified according to the patients' age is unknown. The aim of this study was to evaluate the impact of age on the effect of PTx on QoL and frailty in patients with PHPT, six months post-PTx.
Methods
This was a prospective cohort study, including patients with PHPT, admitted from January 2016 to December 2019, divided into two categories: younger ($\leq$65 years old) and older ($>$65 years old). QoL was assessed with the Pasieka questionnaire (PAS-Q) two days pre- and six months post-operatively. Frailty was also assessed at the same time intervals, with the Frailty Index (FI).
Results
One-hundred thirty-four patients (younger group: 96 patients, mean age 50.4$\pm$9.8 years; older group: 38 patients, mean age 72.1$\pm$4.9 years) were included. PTx resulted in a significant reduction in PAS-Q score in both groups. Notably, a greater reduction in 'mood swings', 'irritability', 'itchy skin' and 'feeling thirsty' PAS-Q domains was observed in younger group. In contrast, a greater decrease in 'bone-pain', 'tiredness', 'weakness', 'joint pain', 'getting off chair' and 'headaches' items was observed in older group. Moreover, PTx led to a decrease in FI only in this group.
Conclusions
PTx leads to an improvement in QoL both in older ($>$65 years) and younger ($\leq$65 years) patients with PHPT, attributed to a differential effect on PAS-Q items. Frailty improves only in the older group.

Background
Testosterone (T) is essential for bone health during all ages, helping to achieve a proper peak bone mass and, later, to maintain bone density and strength. Guidelines on management of male osteoporosis recommend testosterone replacement in young-adult hypogonadal to prevent bone loss and anti-resorbitive drugs in case of high fracture risk, but the role of T replacement therapy (TRT) alone in subjects with late onset hypogonadism is still the object of an intense debate.
Methods
All observational studies and placebo-controlled or -uncontrolled randomized trials (RCTs) comparing the effect of TRT on different bone parameters were considered. Studies using androgens other than T, as well as studies with concomitant treatment with other hormones and drugs were also excluded, unless there was a clearly defined treatment arm that received only T treatment. Similarly, studies including only patients with genetic causes of male hypogonadism were excluded.
Results
Out of 349 articles, 36 were considered, including 3103 individuals with a mean trial duration of 66.6 weeks. TRT improves significantly areal bone mineral density (aBMD) at the spine (mean +2.6%, 2-5.1%, CI 95%;P= 0,026) and femoral neck (mean +3.6%, 1-6.1%, CI95%;P=0,020) levels in observational studies, whereas placebo controlled RTCs showed a positive effect of TRT only at lumber spine (+2.2%, 0.4-4.8%, CI 95%;P= 0,097) and when trials included only hypogonadal patients at baseline (total testosterone $<$ 12 nM)(+5.2%, 0.7-9.7%, CI 95%;P=0,024). The effects on aBMD were more evident in subjects with lower T levels at baseline and increased as a function of trial duration and a higher prevalence of diabetic subjects. Either T or estradiol increase at endpoint contributed to aBMD improvement. TRT was associated with a significant reduction of bone resorption markers in observational but not in controlled studies.
Conclusion
TRT alone is able to inhibit bone resorption and increase bone mass, particularly at the lumbar spine level and when the duration is long enough to allow the anabolic effect of T and estrogens on bone metabolism to take place. However, whether or not TRT is associated with a decreased risk of bone fractures remains to be established.

Impact of hypoparathyroidism on quality of life in patients with differentiated thyroid cancer

Ana Rita Elvas[1], Bernardo Marques[2], Joana Couto[1], Raquel G. Martins[1], Jacinta Santos[1], Teresa Martins[1] & Fernando Rodrigues[1]
[1]Portuguese Oncology Institute of Coimbra, Endocrinology, Coimbra, Portugal; [2]Hospital Egas Moniz, Endocrinology, Lisboa, Portugal

Introduction
Hypoparathyroidism (hypoPTH) is one of the most feared iatrogenic complications of the surgical treatment for thyroid cancer (TC). Despite supplementation with calcium salts and calcitriol, hypoPTH seems to be associated with a negative impact on quality of life (QoL), which has not been evaluated in the Portuguese patients.
Objectives
To evaluate the impact of hypoPTH on the QoL of Portuguese patients with TC and its correlation with serum analytical parameters.
Material and methods
Cross-sectional study of patients diagnosed with TC and chronic hypoPTH (persistent one year after surgery), randomly selected, compared to a control group of patients submitted to surgery for TC without hypoPTH. QoL was assessed using the SF-36v2 health questionnaire, validated for the Portuguese population (which includes eight scales: physical functioning (PF), role physical (RP), bodily pain (BP), general health (GH), vitality (VT), social functioning (SF), role emotional (RE) and mental health (MH)). The levels of ionized and total calcium, albumin, phosphorus, magnesium, creatinine, urea, PTH, vitamin D, TSH and free T4 were measured. Hypothyroid patients were excluded. The information collected was analysed in SPSS®. Data was analysed with Independent Samples t Test and Pearson's correlation test.
Results
Of the 164 patients surveyed, 49 (29.9%) had hypoPTH and 78.7% were female. The mean age was 53.7$\pm$14.7 years. Patients with hypoPTH had statistically significant lower scores on the BP scales (55.8%$\pm$22.7 vs 63.4%$\pm$28.6;P=0.050) and SF (69.4%$\pm$25.5 vs 78. 6%$\pm$21.8;P=0.040) when compared to patients without hypoPTH. Regarding patients with hypoPTH, there was an inverse correlation between phosphorus levels and the scores of the GH (P=0.016), PF (P=0.006) and RP (P=0.020) scales; between age and scores of BP (P=0.017) and PF (P=0.019) scales. In these patients, lower PTH values were equally associated with worse results on BP scale (P=0.013).
Conclusions
This was the first study to assess the impact of hypoPTH on QoL in Portuguese patients. The results obtained suggest a relationship between phosphorus levels and QoL in patients with hypoPTH. Its monitoring seems particularly important in this population in order to identify more vulnerable patients, who may benefit from additional measures.

Trabecular bone score captures low bone quality in women with normal bone mineral density or osteopenia initiating aromatase inhibitors for breast cancer

Matteo Malagrino, Paola Altieri, Uberto Pagotto & Guido Zavatta
Division of Endocrinology and Diabetes Prevention and Care, IRCCS Azienda Ospedaliero-Universitaria di Bologna, Department of Medical and Surgical Sciences (DIMEC), Alma Mater Studiorum University of Bologna, Bologna, Italy

Introduction
Hypoparathyroidism Bone Score (TBS) has been associated with fragility fractures in post-menopausal women. Estrogen-receptor positive breast cancer is usually treated with aromatase inhibitors (AIs), with international guidelines recommending initial bone density (BMD) evaluation, since this therapy is associated with high rates of fragility fractures. Each Country has different thresholds of intervention to recommend pharmacologic treatment for fracture prevention. Patients with normal bone density or osteopenia often miss the chance of receiving any anti-osteoporotic treatment, beyond calcium and vitamin D.
Objective
To describe prevalence of low bone quality measured by TBS in women initiating aromatase inhibitors.
Design
Cross-sectional, observational.
Setting
University hospital.
Patients
From January to December 2021, 75 consecutive unselected ambulatory women with normal BMD or osteopenia referred from the Oncology Department for bone metabolism evaluation with a standardized protocol, after recent diagnosis of estrogen-receptor-positive breast cancer. The patients were naïve to any kind of osteoporotic treatment, including calcium or vitamin D3 supplements. History of clinical or morphometric fractures was an exclusion criterion.
Main outcome measures
TBS, BMD and biochemistries at first endocrine referral before the start of AIs. TBS T-score $\leq$ -2 was used to discriminate low bone quality.
Results
Twenty-five patients (33.3% of the whole cohort) aged 64.8 $\pm$ 10.7 had low TBS (1.238 $\pm$ 0.043). TBS negatively correlated with age (r=-0.41, $P<0.001$), time from menopause (r=-0.312,P=0.012) and positively associated with BMD at all sites (L1-L4, total hip and femur neck, $P<0.001$). TBS was positively associated with urinary calcium (r=0.238,P=0.047), and negatively with 25(OH)vitamin D levels (r=-0.243,P=0.033). By contrast, BMD was not associated with 25(OH) vitamin D levels. TBS showed no association with PTH, renal function or bone turnover markers. As opposed to TBS, lumbar spine BMD was negatively correlated with Beta-CTX (R=-0.231,P=0.047). Both femur neck BMD T-score (R=-0.233,P=0.044) and total hip BMD T-score (r=-0.299,P=0.009) were negatively associated with PTH levels.
Conclusions
A considerable proportion of women with normal BMD or osteopenia appears to present with low bone quality at the start of hormone adjuvant therapy for breast cancer. TBS could be used as a complementary quantitative clinical tool in the initial evaluation and management of these patients and might be adopted to recommend antifracture treatment in this gray zone. TBS might also be correlated with underlying bone metabolism indices.

Effect of bisphosphonates on vertebral fractures in HIV infected males: 7-years study

Letizia Chiara Pezzaioli[1], Teresa Porcelli[2], Emanuele Storti[3], Andrea Delbarba[4], Giorgio Tiecco[3], Francesco Castelli[3], Carlo Cappelli[1], Alberto Ferlin[4] & Eugenia Quiros-Roldan[3]
[1]University of Brescia, Department of Clinical and Experimental Sciences, Unit of Endocrinology and Metabolism, Brescia, Italy; [2]Endocrinology, Montichiari Hospital, ASST Spedali Civili Brescia, Brescia, Italy; [3]University of Brescia and ASST Spedali Civili di Brescia, Department of Infectious and Tropical Diseases, Brescia, Italy; [4]University of Padova, 5Department of Medicine, Unit of Andrology and Reproductive Medicine, Padova, Italy

Objective
Osteoporosis and vertebral fractures (VFs) are frequently observed in HIV-infected men. Whereas bisphosphonates seem effective on bone mineral density (BMD) maintenance in HIV-men, data on VFs are lacking. We aimed to evaluate the long-term efficacy of bisphosphonates on VFs in HIV-infected men.
Design
Real-life longitudinal retrospective study on 118 consecutive HIV-infected males (median age at inclusion 53 years). Median time between first and second visit was 2 years, and between first and latest visit available was 7 years.
Methods
Inclusion criteria were age $>$18 years, HIV infection in stable conditions under antiretroviral therapy, no previous bisphosphonates treatment, blood samples carried out at the same laboratory, and three densitometric and morphometric assays performed with the same densitometer.
Results
At baseline, VFs were detected in 29/118 patients (24.6%), of which 18/29 (62.1%) were osteoporotic and 11/29 (37.9%) had osteopenia. Fractured patients were older (P.0.042), had longer HIV infection duration (P.0.046), antiretroviral exposure (P.0.025) and higher luteinizing hormone (LH) (P.0.044). Of the 29 patients already fractured at baseline, 11 (37.9%) developed new VFs during follow-up, of which 8 were under bisphosphonates treatment (P.0.018). Among the 89 patients without baseline VFs, 26/89 (29.2%) were osteoporotic, 50/89 (56.2%) had osteopenia and 13/89 (14.6%) had normal BMD. Of the 89 patients without baseline VFs, 11 (12.4%) developed VFs, being treated with bisphosphonates in only 2 cases (P.0.811). Overall, BMD remained stable over time and a progressive decrease of parathyroid hormone, bone alkaline phosphatase and C-terminal telopeptide was observed. Patients with worsened bone condition, both in term of BMD and VFs (n. 32), showed more frequently LH values $>$ 9.4 mIU/ml (P.0.046) and were more HCV coinfected (P.0.045). Noteworthy, 38.6% of the patients discontinued bisphosphonates, due to medical indication or personal choice, and 14.0% never started them.
Conclusions
We found that bisphosphonates were not completely effective in preventing VFs in patients already suffering from previous VFs, probably due to the multifactorial pathogenesis of fragility fractures in this population and also to poor adherence to medication.

Disease characteristics, disability, and quality of life in adult HPP patients with muscular symptoms and pain without skeletal manifestations – a cross-sectional analysis from the Global HPP Registry

Kathryn M. Dahir[1], Gabriel Ángel Martos-Moreno[2], Agnès Linglart[3], Anna Petryk[4], Priya S. Kishnani[5], Cheryl Rockman-Greenberg[6], Samantha E. Martel[4], Keiichi Ozono[7], Wolfgang Högler[8] & Lothar Seefried[9]
[1]Vanderbilt University Medical Center, Nashville, United States; [2]Hospital Infantil Universitario Niño Jesús, Madrid, Spain; [3]Paris-Sud University, APHP and INSERM, Paris, France; [4]Alexion Pharmaceuticals, Inc., Boston, United States; [5]Duke University Medical Center, Durham, United States; [6]University of Manitoba, Winnipeg, Canada; [7]Osaka University, Suita, Japan; [8]Johannes Kepler University, Linz, Austria; [9]University of Würzburg, Würzburg, Germany

Background
Hypophosphatasia (HPP) is a rare, inherited metabolic disease caused by deficient activity of tissue nonspecific alkaline phosphatase (TNSALP).
Methods
Baseline/pretreatment data from the Global HPP Registry were analyzed to compare HPP disease burden between adults ($\geq$18 years of age) with skeletal manifestations (history of rickets, biopsy-proven osteomalacia, recurrent or poorly healing fractures/pseudofractures, etc; Skeletal group) and those with only non-skeletal manifestations (history of muscle weakness, fatigue, and/or pain; Non-skeletal group).
Results
Among 468 adults with HPP, 300 comprising the Skeletal group were compared with 73 comprising the Non-skeletal group (**Table**). The median number of body systems involved at baseline was higher in the Skeletal group than in the Non-skeletal group. Median 6-Minute Walk Test distance was similar between groups, although data in the Non-skeletal group were limited. Pain severity (Brief Pain Inventory-Short Form [BPI-SF]), disability (Health Assessment Questionnaire – Disability Index [HAQ-DI]), and quality of life (Medical Outcomes Study Short Form-36 Health Survey [SF-36]) were also similar between groups.

Conclusions
The impairment associated with pain, disability, and general quality of life in patients with HPP who had muscular/pain manifestations without overt bone disease was similar to that in adults who had any skeletal manifestations, regardless of HPP onset. Further analyses are required to understand the disease characteristics of these patients.

Table 1

	Skeletal ($n=300$)	Non-skeletal ($n=73$)
Age at baseline (years)		
n	300	73
Median (min, max)	50.1 (18.3, 81.2)	44.4 (19.3, 72.8)
HPP onset, n (%)		
Patients with data reported	299	72
Perinatal/infantile-onset	10 (3.3)	2 (2.8)
Juvenile-onset	126 (42.1)	16 (22.2)
Pediatric-onset, specific type unknown	29 (9.7)	6 (8.3)
Adult-onset	95 (31.8)	34 (47.2)
Unknown	39 (13.0)	14 (19.4)
Number of body systems impacted per patient		
n	282	73
Median (min, max)	3 (1, 8)	2 (1, 5)
6-Minute Walk Test, distance walked (meters)		
n	41	5
Median (min, max)	465 (180, 740)	466 (316, 580)
Pain severity (BPI-SF)[1]		
n	188	48
Median (min, max)	3.8 (0.0, 10.0)	3.6 (0.0, 9.5)
Disability (HAQ-DI)[2]		
n	191	48
Median (min, max)	0.4 (0.0, 2.7)	0.3 (0.0, 2.1)
SF-36 Physical Component Summary Score[3]		
n	191	47
Median (min, max)	40.1 (16.5, 64.7)	44.2 (17.9, 62.0)
SF-36 Mental Component Summary Score[3]		
N	191	47
Median (min, max)	42.4 (13.2, 62.3)	43.9 (20.4, 61.9)

Scales: [1]0-10, lower is less pain; [2]0-3, lower is less disability; [3]0-100, lower is more disability.

Artificial intelligence based on radiomic analysis of lumbar spine computed tomography (ct) scan may improve accuracy in detecting osteoporosis

Emilia Biamonte[1], Federico Garoli[2], Riccardo Levi[3], Walter Vena[1], Flaminia Carrone[1], Simona Jafaar[1], Maurizio Fornari[4], Marco Grimaldi[2], Letterio Politi[2], Andrea Lania[1] & Gherardo Mazziotti[1]
[1]Humanitas Research Hospital, Endocrinology, Diabetology and Andrology Unit, Rozzano, Italy; [2]Humanitas Research Hospital, Radiology, Rozzano, Italy; [3]Humanitas Research Hospital, Rozzano, Italy; [4]Humanitas Research Hospital, Neurosurgery, Rozzano, Italy

Background
Osteoporosis is characterized by reduced bone mass and a compromised bone microstructure, leading to increased bone fragility and fracture risk. Currently, the gold standard for diagnosis is the bone mineral density (BMD) measurement by DXA. However, approximately half of fragility fractures occurs in the context of normal or slightly decreased BMD values.
Protocol
In this cross-sectional study, we performed an artificial intelligence (AI)-based analysis on radiomic of images of opportunistic computed tomography (CT) of lumbar spine in 240 consecutive subjects (mean age $61 \pm 14,5$, 130 males). Exclusion criteria were: 1) bone-active drugs; 2) neoplastic diseases; 3) spine surgical intervention; 4) spine trauma. Fifty-eight subjects had vertebral fractures (VFs) as assessed by a morphometric approach on CT or XR-ray spine (D4-L4) images. On CT images, the ROI was acquired as a 3D-spherical region of 9 mm in the middle of non-fractured lumbar vertebral bodies. A total of 93 RF were extracted: 19 first-order and 74 textural features. The most discriminative ones were selected by applying bootstrap recursive feature elimination procedures with random sampling for train/test split (100 iterations). The Linear Support Vector (LSV) model was adopted, and the Tree-Parzen Estimator Bayesian approach was employed. Results were evaluated on a stratified test set (25% of the total population), not included in the training phase. The final model was evaluated on the test set, using accuracy, sensitivity, specificity, and area under the ROC curve.
Results
Univariate analysis showed 20 significative RF ($P<0.05$), used to develop the LSV model. The model reached 0.83 of ROC, and the 71,7%, 78.0%, and 69,6 % of accuracy, sensitivity, and specificity respectively. Patients with VFs had significatively lower first-order features compared with those without VFs and were associated with textural features denoting a bone microarchitecture more rarefied and with higher inter-trabeculae distance. Furthermore, patients with a more compromised spine (SDI $\geq$ 2) had significatively lower first-order features compared with those without or with a mild VFs (SDI 0 and SDI 1) and, conversely, were significantly associated with textural features denoting a bone structure more rarefied and less coarse.
Conclusions
Artificial intelligence-based radiomic of lumbar CT scans identifies patients with skeletal fragility. If confirmed, these results may suggest that radiomics could be an important diagnostic tool in osteoporosis detection and in fragility fracture prediction in the next future.

Biochemical parameters in metabolic bone disease of obese patients

Raquel Binda Pereira[1], Ana Carolina Santos[1,2], Joana Ferreira[1,2], Mário Rui Mascarenhas[3,4], Pilar De Quinhones Levy[1], Paula Barbosa[3,4] & Manuel Bicho[1,2]
[1]Faculty of Medicine, University of Lisbon, Genetics Laboratory, Ecogenetics and Human Health Group, Institute for Environmental Health (ISAMB), Lisbon, Portugal; [2]Scientific Research Institute Bento da Rocha Cabral, Lisbon, Portugal; [3]Faculty of Medicine, University of Lisbon, Institute for Environmental Health, Lisbon, Portugal; [4]Clinic of Endocrinology, Diabetes and Metabolism of Lisbon, Lisbon, Portugal

Introduction
Obesity is a pathological condition characterized by a low-grade systemic inflammatory state that predisposes to the onset of some diseases, such as hypertension, diabetes, and hyperlipidemia. Also, obesity can impact bone metabolism, but its effects are controversial.
Aims
This observational study aimed to evaluate and correlate the bone mass with the lipidic profile, adipocytokines, glucose metabolism, hepatic function and purine metabolism in obese patients.
Methods
372 obese patients were divided into three groups of bone mineral density (BMD) by DXA, according to the ISCD guidelines: normal (BMD-N; $n=103$), reduced (BMD-R; $n=168$), and osteoporosis (OST; $n=101$). The obesity classification was based on the fat mass index (FMI) criteria, accessed by DXA. In this classification, the body fat categories are divided into three classes, according to the sex- and race-specific reference ranges. Biochemical parameters were determined by standard methods. The Quantitative Insulin Sensitivity Check Index (QUICKI) was used to assess insulin sensitivity.
Results
The mean age was 62.4 ± 8.80 years, 72% were female, and, for obesity classification, 84,1% of patients were in class 3, 10,8% in class 2, and 5,1% in class 1. FMI was increased in BMD-N ($P<0.001$) compared to BMD-R and OST groups. The three classes of obesity and the lipid profile were similar between the three groups of BMD. The alanine aminotransferase was increased in the BMD-N group ($P=0.019$), while the other hepatic enzymes were identical between the groups. Regarding glucose metabolism, despite the similar glycemia, the insulin level was increased in the BMD-N group ($P=0.023$). By contrast, the QUICKI was decreased in the BMD-N group ($P=0.002$). Concerning the adipocytokines analyzed, adiponectin was reduced in the BMD-N group ($P=0.005$). The

uricemia was increased in the BMD-N group ($P=0.015$) and was directly correlated with insulin level ($P<0,001$, $r=0,313$).
Conclusions
In obese patients, impaired insulin sensitivity and increased purine metabolism suggested a protective role on bone, preserving its density.

Relationship between serum Vitamin D and statin-associated muscle symptoms
Oksana Obertynska
National Pirogov Memorial Medical University, Vinnytsya, Department of Propedeutics of Internal Medicine, Vinnytsya, Ukraine

Muscle symptoms are the most common side effects of statin therapy and reasons for its discontinuation. Low serum vitamin D may contribute to statin-associated muscle symptoms (SAMS). The aim was to investigate the relationship between occurrence of SAMS and level of vitamin D (D), determine predictors of SAMS.
Methods
84 statin-treated patients were included in the study: 41 with SAMS (intolerant to ≥ 2 statins) and 43 patients without SAMS. We use SAMS clinical index (SAMS-CI) to determine SAMS. The vitamin D levels, parathyroid hormone (PTH), hematology and high sensitive protein (hsCRP) were performed.
Results
D was significantly lower (22.3 ± 12.20 ng/ml and 37.53 ± 10.21 ng/ml) and PTH was significantly higher (42.1 ± 14.2 and 30.4 ± 10.2 pg/l, $P<.001$) in patients with SAMS compared with those without SAMS. In 29% of patient with SAMS were observed vitamin D deficient (D < 20 ng/ml) and 43% had an insufficient D (21–29 ng/ml), while only 7% of patient without SAMS had vitamin D deficient and 11% an insufficient D. In patients with SAMS levels hsCRP was significantly higher ($P<.001$) and hemoglobin (Hb) concentrations were 0.5 g/dL lower than in patients without SAMS ($P<.05$). Regarding D, mean Hb were 1.2 g/dL lower in vitamin D deficient category than in adequate D category ($P<.001$). In multivariable modelling we have found an excellent correlation between D and SAMS-CI, Hb and hsCRP ($P<.001$; $P<.05$; $P<.05$; respectively). The correlation between vitamin D and hsCRP was highly significant ($r = -0.879$, $P<.001$) in patients with SAMS and less significant in patients without SAMS ($r = -0.402$, $P<.05$). It was shown that decreasing vitamin D levels are associated with increasing hsCRP levels (sign of inflammatory state) in non statin-treated patients. Age, D < 25 ng/ml, Hb < 12.5 g/dL and hsCRP > 3 mg/l at baseline had modest discriminative powers for predicting SAMS (0.56, $P<.01$; 0.45, $P<.01$; 0.542, $P<.001$; 0.712, $P<.001$; respectively).
Conclusion
We found an inverse association between vitamin D level and a statin-induced muscle symptoms in statin-treated patients. The prevalence of vitamin D deficiency 29% and an insufficiency D 43% in patients with SAMS. A low vitamin D concentration is accompanied by microinflammatory state and anemia risk. Age, lower level of vitamin D and Hb, higher level of hsCRP were identified as potential predictors of statin associated muscle symptoms. So, assessment of vitamin D status may be useful for the diagnosis and management of SAMS, especially in older patients with Hb < 12.5 g/dl and hsCRP > 3 mg/l.

Parathyroid function index does not differentiate between Normocalcaemic primary hyperparathyroidism and Vitamin D deficiency associated secondary hyperparathyroidism
Mohsin S Siddiqui, Saradalekshmi Koramannil Radha, Sajid Iqbal, Adam Buckley & Nader Lessan
Imperial College London Diabetes Centre, Abu Dhabi, United Arab Emirates

Background
Normocalcaemic primary hyperparathyroidism (NPHPT) can be considered as an early biochemical manifestation of hypercalcaemic primary hyperparathyroidism (PHPT). Vitamin D repletion and exclusion of other conditions is recommended before diagnosing NPHPT. It is often challenging to distinguish Vitamin D deficiency associated secondary hyperparathyroidism (SHPT) from NPHPT and the two conditions may coexist. A parathyroid function (PF) index [(Parathyroid hormone (PTH) in pmol/l * Corrected Calcium in mmol/l)/ Phosphate in mmol/l] has been previously proposed as a reliable marker in distinguishing the two conditions. However, the patients in NPHPT group in that study were vitamin D deficient. We have evaluated the utility of PF index and other biochemical markers in a larger cohort of patients with or without Vitamin D replacement.
Methods
Patients were selected from electronic health records based on their consistently abnormal metabolic bone profile after exclusion of chronic kidney disease (eGFR < 60 ml/min/1.73 m^2), concomitant pregnancy, interfering drugs and conditions that could cause hypercalcemia. Patients were categorised into four groups: Classic PHPT ($n=60$), NPHPT in those with serum 25(OHD) > 50 nmol/l ($n = 329$), Vitamin D deficiency related SHPT ($n = 259$) and age matched healthy controls ($n = 118$). ROC analyses was performed to determine a reliable PF index cut-off between NPHPT and SHPT.
Results
The PF index was highest in the classic PHPT group in comparison to others [Mean(SD) was 37.95 ± 20.1 PHPT vs 21.51 ± 6.90 NPHT, 21.27 ± 6.91 SHPT, 9.36 ± 3.00 controls]. When comparing NPHPT with SHPT, AUROC was 0.51. In a separate analysis, when comparing pre-treatment PFindex between those who normalised their PTH after vitamin D repletion and those who did not, AUROC was 0.62. Thus, in patients with normocalcaemia, vitamin D deficiency and elevated PTH, PF index did not usefully predict which individuals would normalise PTH after vitamin D repletion and therefore did not distinguish patients with NPHPT from those with SHPT. Moreover, serum phosphate between the two groups was not significantly different.
Conclusion
After Vitamin D repletion, PF index did not discriminate NPHPT from those with Vitamin D deficiency related SHPT. Hence as recommended in recent guidelines, it is imperative to replace Vitamin D before diagnosing patients with NPHPT. Further studies are warranted to identify better markers for NPHPT so that they can be closely monitored for PHPT related bone and renal complications and thus referred for timely surgical intervention.

Case report: an unusual presentation of hypercalcaemia in pregnancy
Scott Williams[1], Helmine Kejem[1], Sian Wynne[1], Jael Nizza[1], Rachel Tildesley[1], Susannah Shore[2] & Rebecca Lim[1]
[1]Wirral University Teaching Hospital NHS Foundation Trust (WUTH), Birkenhead, United Kingdom; [2]Liverpool University Hospitals Foundation Trust, Endocrine Surgery, Liverpool, United Kingdom

A 26-year-old Caucasian female presented at 14 weeks gestation with a 6-week history of lethargy, nausea and vomiting during her first pregnancy. Her adjusted Calcium was 4.12 mmol/l and parathyroid hormone (PTH) 26 pmol/l, consistent with possible primary hyperparathyroidism. She was previously well apart from occasional migraines. There was no known history of familial hypercalcaemia or MEN. Other biochemistry results revealed hypokalaemia of 3.2 mmol/l, low vitamin D at 16 nmol/l, raised 24-hour urine calcium at 8.11 mmol/24 hr, and a transient thyrotoxicosis, associated with hyperemesis gravidarum which later resolved. MEN screen negative. She was treated with intravenous isotonic saline and electrolytes deficiencies were replaced. She was also commenced on a maintenance dose of vitamin D with colecalciferol 400 units once daily. An ultrasound neck showed no evidence of parathyroid adenoma and a sestamibi nuclear medicine scan was contraindicated due to pregnancy. MRI neck was deemed not sufficiently sensitive to identify a small parathyroid adenoma. Her calcium level normalised prior to discharge. She was readmitted 3 weeks later with symptoms of generally unwell, nausea and vomiting, with an adjusted calcium of 3.41 mmol/l. Her calcium levels responded well to intravenous saline rehydration, and as she was now in her second trimester, she was referred to the tertiary centre hospital for exploratory neck surgery. This had demonstrated four normal parathyroid glands with no evidence of an adenoma. Working diagnosis was now towards an ectopic fifth parathyroid gland or mediastinal adenoma or possibly a placental-driven cause. Meanwhile, patient had struggled with recurrence of symptoms and persistent hypercalcaemia when not receiving aggressive intravenous rehydration. Following discussions with the patient and the multidisciplinary team across both tertiary and local hospitals, she was started on cinacalcet 30 mg twice daily. Her adjusted calcium had improved to 2.62 mmol/l. She later had spontaneous rupture of membranes and went into premature labour at

24 + 5 weeks gestation, delivering a live baby boy who needed care in the neonatal unit, in view of prematurity. Further investigations are underway, and placental histology is awaited. This case highlights the challenges of diagnosing as well as adequately treating hypercalcaemia in pregnancy. Hypercalcaemia is rare in pregnancy, and symptoms can be nonspecific and mimic those in early pregnancy. Therefore, it is important to have a low threshold in screening and early involvement of the multidisciplinary team with patient and her partner, in order to mitigate harm to both mother and fetus.

Effect of glucocorticoid replacement therapy on bone mineral density in addison disease

Dhoha Ben Salah, Khouloud Boujelben, Kawthar El Arbi, Faten Haj Kacem Akid, Siddiqa Soomauroo, Mouna Mnif, Nadia Charfi, Mnif Fatma, Nabila Rekik Majdoub, Mouna Elleuch & Mohamed Abid
Hedi Chaker Hospital, Department of Endocrinology, Sfax, Tunisia

Introduction
Addison disease is associated with high risk of fractures and low bone mineral density. Causes are complex, including supraphysiologic glucocorticoid replacement therapy and concomitant autoimmune disorders. The aim of our study is to assess the influence of glucorticoid replacement therapy on bone mineral density in patients with Addison disease.
Patients and methods
Descriptive and analytical cross- sectional study including 50 patients with Addison disease. The incidence of osteoporosis and osteopenia were analyzed.
Results
The mean age of patients was 49,5 ± 13,9 years (40 females versus 10 males). Average duration of the disease was 13,9 ± 8,7 years (5-35 years). All patients were on hydrocortisone replacement, taking daily 27,4 ± 6,7 mg (15-42,1 mg) corresponding to 0,388 ± 0,128 mg/kg. Thirty-nine (78 %) patients received a mean daily dose of hydrocortisone greater than 11 mg/m^2. Mean cumulative hydrocortisone dose was 374,636 ± 283,821 mg (60 – 1184, 94 mg). The mean alkaline phosphatase level was 77,2 ± 28,5 I/l (15-190 IU/l). A total of 9 patients (18 %) had elevated alkaline phosphatase level after a mean disease duration of 14,9 ± 8,4 years and a mean cumulative hydrocortisone dose of 413;4 ± 348 mg/day. Mean mineral bone density at lumbar site and femoral neck was 0,928 ± 0,174 g/cm^2 (0,596-1,287 g/cm^2) and 0,945 ± 0,145 g/cm^2, respectively. Mean T-score at lumbar site and femoral neck was -1,61 ± 1,06 and -1,18 ± 1,33, respectively. Twenty-four (48 %) patients had reduced bone mineral density on osteodensitometry (less than 2 standard deviations [SD] of the mean value of an age-matched reference population). Twelve (24%) patients had osteoporosis.
Conclusion
Glucocorticoid replacement therapy in Addison disease may induce bone loss. Thus, glucocorticoid therapy must be adjusted to the lowest tolerable dose and regular measurement

Thalassemia major: prevalence and risk factors for hypercalciuria

Ludovica Aliberti[1], maria rita gamberini[2], andrea ziggiotto[1], martina verrienti[1], Irene Gagliardi[1], Maria Chiara Zatelli[1] & Maria Rosaria Ambrosio[1]
[1]Section of Endocrinology and Internal Medicine, Department of Medical Sciences, University of Ferrara, Ferrara, Italy; [2]Day Hospital of Thalassemia, Department of Medicine, AOU Ferrara, Ferrara, Italy

Introduction
Thalassaemia syndromes are a group of inherited haemolytic disorders determining chronic anaemia, iron overload and organ damage (through the production of ROS), necessitating of iron chelation therapy. Nowadays, there is scant knowledge on hypercalciuria in thalassaemic Western patients. Therefore, aim of our study was evaluating the prevalence of hypercalciuria and identifying risk factors and clinical consequences associated with its development.
Methods
We enrolled 184 patients with β thalassaemia major (TM) aged ≥ 18 years old, regularly transfused and chelated, and followed up at the Day Hospital of Thalassemia of Ferrara. We excluded patients with severe renal failure, severe hepatopathy, primary hyperparathyroidism, hypoparathyroidism, genetic renal tubular diseases and neoplastic hypercalcemia. Females were not pregnant or breastfeeding. Hypercalciuria was defined by calciuria ≥ 4 mg/kg/day.
Results
The prevalence of hypercalciuria was 69.3% (females 52.5%, mean age 45 ± 7 years old). Hypercalciuric patients had lower ferritin as compared to normocalciuric patients (663,9 ± 766,9 vs 913,2 ± 1151,89 ng/ml, $P < 0.05$). Deferasirox was used mostly in hypercalciuric group (49.2%) rather than in normocalciuric one (28.6%) ($P < 0.05$). Plasma PTH, phosphate and uricemia were lower ($P < 0,05$) in hypercalciuric as compared to normocalciuric patients (PTH 24,1 ± 10,3 vs. 31,4 ± 16,1 pg/ml; phosphoremia 3,6 ± 0,5 vs. 3,8 ± 0,7 mg/dl; uricemia 4 ± 1,3 vs. 4,4 ± 1,4 mg/dl), whereas phosphaturia/24h was higher (0,9 ± 0,4 vs. 0,6 ± 0,3 g/day, $P < 0,05$) (iron mediated subclinical hypoparathyroidism associated with FGF-23 erythropoietin induced hyperphosphaturia?). Supplementation with oral calcium and cholecalciferol was similar in the two groups. Hypercalciuria was associated with a higher frequency of renal lithiasis, vertebral fractures and use of anti-osteoporotic therapy as compared to patients with normocalciuria. Bilateral renal lithiasis, hydronephrosis and nephrocalcinosis were found only in hypercalciuric patients.
Conclusions
Hypercalciuria is a frequent complication in TM. Deferasirox may cause hypercalciuria (through proximal renal tubulopathy) whereas supplementation with oral calcium/cholecalciferol was not associated with this complication. Our study hypothesize a role of 'FGF23 erythropoietin induced hyperphosphaturia' and 'subclinical hypoparathyroidism' in the pathogenesis of hypercalciuria. Hypercalciuric TM patients have to be monitored for the development of renal damage and osteoporosis.

Fine-needle aspiration of parathyroid lesions prior to parathyroidectomy- a tertiary center experience

Pinchas Klein, Galit Avior, Ohad Cohen, Jacob Ilany, Rina Hemi, Ehud Barhod, Iris Vered & Liana Tripro-Shkolnik
Sheba Medical Center, Division of Endocrinology, Diabetes and Metabolism, Israel

Background
Parathyroid lesion aspiration as a preoperative adenoma localization tool is a matter of controversy. Concerns are being raised regarding both the immediate (hematoma, infection, alterations on a subsequent histologic preparate) and long term (seeding) safety.
Objective
To evaluate safety and efficacy of parathyroid fine-needle aspiration (FNA) with parathyroid hormone (PTH) washout as a localization of parathyroid lesions in patients with primary hyperparathyroidism.
Methods
We retrospectively reviewed all parathyroid FNA procedures performed by in a tertiary referral center between 2011 and 2021. Clinical, biochemical, and imaging information as well as cytology, surgery, and pathology reports were extracted from electronic medical records.
Results
Twenty-nine hyperparathyroid patients referred to parathyroidectomy following a positive localization with FNA -PTH washout were available for review. The indications for aspiration were re-confirmation of location (13/29), mismatch between imaging modalities (6/29), intra-thyroid lesion (4/29), previous neck operation (3/29) and unknown (3/29). PTH levels from the needle wash were 2.6-112.5 times the upper limit of serum norm. No immediate procedure complications except for mild neck discomfort were documented. Among 24 patients with an available pathology report, parathyroid adenoma was identified in 22, non-adenomatous parathyroid tissue in one and thyroid tissue in one patient.

No cases of hematoma or abscesses were reported by the surgeons, and no histologic alternations (hemorrhage, abscess, inflammation or capsule rupture) were reported by the pathologists. There was one case of necrosis and one case of parathyroid adenoma with fibrotic changes that may or may not be related to the FNA. Twenty-six (89.6%) of the 29 patients who underwent parathyroidectomy, were biochemically cured up to a follow-up of 41.6 ± 34.6 months.
Conclusions
Parathyroid FNA with PTH washout was accurate and neither immediate nor surgical or preparate-related complications were demonstrated in our series. This approach might be considered in selected cases.

Hyperparathyroidism development after oncogenic osteomalacia treatment

Bohdan Patera, Federica Martina Bianchi, Ilaria Clementi, Gaia Francesca Maria Fazzino, Nicola Lanzo, Silvia Lepanto, Francesca Manzella La Barbera, Eliana Piantanida & Maria Laura Tanda
Ospedale di Circolo e Fondazione Macchi - ASST dei Sette Laghi, Department of Medicine and Surgery, Endocrine Unit, Insubria University, Varese, Italy

Tumor-induced osteomalacia (TIO) or 'oncogenic osteomalacia' is a rare paraneoplastic disorder, usually resulting from Fibroblast Growth Factor 23 (FGF23) oversecretion by a benign small 'phosphaturic mesenchymal tumor', causing hypophosphatemia and reduced 1,25-dihydroxyvitamin D synthesis. Calcium and parathyroid hormone (PTH) levels are usually normal, but secondary/tertiary hyperparathyroidism has been reported in up to 5% of the cases, mainly due to 1,25-dihydroxyvitamin D deficiency and long-term phosphate supplementation. Non-specific clinical manifestations (muscle weakness, osteomalacia, bone pain) and difficult localization of the tumor often delay diagnosis for years. Surgical removal represents the first-line treatment. We report a case of a patient with TIO, supplemented for years with phosphate salts, who developed hyperparathyroidism after tumor removal.
Case report
In 1987, after femur stress fracture, a 27-year-old man was diagnosed with 'phosphate diabetes' and then treated until 2010 with phosphate, calcium and vitamin D supplementation. The late onset of disease with no family history of hypophosphatemia nor skeletal deformities did not suggest hereditary conditions. Medical history included only beta-thalassemia trait. No further evaluation was made until 2010, when a small phosphaturic mesenchymal tumor was identified during investigations of non-healing tibial fracture. Histological specimens confirmed a FGF23-expressing neoplasia. Before surgery hypophosphatemic hyperphosphaturia with normal PTH, calcium and creatinine levels and borderline 25-hydroxyvitamin D were observed. Immediately post-surgery phosphatemia normalized. However, calcemia and PTH levels slowly increased and few months later the patient was diagnosed with primary hyperparathyroidism (PTH 110 pg/ml normal range 5-39, calcemia 11.1 mg/dl, mild hypophosphatemia, increased 1,25-dihydroxyvitamin D and reduced 25-hydroxyvitamin D levels). Neck ultrasonography and parathyroid MIBI-scintigraphy did not reveal adenomas. Exploratory cervicotomy was proposed, but the patient was lost at follow-up. In 2019 hypercalcemic hyperparathyroidism with hypophosphatemia and nephrolithiasis was observed (calcemia 10.5 mg/dl, phosphatemia 1.8 mg/dl, PTH 78 pg/ml, normal creatinine and 25-hydroxyvitamin D levels). FGF23 levels were normal. After negative imaging, exploratory cervicotomy with subtotal parathyroidectomy was performed; histology confirmed parathyroid hyperplasia. Post-surgery PTH fell to undetectable levels while phosphatemia normalized; treatment with calcium salts, calcitriol and Cholecalciferol was introduced.
Conclusions
TIO diagnosis should always be excluded when treating persistent hypophosphatemia, as tumor removal is usually curative. Long-term treatment with phosphate salts may induce secondary/tertiary hyperparathyroidism. Thus, phosphocalcic metabolism should be periodically evaluated during follow-up of surgically untreated TIO, but also after tumor removal, due to the possible hyperparathyroidism development.

Clinical and biochemical response to Burosumab treatment in two patients with X-linked hypophosfatemic rickets and tertiary hyperparathyroidism

Alberto Ghielmetti[1,2], Marta Zampogna[1,2], Serena Palmieri[2], Giorgia Grassi[2], Maria Rosa Caruso[3], Maura Arosio[1,2] & Cristina Eller Vainicher[2]
[1]University of Milan, Department of Clinical Sciences and Community Health, Italy; [2]Fondazione IRCCS Ca'Granda Ospedale Maggiore Policlinico, Unit of Endocrinology, Milan, Italy; [3]Azienda Ospedaliera Papa Giovanni XXIII, Unit of Nephrology, Bergamo, Italy

Introduction
in X-linked hypophosfatemic rickets (XLH) mutations of PHEX lead to elevated FGF-23 levels. Phosphate salts and calcitriol represented the only treatment option. Tertiary hyperparathyroidism (THPT) is a complication of XLH worsening the clinical features and constituting a contraindication to conventional treatment. Burosumab, a monoclonal antibody anti-FGF23, was recently approved in XLH. No data about Burosumab treatment in patients with XLH and THPT are available.
Patients
two patients (M 61, F 67 yrs) affected with XLH and THPT were treated with Burosumab (standard dose 1 mg/kg/28 days). Its compassionate use was approved by local Ethics Committees (Fondazione Ca'Granda Milan and Papa Giovanni XXIII Bergamo, Italy, for patients M and F, respectively).
Results
values at baseline in M and F, were, respectively, phosphoremia 1.4 and 1.4 mg/dl, Ca++ 1.53 and 1.39 mmol/l (1.13-1.32), PTH 76.4 and 91.75 ng/l (6.5-36.8), 25OHvitamin D 31.8 and 46.4 μg/l, creatinine 1.14 and 0.87 mg/dl, TmP/GFR 0.33 and 0.35 mg/dl, ALP 78 and 110U/l, CTX 846 and 902 ng/l. At 1 month: phosphoremia 2.27 and 2.2 mg/dl, Ca++ 1.57 and 1.45 mmol/l, PTH 95.2 and 70 ng/l, TmP/GFR 0.63 and 0.59 mg/dl, ALP 78 and 130 U/l, CTX 2250 and 1405 ng/l. At 6 months: phosphoremia 1.74 and 2.1 mg/dl, Ca++ 1.55 and 1.39 mmol/l, PTH 75 and 65 ng/l, TmP/GFR 0.41 and 0.52 mg/dl, ALP 78 and 130 U/l, CTX 1910 and 1605 ng/l. In both patients an improvement in myalgias, arthralgias and mood was noticed. At 6 months six-minute walk test in M improved (455 m vs 335 m at baseline, +36%). In M, after the introduction of cinacalcet at 3 months, calcium and PTH levels decreased without normalization and minimal effects on phosphoremia and TmP/GFR were observed. At 6 months in M we increased Burosumab dose to 1.2 mg/kg/28 days and the patient showed further improvement of symptoms at 9 months (pain assessed through VAS score decreased from 3 at 6 months and 5 at baseline to 2), despite persistent hypophosphatemia (phosphoremia 2.28 mg/dl, TmP/GFR 0.5 mg/dl).
Conclusions
Burosumab, in XLH complicated with THPT, ameliorates the symptoms, without normalizing phosphoremia, and in this subset of patients a higher dose may be needed. Clinical improvement despite hypophosphatemia could suggest a direct role of FGF-23 in the development of symptoms.

Extreme hypercalcemia due to primary hyperparathyroidism– a look-back on over a decade in a tertiary care center

Reut Halperin, Yair Schwartz, Yehudit Eden-Friedman, Genya Hananel, Roi Shalit, Pini Klein, Ehud Barhud, Rina Hemi, Iris Vered & Liana Tripto-Shkolnik
Sheba Medical Center, Division of Endocrinology, Diabetes and Metabolism, Tel Hashomer, Israel

Background
Extreme hypercalcemia is an endocrine emergency. Given parathyroid hormone (PTH)-dependent cause, carcinoma should be suspected as a possible etiology. The prevalence of parathyroid carcinoma among patients presenting with extreme hypercalcemia is not well elucidated.
Aim
Establish proportion of patients with parathyroid carcinoma among those presenting with severe hypercalcemia and compare clinical and laboratory features between benign and malignant etiologies.
Methods
Admissions during 2009-2021 with serum calcium ≥ 14 mg/dl were identified via MD-clone platform. Cases with PTH < mid-reference range or serum creatinine

> 1.5 mg/dl were excluded. Clinical, biochemical and histological data were retrieved.
Results
Twenty-seven patients meeting an inclusion criteria were identified (44% males). Those constitutes 5.3% percent of severe hypercalcemia hospitalized during 2009-2021. Calcium level was 15.3 ± 0.3 mg\dl and PTH level 461 ± 66 pg\ml. Twenty patients (74%) were symptomatic (constipation, polyuria/polydipsia, change in mental status). Eleven (40%) had a precipitating event. Ten (37%) patients were referred due to abnormal laboratory. Twenty-one underwent parathyroidectomy, with pathology of adenoma/ hyperplasia in 19 and carcinoma in 2 cases. Long-term (up to 6 years) follow-up of 2 non-operated patients suggests benign etiology. Levels of PTH, calcium, albumin and creatinine were indistinguishable between etiologies. Age at presentation was 78 and 79 years for carcinoma compared with 57.6 years (19-82 years) in the adenoma\hyperplasia group.
Conclusions
Severe hypercalcemia is uncommon and PTH-dependent etiologies constitute a minority of those. Benign parathyroid disease was the most common etiology of severe PTH-dependent hypercalcemia. Due to the extreme rarity of parathyroid malignancy, significant clinical or laboratory predictors were not identified.

Syringomyelia and neurologic symptoms as rare complications in untreated adult with X-linked hypophosphatemic rickets

Mihaela Tarna[1], Ana-Maria Stancu[2,3], Marian Andrei[1], Raluca Oprescu[1], Marina Iliescu[1], Iulia Soare[2], Anca Elena Sirbu[1,2], Luminita Nicoleta Cima[1,2] & Fica Simona[1,2]
[1]"Elias" Emergency and Universitary Hospital, Endocrinology, Bucharest, Romania; [2]"Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania; [3]National Institute of Endocrinology "C.I. Parhon", Bucharest, Romania

X-linked hypophosphatemia is a rare inherited disorder, yet the most common among the inherited causes of rickets. It is caused by different mutations in the PHEX gene leading to an impaired regulation of fibroblast growth factor 23 (FGF 23) and renal phosphate wasting. Patients with XLH show multiple musculoskeletal complications which usually can lead to early diagnosis in childhood. Nevertheless XLH is a lifelong disease, with multisystemic manifestations, including enthesopathies, dental and periodontal recurrent lesions, hearing loss, fractures and pseudofractures, muscle pain and diminished quality of life. We describe the case of a 21 years old male patient, misdiagnosed as vitamin D deficient rickets in infancy, with short stature, progressive bone deformities, leg bowing and waddling gait which required multiple orthopedic interventions. As a particular manifestation he accused episodes of moderate occipital headaches, aggravated with Valsalva maneuvers, and mildly impaired lower limb proprioception. MRI imaging showed a syringomyelic cavity at C5-T1, but with cerebellar tonsils above the foramen magnum. A few months later, episodes of bilateral upper limb paresthesia have appeared, so that repeated MRI monitoring is required and a neurosurgical approach should be considered. With this case we want to draw attention to the severe and rare neurological complications of this rare condition, and to the importance of long term follow-up with a multidisciplinary approach.

Nutritional and clinical manifestations of normocalcemic hyperparathyroidism in women: interim results from a case-control cross-sectional study evaluating dietary calcium intake with three validated questionnaires

Matteo Malagrinò[1], Paola Altieri[1], Bart Clarke[2], Uberto Pagotto[1] & Guido Zavatta[1]
[1]Division of Endocrinology and Diabetes Prevention and Care, IRCCS Azienda Ospedaliero-Universitaria di Bologna, Department of Medical and Surgical Sciences (DIMEC), Alma Mater Studiorum University of Bologna, Bologna, Italy.; [2]Division of Endocrinology, Diabetes, Metabolism, and Nutrition, Mayo Clinic, Rochester, MN 55905, USA.

Context
Normocalcemic hyperparathyroidism (NHPT) is considered as an earlier or milder phenotype compared to traditional primary hyperparathyroidism (PHPT). To make a correct diagnosis, secondary hyperparathyroidism due to low calcium intake must be excluded. Whether calcium intake might affect presentation of PHPT vs NHPT has never been addressed consistently.
Objective
To describe patients with a diagnosis of NHPT or PHPT in relation to their calcium intake, through three standard validated questionnaires.
Design
Cross-sectional study.
Setting
Outpatient, single academic medical center.
Patients
44 consecutive women recruited from March through December 2021. 22 patients with mild primary hyperparathyroidism (PHPT or NHPT) were age-matched with 22 women undergoing bone mineral evaluation for the first time due to recently diagnosed hormone-positive breast cancer. NHPT diagnosis was based on multiple determinations of both total calcium and albumin-corrected calcium within normal limits, as per current international guidelines.
Interventions
Administration of all the following: a validated local food-frequency questionnaire (LOC), International Osteoporosis Foundation Calcium Calculator (IOF) and National Osteoporosis Foundation Calcium Calculator (NOF).
Main outcome measures
Any association with biochemistries or clinical features.
Results
All three questionnaires confirmed that NHPT patients had similar calcium intake as compared with PHPT or controls. Calcium intake evaluated with all three questionnaires was not correlated with any biochemical index in NHPT nor PHPT, although it showed an association with hip T-scores in PHPT patients ($r = -0.821$, $P = 0.027$ for total hip T-scores). Maximum serum calcium reached over time (CaMax), SCa ranges and 24-Hour Urinary Calcium were significantly greater in PHPT than in NHPT. The remaining biochemistries and bone turnover markers were similar, even when compared with controls. Age positively correlated with calcium intake only in PHPT patients ($r = 0.630$, $P = 0.038$). Multivariate analysis investigating predictors of CaMax (age, BMI, albumin-corrected SCa, serum phosphate, GFR, calcium intake, PTH and 25(OH)vitamin D) showed that only albumin-corrected SCa predicted CaMax. GFR was a much milder positive predictor.
Conclusions
NHPT appears to represent a milder phenotype of PHPT. Presentation of NHPT is independent of calcium intake, when this is sufficient. The setpoint of albumin-corrected serum calcium probably determines the subtype of primary hyperparathyroidism, with greater values having greater chances of reaching calcium levels above normal, independent of other biochemistries.

Serum 25-hydroxyvitamin D (25(OH)D) levels in Pregnant women with gestational diabetes mellitus

Edward Jude[1,2], Susan Mathew[1], Jennifer Heath[1], Denise Saw[1], Kate Meredith[1] & Roopa Krishnamurthy[1]
[1]Tameside and Glossop Integrated Care NHS Foundation Trust, United Kingdom; [2]The University of Manchester, Manchester, United Kingdom

Background
The importance of vitamin D supplementation in pregnancy is well known. Hypovitaminosis D is associated with adverse maternal and foetal outcomes such as pre-eclampsia, gestational diabetes mellitus, bacterial vaginosis, increased incidence of caesarean section delivery, intra-uterine growth restriction and reduced bone and muscle mass in childhood. The recommendations for vitamin D supplementation vary widely, with NICE guidelines suggesting a daily replacement dose of 400 IU/ day. The aim of this study was to determine whether the recommended replacement dose of cholecalciferol of 400 IU/day was sufficient to maintain normal vitamin D level (25(OH)D > 50 nmol/l) in pregnant patients.

Methods
Serum 25-hydroxyvitamin D (25(OH)D) levels of 129 pregnant women who attended the joint antenatal and diabetes clinic between 17/02/21 to 27/04/21 were analysed. All the patients were on standard vitamin D supplement of 400 IU/ day (pregnacare) from the time of antenatal booking. Blood was collected for 25(OH) Dat the time of oral glucose tolerance test at 26-28 weeks of gestation.
Results
The mean 25(OH)D level was noted to be suboptimal across the study population (47.92 nmol/l), with the mean in South Asians (43.99 nmol/l, $n=37$) lower than their Caucasian counterparts (49.50 nmol/l, $n=92$) ($P=0.0487$). Low 25(OH)D level (<50 nmol/l) was observed in 58.91% of the patients, more prevalent in South Asians (67.57%), compared to Caucasians(55.43%). Significantly reduced 25(OH)D (<30 nmol/l) was noted in 15.5% of the patients, also more prevalent among South Asians (21.62%) compared with Caucasians (13.04%).

Table 1 Distribution of Serum 25(OH)D levels among Caucasian and South Asian Pregnant Women.

	Caucasians ($n=92$)		South Asians ($n=37$)	
Serum 25(OH)D (nmol/l)	Number of women	Percentage (%)	Number of women	Percentage (%)
<30	12	13.04	8	21.62
30-50	39	42.39	17	45.95
>50	41	44.57	12	32.43

Conclusion
Our study suggested that vitamin D supplementation of 400 IU/day in pregnant women resulted in suboptimal 25(OH)D levels, more pronounced in South Asians compared to Caucasians. The results suggest the need to revise the guidelines for higher dose of vitamin D supplementation during pregnancy. Larger studies are required to validate the findings.

Analysis of bone mass and body composition in transgender men at 1 year : a follow up study

Bruno Marcos Mazoca Orozco, Otavio Lima De Oliveira, João Victor Magliari Haddad, Livia Marcela Santos & Leonardo Alvares
University Center São Camilo, Brazil

Introduction
Sex steroid hormones play a key role in bone health, however medical therapies for gender dysphoria lead to hormonal changes.
Purpose
Understanding the change in bone mass and body composition is extremely important, because this treatment will be carried out over a long period of time
Methods
In a prospective study, we included 19 transgender men (female-to-male trans persons) before treatment and after 1 year of treatment with undecanoate (1000 mg i.m./12 weeks). Bone densitometry model Hologic-Discovery performed at baseline and after 6, 12 months of therapy. All participants signed the TCLE, project approved by CEP-CAAE: 36823220.6.0000.0062.

Results
Analysis of 19 transgender men with a mean age of 24 years +/- 10 years. LS-BMD (lumbar spine) at initial time (0 m) 1,075±0,238 g/cm^2 and after 6 months (6 m) 1,044±0,117 g/cm^2 and 12 months (12 m) after 1,052±0.122 g/cm^2,$P=0.21$; FN-BMD (Femur Neck) 0 m= 0.904±0.121 g/cm^2; 6 m= 0.918±0.108 g/cm^2 and 12 m= 0.905±0.107 g/cm^2;$P=0.90$. TH-BMD (Total Hip) 0 m=1.017±0.139 g/cm^2; and 6 m= 1.023±0.134 g/cm^2; 12 m= 1.032± 0.136 g/cm^2;$P=0.05$. About body composition: the percentage of body fat: 0 m= 38.8±6.7%, 6 m=34.5±7.1%; 12 m=34.9±9.0;$P=0.09$; android/gynecoid ratio: 0.93±0.16, 6 m=0.94±0.17; 12 m=0.94±0.18$P=0.06$, VAT mass (cm3) 431.8±262.1, 6 m= 401.8±298.6, 12 m= 455.5±322.7 and Lean/Height^2 (kg/m^2) 0 m= 15.52±3.24 6 m= 16.15±2.19 kg/ m^2 ; 12 m= 15.86±2.22 kg/m^2; $P<0.01$ and Appen. Lean/Height^2 (kg/m^2) 6.92±1.74, 6 m= 7.32±1.22 and 12 m= 7.31±1.07; $P<0.01$
Conclusion
In 1 year of hormone therapy with testosterone, we did not observe significant differences in bone mass, but in body composition there was a gain in appendicular lean mass.

Quantification of cerebral calcification and nephrocalcinosis in patients with hypoparathyroidism

Foteini Adamidou[1], Evagelos Chartampilas[2], Paraskevi Komzia[1], Panagiotis Prassopoulos[2], Marina Kita[1] & Theodosios S. Papavramidis[3]
[1]Ippokration General Hospital, Department of Endocrinology, Thessaloniki, Greece; [2] AHEPA University Hospital, Department of Radiology, Thessaloniki, Greece; [3]AHEPA University Hospital, A' Department of Surgery, Thesaloniki, Greece

Introduction
Various methods to quantify calcified coronary plaque have been used in common clinical practice in the past few decades to compliment cardiovascular risk assessment. The estimation of calcium load in other organs and conditions has been at best semi-quantitative. Patients with long-standing hypoparathyroidism are known to suffer with nephrocalcinosis and basal ganglia calcification. We attempted to quantify end-organ calcium burden in a series of patients with various forms of hypoparathyroidism by use of a modified Agatston score.
Patients and Methods
Five patients (4 females and one male, median age 30 years) with various forms of permanent hypoparathyroidism who had a noncontrast CT scan of the brain and/or kidneys as part of usual clinical care in the past three months were included. All CT imaging were performed on a GE Optima 660 scanner. The CT protocol included helical scanning with 0.625 mm slice thickness. The areal limit of detection was 0.1 mm^2 . Images were analyzed on a Philips workstation irrespective of whether calcium deposits were visible. The Agatston score algorithm (HeartBeat-CS, v4.1.7.22037) was modified to identify calcium-based stones using an attenuation threshold of 90 HU within the regions of interest (basal ganglia and renal medulla).

Results

Patients	Age	Condition	Duration	Treatment	Score Renal Medulla	Score Basal Ganglia
1	30	Mild Surgical hypoparathyroidism	4 years	Calcium 500 mg bid & vitamin D3 50.000IU bimonthly	0	NA
2	87	Idiopathic hypoparathyroidism	lifelong	Alfacalcidol 0.5 mcg/d	0.04	0.24
3	26	Severe Surgical hypoparathyroidism	10 years	rhPTH(1-84) 75 mcg/d	9.4	NA
4	34	Pseudohypoparathyroidism Type 1a	lifelong	vitamin D3 50.000IU bimonthly	NA	0
5	24	Severe Idiopathic hypoparathyroidism	7 years	rhPTH(1-84) 75 mcg/d	NA	260.3

NA: not performed

Conclusions

Application of an appropriately modified Agatston score may offer a practical means to accurately diagnose and follow changes in end-organ calcifications in patients with hypoparathyroidism at the point of care.

A case of severe hypercalcaemia secondary to primary hyperparathyroidism responding to steroids

Susan Mathew[1], Tracey Ellis[1] & Edward Jude[1,2]

[1]Tameside and Glossop Integrated Care NHS Foundation Trust, United Kingdom; [2]The University of Manchester, Manchester United Kingdom

Case History

A 57 year old male, who was known to have primary hyperparathyroidism was admitted to hospital due to hypercalcaemia on routine blood tests (adjusted S. calcium- 3.44 mmol/l.) He had no symptoms due to hypercalcaemia. This was his 5th admission since the diagnosis 18 months ago, each admission requiring treatment with IV fluids and IV bisphosphonates. SESTAMIBI and ultrasound scans of the thyroid and parathyroids had previously localised a likely right inferior parathyroid adenoma. Myeloma screen was negative. His past medical history included schizophrenia, vitamin D deficiency and psoriasis.

Treatment

He was initially treated with intravenous fluids, zolendronic acid and cinacalcet. Due to persistent hypercalcaemia, the dose of cinacalcet was increased to 60 mg TDS and intravenous calcitonin was added on. However, adjusted calcium remained around 3.4 mmol/l. He was hence re-referred to ENT surgeons for urgent parathyroidectomy. Unfortunately, he contracted COVID, which delayed the surgery. At this point, he was symptomatic with confusion, agitation, nausea, dehydration and abdominal cramps. He had repeat IV zolendronate 4 weeks from the previous dose and was also prescribed IV hydrocortisone 100 mg IV QDS 6 weeks into the hospital stay. The corrected calcium level reduced from 4.2 mmol/l to 2.2 mmol/l within a week. With the resolution of hypercalcaemia, his confusion resolved. He was switched to oral prednisolone 40 mg OD, which was slowly weaned down. His adjusted calcium levels started rising again shortly after the prednisolone was weaned. Three weeks later he had parathyroidectomy. Following this, his PTH level normalised from a peak pre-operative level of 660 pg/ml to 22 pg/ml post operatively. Two days following parathyroidectomy, he became hypocalcaemic with adjusted serum calcium of 1.92 mmol/l. He was discharged on 3000 mg of calcium carbonate and 1600 units of vitamin D3 daily. He was asymptomatic on follow-up.

Follow-up

The histopathology was suggestive of parathyroid carcinoma. He remains under endocrine and ENT follow-up.

Discussion

Parathyroid carcinoma should be suspected in cases with significantly raised PTH and resistant hypercalcaemia. Emergency parathyroidectomy should be considered in severe cases of hyperparathyroidism unresponsive to medical management. A trial of steroids may be useful as an adjunct in cases of severe resistant hypercalcaemia due to primary hyperparathyroidism, but remains an exception rather than the rule. The mechanism of action remains unknown. Potentiation of the action of calcitonin by upregulation of calcitonin receptors on osteoclast by steroids may be a plausible explanation.

High prevalence of thoracic vertebral fractures in patients with medullary thyroid cancer

Luigi Di Filippo, Lucrezia Albanese, Laura Castellino, Mauro Doga, Anna Maria Formenti, Stefano Frara, Francesca Perticone & Andrea Giustina

Institute of Endocrine and Metabolic Sciences, Università Vita-Salute San Raffaele and IRCCS Ospedale San Raffaele, Milan, Italy

Medullary thyroid cancer (MTC) is a rare malignancy of the thyroid gland. MTCs originate from thyroid-C cells and account for 2-4% of all thyroid neoplasms. Originating from thyroid-C cells, the main secretory product of MTCs is calcitonin, used as sensitive and specific MTC-biomarker. Calcitonin is a hormone known to participate in calcium-bone metabolism suppressing bone-resorption by inhibiting the activity of osteoclasts, and inhibiting the kidney reabsorption of calcium and phosphorus. Despite these well recognized effects, little is known about skeletal health of patients affected by MTCs. Vertebral Fractures (VFs) are one of the most relevant clinical manifestations of skeletal fragility. To date, no data are reported in literature about VFs prevalence in patients affected by MTCs. The aim of our study was to investigate the VFs prevalence in patients with MTCs and in control-matched patients. VFs were detected on lateral chest X-rays using a qualitative and quantitative evaluation of vertebral shape. X-rays were performed prior the thyroid surgical treatment in MTCs patients and at hospitalization for infectious respiratory disease in control patients. MTCs and control patients were matched in a 1:1 ratio for age, sex and comorbidities, excluding those with comorbidities and therapies influencing bone metabolism. Sixty-two patients were included in the study, 31 affected by MTCs and 31 in control group. Median (IQR) age was 51 (38-66) years and 24 were male (38.7%). No statistical differences regarding age and sex were observed between the MTCs and control groups ($P=0.84$,$P=1$, respectively). VFs were detected in 9 (29%) MTCs patients and 2 (6.5%) control patients ($P=0.043$). In MTCs group, no statistical difference was observed regarding age between patients with and without VFs ($P=0.27$), and VFs were observed more frequently in male patients compared to female (50% vs 16%,$P=0.044$). No statistical associations were found between calcitonin levels and VFs occurrence. For the first-time to our knowledge, we have reported a high prevalence of VFs in patients affected by MTCs. It can be hypothesized that constantly elevated calcitonin levels directly or indirectly through changes in other parameters of bone metabolism may negatively impacts skeletal health.

Remote management of osteoporosis in the first wave of the Covid-19 pandemic

Gianmaria Salvio[1], Claudio Gianfelice[2], Francesca Firmani[1], Stefano Lunetti[1], Rossella Ferroni[1], Giancarlo Balercia[1] & Gilberta Giacchetti[1]

[1]Azienda Ospedaliero-Universitaria Ancona, Clinica di Endocrinologia-Specialità Mediche e Chirurgiche, Torrette-Ancona, Italy; [1]Azienda Ospedaliero-Universitaria Ancona, Clinica di Endocrinologia-Specialità Mediche e Chirurgiche, Torrette-Ancona, Italy

We conducted a survey during the first pandemic wave of coronavirus disease 2019 (COVID-19) on a large group of osteoporotic patients to evaluate the general conditions of osteoporotic patients and the impact of the pandemic on the management of osteoporosis, finding high compliance to treatments and low COVID-19 lethality. In a telephone survey conducted from April to May 2020, patients from the Osteoporosis Center, Clinic of Endocrinology and Metabolic Diseases of Umberto I Hospital (Ancona, Italy) were interviewed.

Results

Of a total of 910 interview subjects, 892 provided consent to participate in the survey (response rate 98%), including 785 women (88%) and 107 men (12%) Among the 892 patients interviewed, 77.9% were taking osteoporosis treatment and 94.6% vitamin D supplementation as prescribed at the last visit. COVID-19-like symptoms were reported by 5.1% (44 subjects), whereas confirmed cases were 1.2% (10 patients). A total number of 33 patients had been in hospital and the hospitalization rate of those who had not discontinued vitamin D supplementation was less than 4%. There were eight deaths, two with a concomitant COVID-19 diagnosis. The COVID-19 patients (10, all female) were significantly older than non-COVID-19 subjects (79.9 ± 8.1 vs 70.8 ± 11.4 years, $P = 0.01$) but showed no significant differences in terms of comorbidities. The 2 patients who died of COVID-19 infection were both female; their family members said they were taking vitamin D, although dosing just before the lock down indicated vitamin D deficiency. The prevalence of severe osteoporosis was 50% in total COVID-19 patients and 87.5% in deceased COVID-19 patients. The overall COVID-19 mortality was 0.2%; lethality was 20%, lower than the national rate of the same age group. According to the logistic regression model considering only vitamin D supplementation, the supplement had a protective effect against the risk of hospitalization (OR 0.31, CI 0.11-0.84,$P = 0.02$).

Conclusions

Our frail patients followed up by phone felt reassured, they showed high treatment compliance, and experienced a lower COVID-19 lethality rate than patients of the same age; those who had not discontinued their vitamin D supplement also had a reduced hospitalization rate. The results of our survey, support a possible protective role of vitamin D against severity of COVID-19. The study moreover highlighted the critical value of telemedicine in the context of the pandemic as well as in the routine monitoring and care of old and frail patients and of those with chronic disease.

The investigation of serum and saliva phoenixin levels in patients with type 2 diabetes mellitus

Muhammed Burak Öz[1], Kader Ugur[2], Zeynep Dila Öz[3], Ramazan Fazıl Akkoç[4] & Süleyman Aydin[5]

[1]Faculty of Medicine, Firat University, Department of Internal Medicine, Elazığ, Turkey; [2]Faculty of Medicine, Firat University, Department of Internal Medicine (Endocrinology and Metabolism Diseases), Elazığ, Turkey; [3]Faculty of Medicine, Firat University, Department of Physiology, Elazığ, Turkey; [4]Faculty of Medicine, Firat University, Department of Anatomy, Elazığ, Turkey; [5]Faculty of Medicine, Firat University, Department of Medical Biochemistry and Clinical Biochemistry (Firat Hormones Research Group), Elazığ, Turkey

Purpose: Diabetes is one of the most common metabolic disease which has got many peptide hormones have in its etiology. Phoenixin (PNX), a recently discovered neuropeptide appears to have a role in energy management and metabolism through regulating insulin neogenesis and secretion, according to research. There is no research has been studied on the association between diabetes and PNX levels. The aim of the study was to see if there was a relation between PNX levels in the serum and saliva of patients with diabetes and HbA1c levels.

Materials and methods

A total of 100 participants were included in the study, with 80 patients divided into four groups based on HbA1c [Group 1: 5.7-6.4 % ($n = 20$), Group 2: 6.5-8.4 % ($n = 20$), Group 3: 8.5-9.9 % ($n = 20$), and Group 4: 10 % and above ($n = 20$)] and a control group of 20 healthy individuals. After at least 8 hours of fasting, venous serum and saliva samples were obtained from the patient and control groups., and HbA1c were measured. The levels of phoenixin in serum and saliva were determined by using the enzyme-linked immunosorbent assay (ELISA). The statistical analyses were performed with the SPSS 22 package program and also one-way Anova test and Pearson's correlation test were used. The significance value was taken as $p \leq 0.05$.

Result

When PNX serum levels were analyzed, it was shown that the prediabetic group (Group 1 (5.7-6.4 %)) had statistically higher levels than type 2 diabetes mellitus patients ($p \leq 0.05$). PNX salivary levels were found to be significantly higher than serum levels in the control and type 2 diabetes mellitus groups.

Conclusion

The PNX molecule is a neuropeptide that may be found in saliva and serum. It's thought that the prediabetic groups' higher serum PNX level is attributable to the effect of hyperinsulinemia, and that when overt diabetes occurs, it will be detected at a lower level in the serum related to relative insulin insufficiency. This leads us to believe that PNX is increased in order to control the higher glucose levels in the prediabetic group. Saliva PNX is expected to be favoured over serum PNX in future investigations on PNX metabolic pathways, as serum PNX is an invasive procedure.

Glucose prediction model based on continuous glucose monitoring in patients with type 1 diabetes mellitus: GlucoseML study preliminary results

Maria Christou[1], Daphne N. Katsarou[2], Eleni I. Georga[2], Christos Zisidis[1], Athanasios Siolos[1], Costas Papaloukas[3,4], Stelios Tigas[1] & Dimitrios I. Fotiadis[2,4]

[1]University Hospital of Ioannina, Department of Endocrinology, Ioannina, Greece; [2]University of Ioannina, Unit of Medical Technology and Intelligent Information Systems, Department of Materials Science and Engineering, Ioannina, Greece; [3]University of Ioannina, Department of Biological Applications and Technology, Ioannina, Greece; [4]University Campus of Ioannina, Biomedical Research Institute, FORTH, Ioannina, Greece

Introduction

Current guidelines emphasize the important role of Continuous Glucose Monitoring (CGM) for type 1 diabetes mellitus (T1DM) management. The aim of the GlucoseML study is the development of a mobile health system for T1DM self-management based on CGM data, physical activity, food intake and insulin dosage. We herein present the development and evaluation of a univariate Autoregressive Moving Average (ARMA) prediction model of interstitial glucose concentration for prediction horizons of 30-, 45- and 60-minutes.

Methods

CGM data (GlucoMen Day, Menarini®) from T1DM patients over a 4-week monitoring period under real life conditions were included in the analysis. Ambulatory Glucose Profile (AGP) report was computed for every patient. Categorical variables are expressed as number (percentage). Continuous variables with or without normal distribution are expressed as mean (standard deviation) or median (range), respectively. An ARMA (p, q) model, where p and q denote, respectively, the order of the AR and MA model of the ARMA equation, was identified upon the glucose data. The partial autocorrelation plot and the Akaike information criterion (AIC) were used to estimate the appropriate values of p and q orders in the model. The root mean square error (RMSE) and the mean absolute error (MAE), were used to evaluate the predictive performance of our models.

Results

Data were included for 29 T1DM patients (38% women) aged 38 years (12). Age at diagnosis was 15 years (2-45) and diabetes duration 20 years (11). Most patients were on insulin treatment with multiple daily injections [19 (66%)] compared to continuous subcutaneous infusion [10 (34%)]. Glycosylated haemoglobin was 7.4% (5.8-10.4). Based on AGP report, time below range (glucose $< 54, < 70$ mg/dl), time in range (70-180 mg/dl) and time above range ($> 180, > 250$ mg/dl) were 1.4% (0-10), 4% (2), 62% (21-82), 22% (6) and 8% (0.9-49), respectively. Average glucose was 150 mg/dl (130-247), glucose management indicator 6.9% (6.4-9.2) and glucose variability 39% (32-51). The RMSE for examined prediction horizons of 30-, 45- and 60-minutes was 9.04 (2.22), 11.84 (3.18) and 14.82 (3.87) mg/dl, respectively. Similarly, MAE was 6.48 (1.7), 9.04 (2.56) and 11.62 (3.38) mg/dl, respectively.

Conclusions
The predictive performance of the identified ARMA models compares favourably with that of existing models of similar or higher computational complexity. More advanced multivariate adaptive deep learning models are currently under way as part of the GlucoseML study. Further analyses are required, to test the model's predictive capacity in the critical region of hypoglycaemia.

Prevalence of undiagnosed depression in patients with type 2 diabetes in central India
Bharat Saboo & Shweta Saboo
Prayas Diabetes Center, Indore, India

Introduction
Type 2 Diabetes Mellitus (T2DM) is the most common type of diabetes in adults, People with Diabetes usually have depression which is many times undiagnosed. Significant data suggest that depression in the context of diabetes is related to a variety of negative outcomes, including poor treatment adherence, decreased quality of life, deranged blood sugar values and HbA1c levels, and increased health costs.
Method
40 patients who consented to be part of the study were surveyed with **Patient Health Questionnaire (PHQ-9).** Patients with T2DM, between the age of 20 and 65 years and residing in Central India were included in the study. Exclusion criterion: Patients with type I DM, the previous history of psychiatric illness or on psychiatric treatment, a family history of depression. The responses were analyzed using MS excel.
Result
The overall depression prevalence PHQ-9 score $\geq$10 was 23%, with a higher prevalence of depression in T2DM females than males (25.5 vs. 21.5%, $P<0.0001$), We found a significant association between depression prevalence in T2DM patients and their education level more prevalent in lower education ($P<0.00001$) and employment status those not employed had higher rates of depression ($P<0.0001$).
Conclusion
This study is the first to examine depression in patients with T2DM in Central India. There is a need for the development of more awareness drives and academic programs for doctors on depression in T2DM patients. There should be a regular screening of patients with T2DM for depression which is mostly undiagnosed. Finally, new policies need to be established to focus on the mental health issues of patients with Diabetes. Which can lead to a better outcome in terms of Quality of life and disease outcome.

"Correlation of biomarkers of early diagnosis of diabetic retinopathy"
Fazilyat Bakhritdinova[1], Firuza Urmanova[1] & Guzal Kengilbaeva
Tashkent Medical Academy, Tashkent, Uzbekistan

The purpose of the study is to assess the relationship of the level of growth factor level (VEGF) in blood serum with retinal microcirculation indicators according to oct-A data in patients with type 2 diabetes mellitus (DM2), with different stages of diabetic retinopathy (DR).
Material and research methods
252 people were examined ($n=504$), of which 168 patients with type 2 type and 84 practically healthy persons. The main group (I; $n=174$) with DM2, divided into subgroups, depending on the stage of DR: Easy non-proliferative DR (NDR), moderate NDR, severe NDR and PDR. As a comparison group (II; $n=162$), patients are included without clinical manifestations of others (III; $n=168$) - the control group was almost healthy faces without significant ophthalm and somatic pathology. All patients conducted a standard and specialized ophthalmological examination. Optical coherent tomography in the angio mode is made using an Optical Cherent Tomograph RevOFC with an angiography module with a 3×3 mm scan area. The level of VEGF in serum was evaluated by solid-phase immunoassay analysis using Quantikine ELISA sets.
Results
VEGF levels in blood serum in the studied groups showed a significant tendency to increase from 100.47±49.66 pg/ml (control group) to 463.18±78.69 pg/ml PDR ($P<0.001$). The increase in the VEGF indicator in the blood serum was revealed before the DR occurred clinically 137.29±84.45 pg/ml (comparison group). The average levels of VEGF at easy NDR (177.07±35.37), moderate NDR (255, 29±65.67), heavy NDR (424.34±56.67) also showed a tendency to increase. It was statistically established that the difference between all groups was significant ($P<0.05$). It was found that the VEGF level correlates with Oct-A ($P<0.05$).
Conclusions
The earliest marker of DR is to increase the average level of VEGF growth factor in the blood serum of patients 137.29±84.45 Pg/ml, which comes before the appearance of a clinical picture

Diagnosis of gestational diabetes mellitus in the COVID-19 pandemic: comparative analysis of women with positive O'Sullivan test in the same trimester of 2019 and 2020
José Ignacio Martínez Montoro[1], Víctor José Simón Frapolli[1], María Molina Vega[1], Sonsoles Morcillo Espina[1,2], María Suárez Arana[3], Francisco J. Tinahones[1,2], María José & Picón César[1]
[1]Hospital Universitario Virgen de la Victoria/Instituto de Investigación Biomédica de Málaga-IBIMA, Endocrinology and Nutrition, Málaga, Spain; [2]CIBER Fisiopatología de la Obesidad y Nutrición-CIBEROBN, Spain; [3]Hospital Regional Universitario de Málaga, Gynecology and Obstetrics, Málaga, Spain

Introduction
In May 2020, during the COVID-19 pandemic, the Spanish Group of Diabetes and Pregnancy published a consensus document establishing the alternative diagnostic criteria for gestational diabetes mellitus (GDM) in case of impossibility to perform the two-step traditional approach due to the COVID-19 sanitary emergency. This study aims to compare different characteristics of pregnant women who tested positive in the O'Sullivan test in the same pregnancy trimester of 2019 and 2020 – in the latter trimester, alternative diagnostic criteria were applied due to the impracticability to perform the oral glucose tolerance test (OGTT) in our centre –.
Material and methods
Retrospective observational study comparing clinical data of pregnant women who tested positive in the O'Sullivan test in September-October-November 2019 (GDM diagnosis using 100-g OGTT) and 2020 (GDM diagnosis using basal glycaemia/HbA1c). GDM diagnosis was established if basal glycaemia was $\geq$100 mg/dl ($\geq$5.6 mmol/l) or HbA1c $\geq$5.9% in the first trimester; and basal glycaemia $\geq$95 mg/dl ($\geq$5.3 mmol/l) or HbA1c $\geq$5.7% in the second trimester
Results
Comparative characteristics of both groups are showed in table 1. Notably, in September-October-November 2019 41 women were diagnosed with GDM (16%

Table 1. Comparative characteristics of 2019 and 2020 groups

	2019 Group ($n=257$)	2020 Group ($n=268$)	p
Age (years)	33,6±6,38	33,93±5,01	0,535
Previous BMI(kg/m^2)	27,87±6,86	27,15±6,15	0,222
Primiparous	47.2%	41.9%	<0,001
Family history of GDM	24.9%	30.9%	0,139
Personal history of GDM	4.6%	11.3%	0,013
History of fetal macrosomia	2.1%	10.1%	0,001
O′Sullivan test (mg/dL)	160±16,7	159,41± 28,71	0,577
Glucose 0′ (mg/dL)	84,6±7,88	83,69±11,63	0,293
Glucose 60′ (mg/dL)	160,35± 29,81		
Glucose 120′ (mg/dL)	138,8±29,31		
Glucose 180′ (mg/dL)	109,60± 31,80

OGTT gestational age(-weeks)	25,41±6,27	23,91±6,97	0,010
> 24 weeks	192(74,7%)	171(63,8%)	0,008
≤ 24 weeks	65(25,3%)	96(35,8%)	
GDM(number)	41(16%)	37(13,8%)	**0,489**
Treatment			**0,454**
Insulin	11(26,8%)	14(37,8%)	
Diet	29(70,7%)	21(56,8%)	
Metformin	1(2,4%)	2(5,4%)	

of women with positive O'Sullivan test) versus 37 in 2020 (13.8%), $P=0.489$. 10 of the women with GDM were diagnosed before week 24 in 2019 versus 17 in 2020 (15.4% vs 17.7%$P=0.699$); 31 of the women with GDM were diagnosed after week 24 in 2019 versus 19 in 2020 (16.1% vs 11.1%$P=0.165$). There were no differences between groups with regard to treatment modality during these comparison periods ($P=0.454$).
Conclusion
GDM diagnostic rate was similar using 100-g OGTT criteria (2019) and basal glycaemia/HbA1c criteria due to the COVID-19 pandemic (2020). Besides, there were no differences between periods concerning the number of patients that required pharmacological treatment.

Study of change in physical activity behavior of diabetic patients after regular awareness sessions by primary care physicians

Aniket Inamdar
Samarpan Clinic, Internal Medicine, OMERGA, India

Background
Humans have been increasingly spending more time in sedentary behaviors such as prolonged sitting. Regular physical activity is associated with enhanced physical and mental health. Studies have shown that regular physical activity reduces the risk of cardiovascular diseases, diabetes mellitus, osteoporosis, depression and obesity. Patients frequently identify their family physicians as an important source of constant encouragement for physical activity.
Purpose
We wanted to assess the impact of regular awareness sessions about physical activity by Primary care physicians in diabetic patients.
Methods
73 diabetic patients between the age group 30 to 60 years were recruited in this single center study in rural India.70 participants completed this 6-month intervention study whereas 3 participants dropped out of study. Once in a month audio visual awareness session of one hour were conducted from August 2017 to January 2018 by primary care physicians to educate the diabetic patients about ill effects of sedentary lifestyle and benefits of regular physical activity. Pre and post intervention data were collected by using validated Godin leisure time exercise questionnaire from all 70 participants. Paired t test and Wilcoxon test were used to compare pre- and post-intervention data. Percentage increase in physical activity score was also calculated.
Results
In this study baseline Godin score pre intervention was 38.82 ± 12.22 (Mean $\pm$ SD) and post intervention was 65.98 ± 11.25 (Mean $\pm$ SD). Diabetic patients significantly improved Godin score post intervention which was statistically significant (**p: $<$ 0.001**). Compared to baseline pre intervention score, there was 170% increase in physical activity score post intervention.
Conclusions
Regular awareness sessions using modern technology by primary care physicians definitely showed positive change in physical activity behavior in diabetic patients. These regular sessions also helped to change the attitude and behavior about physical activity. Primary care physicians can play a significant role in counseling patients and promoting physical activity. Active involvement of primary care physician in this intervention further helped in establishing and continuing physical activity behavior. As primary care physicians have direct regular contact with their patients and their families, their role in promotion of physical activity will have more impact and long-lasting effect on diabetic patient's behavior. Similar studies are needed to assess impact of physical activity awareness sessions in diabetic patients.

Introduction
Alzheimer disease (AD) is the leading cause of dementia. While impaired glucose homeostasis has been shown to increase AD risk and pathological loss of tau function, the latter has been suggested to contribute to the emergence of the glucose homeostasis alterations observed in AD patients. However, the links between tau impairments and glucose homeostasis, remains unclear.
Objective
In order to better understand the links between tau and glucose homeostasis, the present study aimed at investigating the metabolic phenotype of a new knock-in (KI) mice model.
Method
Males and females Tau KI mice model expressing a human tau protein bearing the P301L mutation under the control of the endogenous mouse *Mapt* promoter and their non-transgenic littermates (referred as WT) were used. A complete metabolic phenotyping was explored under high fat diet (HFD) versus CHOW diet in both sexes. Also, glucose-stimulated insulin secretion (GSIS) was studied using isolated islets from tau KI and tau knock-out mice and mouse β pancreatic cell line (MIN6).
Results
While under chow diet tau KI mice do not exhibit significant metabolic impairments, we could observe that under HFD male, but not female tau KI animals exhibited glucose homeostasis alterations as compared to control littermates. Interestingly, using immunofluorescence, tau protein was found colocalized with insulin in the β cells of pancreatic islets. Additional experiments performed on isolated islets from tau KI and tau knock-out mice revealed that both exhibit impaired insulin secretion, an effect recapitulated in the mouse β pancreatic cell line (MIN6) following tau knock-down.
Conclusion
Altogether, our data suggest that loss of tau function in pancreatic β cell might favor the development of glucose homeostasis impairment and could contribute to metabolic changes observed in AD.

Performance of EKFC, FAS and 2021 CKD-EPI equations for estimating glomerular filtration rate in people with type 2 diabetes

Bruna Martins Rocha[1], Gustavo Monteiro Escott[1], Luíza Carolina Fagundes Silva[1], Indianara Franciele Porgere[1], Luis Afonso Tochetto[2], Letícia de Almeida Brondani[2] & Sandra Pinho Silveiro[1,2]
[1]Federal University of Rio Grande do Sul, Brazil; [2]Hospital de Clínicas de Porto Alegre, Brazil

Background
Diabetes mellitus (DM) is the leading cause of chronic kidney disease (CKD) worldwide. In clinical practice, kidney function is routinely assessed through glomerular filtration rate (GFR) estimated by equations. However, the accuracy of current equations has been questioned for people with diabetes mellitus (DM).
Aim
To evaluate the performance of the European Kidney Function Consortium (EKFC), the Full Age Spectrum (FAS) and the 2021 Chronic Kidney Disease Epidemiology Collaboration (2021 CKD-EPI) equations based on serum creatinine to estimate GFR in healthy and type 2 DM participants.
Methods
This cross-sectional study evaluated three creatinine-based equations in two different populations: healthy adults (eligibility criteria: BMI ≤ 30 kg/m^2) and people with type 2 DM (eligibility criteria: mGFR $>$ 60 ml/min/1.73 m^2). GFR calculated by the equations was compared with measured GFR (mGFR) by the plasma clearance of ^{51} Cr-EDTA as the reference method. The performance of the

equations was assessed using Bland-Altman plots, bias and P30 accuracy (defined as the percentage of GFR estimations falling within 30% of mGFR values).
Results
We included 100 healthy adults (aged 39±15 years, 67% women), with mean mGFR, 2021 CKD-EPI, FAS and EKFC of 112±20 109±14, 102±18 and 104±19 ml/min/1.73 m^2, respectively ($P=0.109$ between mGFR and 2021 CKD-EPI; $P<0.001$ for the other equations). Overall, the smallest bias was found for 2021 CKD-EPI (5 ml/min/1.73 m^2). All equations presented an acceptable P30 accuracy (92% [CI 95% 86-96] for 2021 CKD-EPI, 89% [82-94] FAS and 87% [79-93] EKFC;$P=0.348$) in the healthy participants. We also included 122 people with type 2 DM (aged 61±10 years, 55% women) in our study. Comparing with mean mGFR (100±28 ml/min/1.73 m^2), 2021 CKD-EPI, FAS and EKFC equations underestimated GFR (mean 86±20, 79±24, and 77±19 ml/min/1.73 m^2, respectively; $P<0.001$ for all equations). No equation achieved optimal P30 accuracy in participants with DM, but 2021 CKD-EPI tended to perform more accurately (74% [CI 95% 65-81] vs. FAS 66% [58-74],$P=0.082$; vs. EKFC 64% [56-72],$P=0.01$). The Bland Altman plots showed positive bias for all equations, with larger biases found in participants with type 2 DM, demonstrating that the underestimation was more pronounced in the presence of diabetes.
Conclusion
In healthy adults, 2021 CKD-EPI, FAS and EKFC are suitable to estimate GFR. However, none of the three equations reached an optimal performance for estimating GFR in participants with type 2 DM. There is still a necessity of improving GFR estimation in people with diabetes.

Single nucleotide polymorphism in the ADIPOQ gene modifies adiponectin levels and glycemic control in type two diabetes mellitus patients

Samir Al Bashir[1], Mahmoud A. Alfaqih[2] & Mohammed Alorjani[1]
[1]Jordan University of Science and Technology, Pathology and Microbiology, Irbid, Jordan; [2]Jordan University of Science and Technology, Physiology and Biochemistry, Irbid, Jordan

Diabetes Mellitus (DM) is the ninth leading cause of death worldwide. Mortality from DM is largely attributed to disease complications. Glycemic control of DM patients reduces mortality. Studies indicated that the lack of glycemic control in DM patients could be influenced by the genetic background of the patients. Evidence suggests that adiponectin levels are dysregulated in DM patients with poor glycemic control. Serum adiponectin level is a heritable trait influenced by single nucleotide polymorphisms (SNPs) in the ADIPOQ gene. It is hypothesized that SNPs in ADIPOQ could modify glycemic control in DM patients. To test this hypothesis, 375 type-II DM (T2DM) patients were recruited. Patients were classified into good vs. poor glycemic control according to Hemoglobin A1c levels. Study subjects were genotyped for variations in rs17300539, rs266729, rs2241766 and rs1501299; SNPs in ADIPOQ. Adiponectin levels were measured from the serum. Our analysis showed that reduced serum adiponectin, a longer duration of treatment, and increased insulin resistance were all significant predictors of poor glycemic control. Moreover, the T allele and the TT genotype of rs2241766 were significantly more frequent in patients with poor glycemic control ($P<0.05$). Individuals with the TT genotype of rs2241766 had significantly lower levels of serum adiponectin ($P<0.05$). It was concluded that lower levels of serum adiponectin and the T allele of rs2241766 SNP in ADIPOQ were associated with poor glycemic control in T2DM patients.

The link between type of antidiabetic agents and COVID 19 severity in patients with pre-existing type 2 diabetes

Ivona Risovic[1], Danijel Djekic[2] & Anja Stanic[3]
[1]University Clinical Center of the Republic of Srpska, Faculty of Medicine, University of Banja Luka, Endocrinology, Banja Luka, Bosnia and Herzegovina; [2]University Clinical Center Republic of Srpska, Endocrinology, Banja Luka, Bosnia and Herzegovina; [3]University Clinical Center of the Republic of Srpska, Endocrinology, Banja Luka, Bosnia and Herzegovina

Introduction
Type 2 diabetes is one of the main risk factors for severe COVID 19 infection. Inadequate glycemic control is related to high inflammation, hypercoagulability, and mortality in COVID-19 patients . Glucose lowering medications commonly used to treat diabetes mellitus (DM) might have effects on COVID 19 pathogenesis. Overall, evidence is conflicting as to which glucose-lowering drugs are associated with the most favourable outcomes in patients with COVID-19. The aim of our study was to evaluate association of COVID-19 severity with different types of DM therapy.
Patients and Methods
CThe retrospective study included 95 patients with type 2 DM and COVID 19: 25 (26.9%) received metformin, 16 (16.8%) metformin and sulfonureas, 12 (12.7%) metformin and dipeptidyl peptidase type 4 inhibitors (DPP-4), 8 (8.5%) metformin and glucagon-like peptide receptor agonists (GLP-1 RA), 13 (13.8%) metformin and basal insulin, 10 (9.5%) premix insulin and 11 (11.8%) basal and bolus insulin. Clinical presentation, ICU admission and death rate has been compared in patients with different types of DM therapy.
Results
Clinical presentation was mild in patients with metformin, metformin and DPP-4, metformin and GLP-1 RA and more pronounced in patients with premix insulin and basal bolus insulin. The three most common symptoms were: fever, cough and fatigue. Glycemic at admission were highest in patients with premix insulin (13.6±4.58 mmol/l), and the lowest in patients with metformin and DPP-4 (7.5±4.23 mmol/l). Our studies showed that inflammatory response and ICU admission rate were the highest in patients with premix insulin therapy and the lowest in metformin group (12.3 vs 7.1%). A total of 16 patients died (16.8 %) during hospitalization. The highest rate was in patient who received premix insulin 6 (50%) and the lowest in patients who received metformin 2 (2.1%).
Conclusion
Our results had showed that therapy with premix and basal bolus insulin had link with severe clinical presentation, ICU admission and death.
Key words
COVID 19, type 2 diabetes mellitus, metformin, insulin

Exceptional genetic transmission of a ABCC8 mutation in two cases of diffuse hyperinsulinism in a dichorionic diamniotic (DCDA) twin pregnancy

Daniela Telehuz[1], Plesa Oana[1], Bouilloud Florence[1], Voican Adela[1], Banu Isabela[1], Arnoux Jean-Baptiste[2], Wucher Helene[1] & Dupuy Olivier[1]
[1]Hospital Paris Saint-Joseph, Endocrinology, Paris, France; [2]Necker Hospital, Paris, France

We present the case of a 36-year-old female with a focal neonatal hyperinsulinism diagnosed at birth in a context of hypoglycemia that was resistant to Diazoxide treatment. A subtotal pancreatectomy was performed and histology showed a focal hyperinsulinism. The mutation of ABCC8 was not searched at this point. The patient developed an insulin dependent diabetes at the age of 9 and required an insulin pump. In 2017 the patient was planning a pregnancy so she consulted a geneticist doctor for his opinion. Considering the patient's history, a genetic test was performed that evidenced a local pancreatic recessive heterozygotic mutation for the ABCC8 gene (exon 39 c.4716C>A, p.Ser1572Arg). This phenotype is related to a uniparental disomy of a paternal origin situated at the pancreatic level. The geneticist concluded that the risk of transmission is very small (1/600) and was favorable for the pregnancy. As there was no consanguinity in the family, testing the father was not deemed necessary. A pregnancy starts in 2020 and at a gestational age of 21 weeks the mother goes into premature labor (premature rupture of membranes) and an emergency C-section is performed in April 2021 which concluded with the birth of bichorial bi amniotic male twins. Right after birth both babies experience severe hypoglycemia which requires a prolonged hospitalization with diazoxide treatment followed by an introduction of a somatostatin analogue treatment by pump and continuous enteral nutrition. The genetic tests evidenced the same two genetic mutations for both babies: exon 28 c63550del=p.Val1184 and exon 39 c.4716C>A=p.Ser1572Arg, which is responsible for a form of diffuse hyperinsulinism. As the already known mutation of ABCC8 was transmitted maternally, the greater risk lied in the transmission of a paternal heterozygotic mutation that was asymptomatic. This situation is very rare outside a consanguinity and was the consequence of the birth of two children that suffer from a severe diffuse hyperinsulinism which requires a somatostatin analogue pump treatment, as their insulin requiring diabetic mother is treated by an insulin pump.

The bidirectional relationship between testosterone and metabolic disorders: testosterone deficiency as an early marker of cardiovascular risk in young men

Davide Menafra[1], Cristina De Angelis[1], Francesco Garifalos[2], Michele Castoro[2], Nunzia Verde[2], Mariangela Piscopo[2], Giacomo Galdiero[2], Claudia Pivonello[2], Renata Simona Auriemma[2], Paolo Chiodini[3], Annamaria Colao[2,4] & Rosario Pivonello[2,4]
[1]Università Federico II di Napoli, Dipartimento di Medicina Clinica e Chirurgia, Sezione di Endocrinologia, Unità di Andrologia e Medicina della Riproduzione e della Sessualità Maschile e Femminile (FERTISEX-CARES), Naples, Italy; [1]Università Federico II di Napoli, Dipartimento di Medicina Clinica e Chirurgia, Sezione di Endocrinologia, Unità di Andrologia e Medicina della Riproduzione e della Sessualità Maschile e Femminile (FERTISEXCARES), Naples, Italy; [3]University of Campania "Luigi Vanvitelli", Medical Statistics Unit, Naples, Italy; [4]Federico II University of Naples, Unesco Chair for Health Education and Sustainable Development, Naples, Italy

In the last years an increasing incidence of cardiovascular diseases (CVD) has been reported in young adults (18-45 yrs), probably accounted by the significant increase in CV risk (CVR) factors. Observational and interventional studies, mainly focused on middle-aged and elderly men, demonstrated that metabolic CVR (mCVR) factors and CVD manifestations are common in hypogonadal men and, conversely, testosterone deficiency is highly prevalent in metabolic disorders; the lack of corresponding robust evidence in younger adults requires more focused investigation. The current single centre, observational, cross-sectional study aimed at better defining the mutual relationship between androgenic status and the prevalence of mCVR factors in a large cohort of 720 young (18-35 yrs) adult men, subjected to physical examination and fasting morning venous blood sampling for the assessment of anthropometric, metabolic and hormonal parameters. Body weight, BMI and waist circumference (WC) significantly decreased across total testosterone (TT) ($P<0.0001$), SHBG ($P<0.01$; $P<0.01$; $P<0.0001$) and calculated free testosterone (cFT) ($P<0.05$) tertiles, whereas systolic blood pressure (SBP) and triglycerides (TG) significantly decreased across TT ($P<0.05$; $P<0.01$) and SHBG ($P<0.05$; $P<0.0001$) tertiles, and diastolic blood pressure (DBP) across SHBG ($P<0.05$) tertiles. Spearman correlation analysis revealed a negative association of TT, SHBG and cFT with BMI ($r=$-0.204; $P<0.001$)($r=$-0.165; $P<0.05$)($r=$-0.132; $P<0.05$), and of TT and SHBG with WC ($r=$-0.234; $P<0.001$)($r=$-0.225; $P<0.01$), SBP ($r=$-0.112; $P<0.05$)($r=$-0.142; $P<0.05$) and TG ($r=$-0.017; $P<0.01$)($r=$-0.204; $P<0.001$), whereas a positive association of TT and SHBG with HDL-cholesterol ($r=0.167$; $P<0.01$)($r=0.251$; $P<0.001$) was demonstrated. In multiple linear regression analysis in models adjusted for age, BMI and WC, TT and SHBG were strong independent predictors of serum HDL-cholesterol ($\beta=0.151$; $P<0.01$) ($\beta=0.186$; $P<0.01$), and SHBG was an independent predictor of SBP and DBP ($\beta=$-0.177; $P<0.05$) ($P=$0,008; $\beta=$-0,204). Lastly, in the subgroup of men with hypotestosteronemia (TT $\leq$ 12.1 nM), the prevalence of normal weight was significantly lower and that of obesity, visceral obesity (WC > 102 cm), hypertension and metabolic syndrome was significantly higher, compared to normal-testosterone subgroup. Consistently, in the subgroup of overweight/obese men, the prevalence of hypotestosteronemia was significantly higher, compared to normal weight subgroup. In conclusion, the current study demonstrated that in young adult men a bidirectional relationship between testosterone deficiency and metabolic disorders exists, and that a worse androgenic status is associated to a worse cardiometabolic profile and might represent a strong early predictor of mCVR factors, potentially associated to the onset of future CVD.

Hypoglycaemia associated with variable rate intravenous insulin infusion and concurrent administration of balanced electrolyte solution: A single hospital experience

Vinit Shah, Sara Jasionowska, Sarah Kelly, Reshma Joseph & Maisarah Amran
London North West University Healthcare NHS Trust, United Kingdom

Background
Variable rate intravenous insulin infusion (VRIII) or 'sliding scale' is required for certain patients with diabetes to keep their blood glucose within the recommended target range during an acute illness or a period of starvation. When used in the right context this has shown to improve outcomes but can also lead to morbidity especially hypoglycaemia.

Aim
Evaluate risk of hypoglycaemia in patients on VRIII with concurrent use of balanced electrolyte solution
Methods
This was an observational study and we included patients who were admitted to medical or surgical wards over a six-week period and who were on a VRIII. Relevant data was collected from patients' paper notes, observation nursing charts and drug charts. The data was collected for the entire duration patients were on the VRIII. Our hospital has guidelines for the management of patients on VRIII including recommendations on frequency of glucose monitoring and choice of concurrent IV fluids. The recommended balanced solution with carbohydrate substrate used in our hospital is combined 0.18% sodium chloride with 4% glucose (0.18% NaCl + 4% glucose). Hypoglycaemia is defined as when the capillary blood glucose falls below 4 mmol/mol.
Results
We included a total of 16 patients in our study with a mean age of 59 years with the majority of patients having type 2 diabetes (87.5%). 0.18% NaCl + 4% glucose was used concurrently with the VRIII in 75% of patients. For all the patients that were included in the study a total of 434 hours were spent on a VRIII for which there were 324 capillary blood glucose readings with 3 recorded hypoglycaemia events (< 1%) with 2 out of 3 occurring in those who were not on a balanced electrolyte solution.
Discussion
Use of concurrent IV fluids (Normal saline or 5% dextrose) is not a new concept, but often this has been prescribed separately and the infusion switched between the two depending on the threshold levels of capillary glucose levels that has been set by the prescriber. This is prone to human error and consequent adverse events. This study demonstrates that with the concurrent use of balanced electrolyte solution such as 0.18% NaCl + 4% glucose, there is a minimal incidence of hypoglycaemia and its concurrent use is recommended to prevent harm to patients on VRIII. This would be of particular importance in general ward or less intensively monitored settings.

The role of empagliflozin in palmitate-induced ER stress and apoptosis in H9C2 cells

Jae Yeop Jeong[1], Sung-E Choi[2], Min Woo Song[1], Suck Ho Park[2], Yup Kang[2], Tae Ho Kim[3], So-Yeon Ahn[4], Hae Jin Kim[1], Seung jin Han[1], Ja Young Jeon[1], Nami Lee[1], Dae Jung Kim[1] & Kwan-Woo Lee[1]
[1]Ajou University School of Medicine, Department of Endocrinology and Metabolism, Suwon, Rep. of South Korea; [2]Ajou University School of Medicine, Department of Physiology, Suwon, Rep. of South Korea; [3]Seoul Medical Center, Division of Endocrinology and Metabolism, Department of Internal Medicine, Seoul, Rep. of South Korea; [4]Busan Bumin Hospital, Division of Endocrinology and Metabolism, Department of Internal Medicine, Busan, Rep. of South Korea

Aim/hypotheses
Ectopic lipid accumulation in the heart contributes to the abnormal function of the heart and to the death of cardiomyocytes.Saturated FFA is one of the most important causes of death in cardiomyocytes. Although empagliflozin has been reported to be beneficial for people with diabetic complications and/or CVD, it has not been confirmed as to how it affects cardiomyocytes death by FFA. This study was designed to evaluate the protective effects of SGLT2 inhibitor on palmitate-induced ER-stress and apoptosis in cardiomyocytes.
Methods
We used differentiated H9C2 cells as cardiomyocytes and palmitate as a saturated fatty acid. To clarify the effects of empagliflozin on apoptosis, free fatty acid was treated with or without empagliflozin in cardiomyocytes and several stress signaling pathways were measured, such as inflammation, endoplasmic reticulum (ER)-stress, and insulin signaling using immunoblotting. Inflammation and cardiac metabolism were analyzed in several related genes. Cardiomyocyte apoptosis was detected using DNA fragmentations assay and immunoblotting using cleaved caspase 3 antibody. DAPI staining was also performed.
Results
Palmitate stimulated increment of ROS (reactive oxygen species) and ER-stress markers such as phospho-eIF2a, CHOP, and phospho-JNK. In addition, cleaved caspase3 and DNA fragmentation was induced by treatment of palmitate. Interestingly, empagliflozin significantly decreased expression levels of ER-stress markers (including phospho-eIF2α, CHOP, and phospho-JNK [Jun N-terminal kinases]) in PA-treated cells. Empagliflozin significantly decreased the activity of cleaved caspase-3 (a well-known apoptotic induced molecule) and DNA fragmentation. To investigate the protective molecular mechanism of empagliflozin, we measured AMPK activation and upstream signal pathways.

Empagliflozin significantly stimulated phospho-CAMKK2 and phospho-AMPK. In addition, phosphorylation of acetyl-CoA carboxylase, target protein of AMPK, was also activated by treatment of empagliflozin. But, LKB did not change. Beneficial effects of empagliflozin was abolished by compound C.
Conclusions/interpretation
This data suggests SGLT2 inhibitors protect palmitate induced cardiomyocytes, ER-stress, and apoptosis. Therefore, attempts to use treatment of SGLT2 inhibitor might be a useful strategy for preventing diabetes associated ventricular remodeling and diabetic cardiac complication.

Leptin increases VLDL triglyceride secretion and reduces hepatic lipid content in lean male subjects

Matthaeus Metz[1], Marianna Beghini[1], Lorenz Pfleger[1], Peter Wolf[2], Magdalena Bastian[2], Jürgen Harreiter[3], Sabina Baumgartner-Parzer[2], Rodrig Marculescu[4], Michael Krebs[2], Martina Hackl[1], Michael Trauner[5], Martin Krssak[3], Herbert Stangl[6], Alexandra Kautzky-Willer[7], Clemens Fürnsinn[3] & Thomas Scherer[1]
[1]Medical University of Vienna, Division of Endocrinology and Metabolism, Vienna, Austria; [1]Medical University of Vienna, Division of Endocrinology and Metabolism, Vienna, Austria; [1]Medical University of Vienna, Division of Endocrinology and Metabolism, Vienna, Austria; [4]Medical University of Vienna, Department of Laboratory Medicine, Vienna,; [5]Medical University of Vienna, Division of Gastroenterology and Hepatology, Vienna, Austria; [6]Medical University of Vienna, Institute of Medical Chemistry, Vienna, Austria; [7]Medical University of Vienna, Department of Medicine III, Division of Endocrinology & Metabolism, Vienna, Austria

Background
Leptin reduces hepatic lipid content in lipodystrophic and overweight, relatively hypoleptinemic NAFLD patients. However, the underlying mechanism is unknown. In rodents, the anti-steatotic action of leptin is mediated by an increase in VLDL secretion and depends on an intact vagal innervation of the liver.
Methods
In this randomized, placebo-controlled, crossover trial, we study the effects of a single metreleptin injection (0.1 mg/kg body weight) on VLDL1 secretion and hepatic energy/lipid metabolism in 13 male, overnight-fasted volunteers. VLDL1 secretion rate was determined with an intralipid infusion test 4 hours after injection. Hepatic lipid content and phosphorous metabolites were measured with ^{1} H/^{31} P-MRS at baseline and 3h after metreleptin injection. In an additional cohort of 10 overnight-fasted, male subjects, we assessed hepatic VLDL1 secretion after modified sham feeding, an established method to stimulate the vagus nerve, where subjects smell, taste and chew, but do not swallow a standardized test meal. Water was served in the control condition.
Results
VLDL1 triglyceride secretion rate was higher after metreleptin than placebo (360 ± 36 vs. 464 ± 45 mg/h; $P = 0.049$) without differences in circulating insulin. As a consequence of the prolonged fasting period, we observed a similar increase in plasma NEFA, ketone bodies and acylcarnitines in both conditions. However, the almost uniform, fasting-associated increase in liver fat in the placebo condition (+ 19% relative to baseline, $P = 0.01$) was prevented by the metreleptin injection. VLDL1 triglyceride secretion correlated with changes in hepatic lipid content ($r = 0.5$, $P = 0.02$). Hepatic ATP/Pi ratio and ATP synthesis rate changed similarly after placebo and metreleptin. In the second cohort, plasma pancreatic polypeptide increased after modified sham feeding ($+296 \pm 109$% vs. -4 ± 35% in the placebo condition) indicating that our test meal stimulated the vagus nerve. Similar to metreleptin, vagus nerve stimulation was associated with an increased hepatic VLDL1 triglyceride secretion (244 ± 39 vs. 348 ± 32 mg/h; $P = 0.02$).
Conclusion
Our study supports the hypothesis that, in humans, leptin's anti-steatotic action is mediated by an increase in hepatic triglyceride export independent of food intake via a brain-vagus-liver axis.

Development and validation of a new gestational diabetes mellitus (gdm) risk algorithm

Leire Mendizabal[1], Maddi Arregui[1], Johanna Valerio[2], Ana María Ramos[2], Ana Barabash[2], Nuria Garcia de la Torre[2], mirella zulueta[3], Eunate Arana[4], Eva Saez[1], Igotz Aránbarri[1], Juan Martinez-Lage[1], Alicia Cortazar[4], Sonia Gaztambide[4], Luis Castaño[4], Laureano Simon[1] & Alfonso Luis Calle-Pascual[2]
[1]Patia Europe, San Sebastian, Spain; [2]Hospital Clínico San Carlos, Madrid, Spain; [3]Patia, Boston, United States; [4]Hospital de Bilbao Biocruces, Bilbao, Spain

Background and Objective
Gestational Diabetes Mellitus (GDM) is associated with life-long adverse outcomes for the mother and the baby. To date there is no rigorous clinical test for the assessment of GDM risk, since estimation of GDM risk is currently primarily based on clinical risk factors. Additional markers are needed to identify women at high risk. Our aim was to develop and validate a risk assessment model to identify women at high risk of GDM through an algorithm that integrates genetic and clinical variables.
Methodology
We analyzed a retrospective cohort of 711 women with 425 control pregnancies and 286 GDM cases. The entire cohort was randomly divided into a training/development dataset (70% of the cohort) for algorithm development and a test dataset (30% of the cohort) for validation. A total of 112 SNPs (Single Nucleotide Polymorphisms) were selected for this analysis after exhaustive exploration of the databases published to date of SNPs associated with GDM. The SNPs were selected based on their predictive power and population frequency, with the following criteria: $OR > 1.2$, $RAF > 0.20$, $P < 1 \times 10^{-5}$. SNPs were grouped into glycemic traits categories. Genotyping was performed using iPlex Gold-MassARRAY from Agena Bioscience. In the clinical and genotype data set of the development/training group, significant attribute selection was performed using Sequence Feature Selection (SFS) techniques. Logistic regression analysis was then applied to obtain prediction coefficients for the selected attributes in the training group data set. Discrimination and calibration of risk scores were evaluated using the receiver operating characteristic (ROC) curve in the training and the validation dataset.
Results
An algorithm was developed on the training dataset that provides a risk score for GDM. The algorithm includes 10 SNPs, maternal age, pregestational body mass index, and number of previous pregnancies. In the training dataset the AUC was 0.7420. The AUC of the 10 SNPS alone (0.6981) and the clinical variables alone (0.6133) were significantly lower than their combination. AUC in the validation set was 0.7139.
Conclusions
a new tool for GDM risk assessment is presented, which suggests that the utilization of genetic markers in combination with clinical characteristics may improve accuracy of GDM risk evaluation and reinforce the adoption of preventive intervention as early as possible. Further clinical validation studies in different patient cohorts are ongoing.

Evaluating a novel virtual simulation tool for clinical training to improve clinician confidence managing cases in diabetes and endocrinology

Wentin Chen[1], Gobeka Ponniah[1], Meghnaa Hebbar[1], Jameela Sheikh[1], Dengyi Zhou[1], Kashish Malhotra[2], Nia Evans[3], Emily Warmington[1], Anisah Ali[1], Fatema Rezai[1], Isabel Allison[4], Carina Synn Cuen Pan[1], Rachel Nirmal[1], Pavithra Sakthivel[1], Vina Soran[1], Zakee Abdi[5,6], Harjeet Kaur[1], Dwi Delson[7], Simran Piya[8], Eka Melson[9,10], Meri Davitadze[11], Punith Kempegowda[10,12] & Simba Simulation[10]
[1]University of Birmingham Medical School, Birmingham, United Kingdom; [2]Dayanand Medical College, Ludhiana, India; [3]Royal Glamorgan Hospital, Ynysmaerdy, United Kingdom; [4]West Middlesex University Hospital, London, United Kingdom; [5]Medical University - Plovdiv, Plovdiv, Bulgaria; [6]Barts and The London School of Medicine and Dentistry, United Kingdom; [7]School of Medicine - University of Dundee, Dundee, United Kingdom; [8]University of Edinburgh Medical School, Edinburgh, United Kingdom; [9]Ninewells Hospital, Dundee, United Kingdom; [10]Institute of Metabolism and Systems Research - University of Birmingham, Birmingham, United Kingdom; [11]Medical House, Tbilisi, Georgia; [12]Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom

Introduction
The delivery of medical education has transformed from in-person to remote teaching, accelerated by the ongoing COVID-19 pandemic. Simulation is a useful teaching modality increasingly used to develop healthcare professionals' knowledge and skills while protecting patients from unnecessary risks. Although simulation has traditionally occurred face-to-face, many of its principles can be

adapted for remote teaching. Simulation via Instant Messaging – Birmingham Advance (SIMBA) is a virtual simulation-based learning tool, run by medical students and junior doctors with support from experts, aimed to increase clinician confidence in managing clinical scenarios. We evaluated the effectiveness of SIMBA to improve participants' confidence and competencies in diabetes and endocrinology.
Methods
Eight sessions were conducted between May 2020 and October 2021 on various endocrine subspecialities (adrenal, thyroid, pituitary, diabetes, metabolic bone, and reproductive). Moderators used standardised transcripts to simulate anonymised, real-life clinical cases via WhatsApp. Following the simulation, specialists chaired interactive Zoom sessions to discuss simulated cases and participant queries. Participants' self-reported confidence levels in approaching clinical scenarios were measured using a Likert scale, and responses were categorised as confident, unsure, and not confident. Changes in these categories pre- and post-SIMBA were compared using Wilcoxon signed-rank test. Improvements in clinical core competencies were also analysed.
Results
326 international participants completed the pre- and post-SIMBA surveys and were included in the analysis. Significant improvements were observed in clinician confidence following SIMBA (pre- vs post-survey, confident: +40.6%, unsure: -34.3%, not confident: -6.3%; $P<0.0001$). In addition, 92.6% ($n=302/326$) participants strongly agreed/agreed that sessions were engaging, while 88.7% ($n=289/326$) strongly agreed/agreed that SIMBA accommodated their learning style and 80.5% ($n=236/293$) preferred SIMBA to traditional pedagogy. The overall quality of the sessions was rated as excellent/good by 96.2% ($n=282/293$) participants. 93.9% ($n=306/326$) participants strongly agreed/agreed that the simulated topics were applicable to their clinical practice, while 93.9% ($n=306/326$) and 92.6% ($n=302/326$) strongly agreed/agreed the content was impactful at personal and professional levels, respectfully. Clinicians reported improvements in core clinical competencies: patient care [56.7% ($n=185/326$)], patient management [83.4% ($n=272/326$)], systems-based practice [43.3% ($n=141/326$)], and practice-based learning [66.9% ($n=218/326$)].
Conclsion
SIMBA proved to be an effective postgraduate training tool in endocrinology which improved clinician confidence managing various endocrine conditions and was highly accepted among learners. In addition, the ubiquity of online platforms enabled international participation, which transcends geographical and financial barriers and could help standardise endocrine training globally. Further studies are underway to explore the long-term translation of SIMBA to clinical practice.

Cause of Death for Patients with Diabetes Mellitus in Korea: Multicenter study

Hyeyeon Moon, Mi Kyoung Park & Sunghwan Suh
Dong-A University Hospital, Endocrinology, Busan, Rep. of South Korea

Background
In Republic of Korea, prevalence of type 2 diabetes mellitus (T2DM) has increased substantially in recent decades, but there are no reliable estimates of the excess mortality currently associated with diabetes.
Methods
We analyzed all subjects were T2DM patients over the age of 30 whose death certificates were issued at three hospitals in the Busan metropolitan area from 2010 to 2014. The causes of death were retrospectively determined based on the information from attending physicians or death certificates.
Results
The study comprised 777 patients of which 60.1% were male. The average age of death was 71 years. The most common cause of death in these patients was infectious disease (28.1%), followed by cardiovascular disease (25.5%), malignant neoplasm (24.5%), and kidney disease (8.1%). This trend was consistent when we sub-analyzed them according to glycemic control status. However, cancer was the most common cause of death in male patients which may be driven by higher rate of smoking and alcohol drinking compared to female patients.
Conclsion
Preventive strategies to promote primary prevention and early detection of infectious disease is urgently needed to reduce this excess mortality in patients with T2DM. In addition, gender difference in cause of death should be taken into consideration.

Table 1 The proportion of cause of death in patients with diabetes mellitus

Cause of death	Total ($n=777$)	Men ($n=467$)	Women ($n=310$)
	Numbers (%)	Numbers (%)	Numbers (%)
Infectious disease	218 (28.1)	120 (25.7)	98 (31.6)
Malignant neoplasm	190 (24.5)	134 (28.7)	56 (18.1)
Cardiovascular disease	198 (25.5)	116 (24.8)	82 (26.4)
Cerebrovascular disease	75 (9.7)	50 (10.7)	25 (8.1)
Ischemic heart disease	67 (8.6)	35 (7.5)	32 (10.3)
Heart failure	56 (7.2)	31 (6.6)	25 (8.1)
Kidney disease	63 (8.1)	38 (8.1)	25 (8.1)
Liver disease	40 (5.1)	25 (5.4)	15 (4.8)
Diabetes mellitus	14 (1.8)	7 (1.5)	7 (2.3)
All other cause*	54 (6.9)	27 (5.8)	27 (8.7)

*All other causes included gastrointestinal bleeding, pulmonary thromboembolism, epilepsy, acute pancreatitis and panperitonitis.

The neural mechanism of selective activation of kisspeptin neurons in the ARC of the hypothalamus regulate bown adipose thermogenesis in female mice

Qinyu Liu[1], Qian Li[2], Xiaofeng Lin[1], Xieyu Xu[1], Gang Chen[1] & Junping Wen[1,3]
[1]Shengli Clinical Medical College of Fujian Medical University, Fujian, China; [2]Department of Endocrine and Metabolic Diseases, Shanghai Institute of Endocrine and Metabolic Diseases, Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China; [3]Department of Endocrinology, Key Laboratory of Endocrinology, Fujian Provincial Hospital, Fujian, China

Objectives
Overweight and obesity currently burden our public health, and especially with the aging process in the world, the incidence of obesity is significantly higher in women than that in men partly. Recent studies reported that hypothalamic kisspeptin neurons, with obvious changes of number and structure in female during life, play a crucial role in the regulation of central energy homeostasis. But the precise mechanism remains an enigma.
Methods
High-fat fed Kiss1-CreGFP female mice were used in this study. Selectively activated kisspeption neurons by using Designer-receptors-exclusively-activated-by-designer-drugs(DREADDs) technology and denervation of the sympathetic nerve in iBAT were used to demonstrate the mechanism by which ARC Kisspeptin neurons activate brown fat thermogenesis in female mice.
Results
The Kiss1-CreGFP female mice were injected with AAV-DIO-hM3D(Gq)-mCherry virus in ARC through Stereotactic injection. Three weeks later, AAV was successfully transfected and expressed the corresponding receptor, which were greatly activated by CNO, then the expression of neuronal activation marker c-fos was significantly enhanced. Selective activation of Kisspeptin neurons resulted in decreased body weight, improved glucose metabolism, increased energy expenditure, increased iBAT(brown adipose tissue), decreased sWAT, gWAT, rWAT (white adipose tissue) in female mice($P<0.05$). The norepinephrine(NE) concentration, sympathetic specific indicator tyrosine hydroxylase (TH), the number of brown adipose cells and the expression of thermogenic related genes were significantly increased in activated group ($P<0.05$). The metabolic improvement effect disappeared in activating kisspeptin^{ARC} neurons after sympathetic nerve denervation of iBAT, and female mice gained weight, impaired glucose metabolism, failed activation of brown fat, and significantly decreased thermogenesis ($P>0.05$). But the control group of beneficial effects by chemogenetics activation on weight reduction, glucose metabolism improvement and brown fat thermogenesis activation still existed ($P<0.05$).
Conclusion
Chemogenetics can relatively specifically activate Kisspeptin neurons in the ARC of the hypothalamus in female mice, and the activated Kisspeptin has an effect on energy metabolism, mainly reduced weight, improved glucose metabolism,

increased thermogenic and dissipative, increased brown adipose tissue, strengthened sympathetic activity innervating iBAT, and significantly improved high fat induced obesity. iBAT sympathetic denervation experiments confirmed that Kisspeptin^{ARC} neurons in female mice modulate iBAT activation through sympathetic nerve to improve systemic energy metabolism.

Clinical and nutritional risk factors for insulin requirement during gestational diabetes mellitus

Rahma Khalaf, Yosra Htira, Zohra Hadj Ali, Chaima Jemai, Imen Hedfi & Faika Ben Mami
National Institute of Nutrition, Department C, Tunisia

Background and aim
Gestational Diabetes Mellitus (GDM) is the commonest medical pregnancy complication. Nutritional interventions come to the fore as one of the few levers for managing GDM, as many medications are either harmful to the growing fetus, or their toxicity is uncertain. The aim of this study was to assess the potential clinical features and nutritional risk factors of insulin treatment during GDM.
Methods
This was a prospective study including 150 patients with GDM. Patients who failed to achieve glycemic targets, defined according to the American Diabetes Association guidelines 2021, were treated with insulin. Clinical caracteristics and dietary intake were compared between the two groups. Dietary intake data were collected by trained nutritionists using a 24-hour recall method.
Results
Among the 150 patients with GDM, insulin use, along with lifestyle interventions, was necessary in 20.3% of patients. Univariate analysis showed that insulin use was significantly associated with a family history of type 2 diabetes in a first degree relative ($P=0.016$), history of GDM ($P=0.02$), pregestational Body Mass Index superior to 25 kg/m^2 ($P=0.005$) and presence of four risk factors of GDM ($P=0.005$). Insulin therapy group had higher protein intake than nutritional therapy group (100.86 $\pm$38.8 g/d vs 80.28 $\pm$36.97 g/d,$P=0.025$) and lower vitamin B12 levels (3.93 $\pm$2.84 µg/d vs 2.59$\pm$1.78 µg/d,$P=0.01$). Energy consumption, carbohydrate intake, fat intake and fiber intake did not statistically differ between the two groups ($P=0.7$,$P=0.09$,$P=0.89$, p=0.6 respectively). The calcium, iron, zinc, magnesium, vitamin B1,B2,B3,B5,B6 and folic acid intakes did not statistically differ between the two groups. Multivariate analysis showed that vitamin B12 level was an independant factor for insulin requirement during GDM (OR 5.52, 95% CI 1.33-22.83, $P=0.018$). The cut-off value of vitamin B12 level, determined by ROC curves analysis, was 2.28 µg/d (sensitivity of 80% and specificity of 52%,$P=0.01$).
Conclsion
The association between vitamin B12 levels during pregnancy and the risk of GDM remains unclear with conflicting data. To our knowledge, this is the first study to elucidate the association between vitamin B12 levels and insulin requirement during GDM. More studies are needed to further strengthen this finding and to clarify possible pathogenetic mechanisms.

Different treatment outcomes (acute dietary restriction vs conventional treatment) in women with new-onset type 2 diabetes (T2DM), with previous gestational diabetes (GDM)

Natalia Asatiani[1,2], Ramaz Kurashvili[3], Ekaterine Inashvili[3], Elena Shelestova[3] & Mzia Dundua[3]
[1]National Center for Diabetes Research, Diabetes in Pregnancy, Tbilisi, Georgia; [2]Petre Shotadze Tbilisi Medical Academy, Tbilisi, Georgia; [3]National Center for Diabetes Research, Tbilisi, Georgia, Tbilisi, Georgia

Some literary data demonstrate that the twin defect of beta-cell failure and insulin resistance that underline T2DM can be reversed by acute negative energy balance alone. The aim of the present work was to assess treatment outcomes in women with new onset T2DM, who were previously diagnosed with GDM treated with acute dietary restriction or conventionally at 32 weeks postpartum (PP).
Methods
In total 174 women with T2DM at 32 weeks PP, were enrolled in the study. Patients were tested at 32, 40 and 48 weeks PP. Patients were divided into two groups (Gr.): Gr.1 - Acute Dietary Energy Restriction - 61 women - 600kcal/day for 8 weeks, during next 8 weeks- 1 200 – 1 400kcal/day. Gr.2 - Conventional Therapy - 113 women - 1 400 – 1800 kcal/day and Metformin.
Results
At entry levels of HbA1c, fasting plasma glucose (FPG), insulin, triglycerides and BMI statistically did not differ in Gr.1 and Gr.2. At week 33 PP (one-week post treatment) FPG decreased: Gr.1 – 170.5 $\pm$18.6 vs. 96.4$\pm$9.1;$P=0.000$ and Gr.2– 169.9$\pm$ 18.8 vs. 145.7$\pm$ 14.9;$P=0.32$, and at week 48 PP- FPG levels decreased in both groups, but in Gr.1 decrease was statistically more evident, than in Gr.2 ($P=0.004$). At week 40 PP HbA1c levels decreased in both groups (Gr.1 – by 1.42 $\pm$0.12 and Gr.2 – 0.68$\pm$ 0.08;$P=0.000$), and at week 48 PP HbA1c levels were statistically lower in Gr.1 ($P=0.000$). At week 40 PP fasting plasma insulin fell from 16.1 $\pm$3.6 to 5.2$\pm$ 1.7 (Gr.1 – $P=0.000$), and 15.9 $\pm$3.1 to 12.1 $\pm$2.3 (Gr.2 -$P=0.3$); and at week 48 PP these indices were statistically lower in Gr.1 when compared to Gr.2 ($P=0.000$). After 16 weeks of treatment BMI also reduced in both groups (Gr.1 – by 7.8$\pm$0.08kg/m$_2$ and Gr.2 – by 2.61 $\pm$0.1%) while at week 48 PP statistically lower BMI was observed in Gr.1 ($P=0.055$). Triglyceride levels have dropped in Gr.1 and 2 (by 0.60 $\pm$0.05 and 0.68 $\pm$0.06 mg/dl, respectively) though this decrease was not statistically evident.
Conclusion
In women with T2DM, who were previously diagnosed with GDM acute dietary restriction at 32 weeks PP significantly reduced plasma fasting glucose, insulin levels, HbA1c, and BMI when compared to traditional dietary management and Metformin. Our data are in complete accordance, that abnormalities underlying T2DM are reversible by reduced dietary energy intake, that is of an utmost importance for young women after pregnancy and breastfeeding.

Prevalence and predictive factors of factitious hypoglycemia in non-diabetic patients

Amani Terzi, Ibtissem Oueslati, Meriem Yazidi, Elyes Kamoun & Melika Chihaoui
La Rabta University Hospital, Department of Endocrinology, Tunis, Tunisia

Introduction
Spontaneous hypoglycemia in non-diabetic patients is a rare metabolic emergency caused by multiple etiologies. Factitious hypoglycemia, a form of the Munchausen syndrome, is defined as the surreptitious use of insulin or oral hypoglycemic agents to deliberately induce self-harm. It is one of the most challenging diagnoses associated with significant morbidity and mortality. The aim of this study was to assess the prevalence and the associated factors of factitious hypoglycemia in non-diabetic patients.
Methods
This was a single-center, retrospective study including 70 non-diabetic patients who were admitted to our department between 2004 and 2020 for the exploration of a spontaneous hypoglycemia. All enrolled patients fulfilled the Whipple triad. Exclusion criteria were: pregnancy, severe renal failure, hepatic failure, cirrhosis, heart failure, and a history of malignant tumors. Age, gender, epidemiological parameters, medical history, clinical and paraclinical data, and the etiology of hypoglycemia were collected from medical records.
Results
The diagnosis of factitious hypoglycemia was confirmed in 11 patients (9 women and 2 men) corresponding to a prevalence of 16%. It was secondary to an intentional insulin use in 6 patients and to the ingestion of Glibenclamide in 5 patients. Their mean age was 30.27 $\pm$13.02 years with extremes of 14 and 54 years. Two patients with factitious hypoglycemia had a personal history of psychiatric disorders. Age $\leq$ 35 years (Odds Ratio= 5.6,$P=0.017$), family history of diabetes mellitus (Odds Ratio=1.29,$P=0.015$), attention disorders (Odds Ratio=12.5,$P=0.017$), and fasting glucose level<0.7 g/l (Odds Ratio= 5.75, $P=0.017$) were positively associated with factitious hypoglycemia.
Conclusion
Factitious hypoglycemia is more frequent in middle-aged women with psychosocial issues and a family history of diabetes mellitus explaining the ease to access to insulin and anti-diabetic agents. A psychiatric referral and a supportive follow up are warranted to provide the appropriate guidance for patients and perform an essential role in the long-term management of factitious hypoglycemia.

Type 1 diabetes technology and quality of life: glucose control and beyond

Silvia Irina Briganti[1], Daria Maggi[2], Rocky Strollo[2], Shadi Kyanvash[2], Oreste Lanza[2], Paolo Pozzilli[3] & Silvia Manfrini[2]
[1]Campus Bio-Medico, Metabolic Diseases, Rome, Italy; [2]Campus Bio-Medico, Metabolic diseases, Rome, Italy; [3]Campus Bio-Medico, Rome, Italy

Background
Technological advances in continuous glucose monitoring (CGM) and continuous subcutaneous insulin infusion (CSII) should aim to improve glucose control and quality of life in patients diagnosed type 1 diabetes (T1D).
Aim
The aim of our study was to compare different CGM and CSII devices on these targets.
Methods
Sixty-nine T1D patients (mean age 39 ± 12; 31 males) were recruited. 36 were on multiple daily insulin injections (MDI), 33 on CSII devices including Medtronic Minimed 640G and 670G, Theras Omnipod, Roche Insight and Movy Tandem. Glucose monitoring was performed with Dexcom-G6, Guardian sensor and Flash Freestyle Libre. The Diabetes Treatment Satisfaction Questionnaire (DTSQ), the Diabetes Specific Quality Of Life Scale (DSQOLS) and The Short Form (36) Health Survey (SF-36) were administered to test quality of life. HbA1c, time in range (TIR), time above the range (TAR) and time below the range (TBR) were investigated as glucose control parameters.
Results
Patients in the CSII group had higher treatment-related satisfaction (84.8% vs 52.8%, $P = 0.005$), and better disease acceptance (84.8% vs 52.8%, $P = 0.012$) compared with patients on MDI, despite similar age (MDI mean age 38 ± 12.5, CSII 41 ± 11.6). No differences were observed among devices ($P =$ ns). TIR resulted higher in the CSII group than in the MDI group ($P = 0.001$). The Dexcom G6 group had higher TIR values than the Freestyle ($P = 0.03$) group, but similar to the Medtronic ($P = 0.12$) group.
Conclusions
Technological devices may improve quality of life over MDI treatment. Type of glucose monitoring system may also impact glucose control.

Hoffmann- La Roche, Roche Innovation Centre Basel, Basel, Switzerland; [11]Stanford University Graduate School of Business, Stanford, California, United States

Background
Cigarette smoking is the leading preventable cause of premature death. Smoking cessation is one of the central goals in medicine, but despite dedicated programs, quit rates remain low due to barriers such as nicotine withdrawal syndrome or post-cessation weight gain. Glucagon-like peptide-1 (GLP-1) analogues reduce energy intake and body weight and seem to modulate addictive behavior. These GLP-1 properties are of major interest in the context of smoking cessation. The aim of this study was to evaluate the GLP-1 analogue dulaglutide as a new add-on therapy for smoking cessation.
Methods
This was a placebo-controlled, double-blind, parallel group, superiority, single-center randomized study including 255 patients. The intervention consisted of a 12-week treatment phase with dulaglutide 1.5 mg or placebo injected subcutaneously at a weekly study visit, in addition to standard of care (behavioral counselling and pharmacotherapy with varenicline). Point-prevalence abstinence rate at week 12 as primary outcome was assessed by self-reported smoking status and biochemical confirmation (end-expiratory exhaled carbon monoxide measurement). We further investigated changes in weight and glucose homeostasis at week 12. In a substudy ($n = 71$), we compared behavioral (i.e., nicotine craving measured by a Visual Analogue Scale) and brain activity changes in response to smoking cue videos using functional magnetic resonance imaging at baseline and week 12.
Results
The point-prevalence abstinence rate after 12 weeks of treatment was 80/127 (63%) in the dulaglutide group and 82/128 (65%) in the placebo group (difference in proportions [95%CI] -1.9% [-10.7, 14.4],$P = 0.859$). We observed an increase in weight in the placebo (+1.8kg [SD 2.4]) and a decrease in the dulaglutide group (-0.7kg [SD 3.3]) between baseline and week 12; baseline-adjusted difference in weight change [95%CI] -2.5kg [-3.3, -1.7], $P < 0.001$. Craving in response to smoking cue videos decreased from baseline to week 12 (estimated mean difference [95%CI] -3.0 [-3.7, -2.3], $P < 0.001$), with no difference between dulaglutide and placebo (estimated mean difference [95%CI] 0.4 [-1.2, 2.0], $P = 0.6$). Similarly, no difference in whole brain functional activity was seen between the two treatments, at both time points and between baseline and follow up.
Conclusion
In this study, an exceptional high point prevalence abstinence rate in both groups was observed, most probably due to the very close (weekly) supervision of the patients. Our data provides no evidence that dulaglutide modulates nicotine craving or smoking cessation rates. Nevertheless, GLP-1 analogues such as dulaglutide may be a promising treatment during smoking cessation as it may avoid post-cessation weight gain.

[1]Queen Mary University of London, Barts Health NHS Trust, London, United Kingdom; [2]Foundation for Prader-Willi Research, Walnut, United States; [3]PATH for PWS Investigators; [4]University of Florida, Gainesville, United States; [5]Emory Children's Center, Druid Hills, United States; [6]Hammersmith Hospital, London, United Kingdom; [7]Chelsea and Westminster Hospital, London, United Kingdom; [8]National Institutes of Health, Bethesda, United States; [9]Rady Children's Hospital - San Diego, San Diego, United States; [10]Kansas University Medical Center, Kansas City, KS, United States; [11]The Research Institute at Nationwide Children's Hospital, Columbus, United States; [12]Indiana University School of Medicine, Indianapolis, United States; [13]Vanderbilt University, Nashville, United States; [14]NYU Winthrop Hospital, Mineola, United States; [15]NYU Langone Hospital-Long Island, Pediatrics, Division of Pediatric Endocrinology, Mineola,; [16]Stanford University, Palo Alto, United States; [17]University of Liverpool, Liverpool, United Kingdom; [18]University of California Irvine, Irvine, United States; [19]Children's Minnesota, Saint Paul, United States; [20] UH Cleveland Medical Center, Cleveland, United States; [21] Hull and East Yorkshire Hospitals NHS Trust, Hull, United Kingdom; [22] Soleno Therapeutics, Inc., Redwood City, United States

Background
PWS is a rare neurodevelopmental genetic disorder characterized by hyperphagia, obesity, hormonal deficiencies, and problem behaviors for which there are no approved treatment. DCCR administration (100-525 mg/day) up to 52 weeks in participants with PWS improved hyperphagia, behavior, body composition and metabolic markers.
Objective
The objective of this study was to compare changes in hyperphagia (using Hyperphagia Questionnaire for Clinical Trials [HQ-CT]) and PWS-related behaviors (via PWS Profile Questionnaire [PWS-P]) between 114 participants enrolled in DCCR placebo-controlled, double-blind (C601, NCT03440814) and

open-label extension (C602, NCT03714373) studies (sponsored by Soleno Therapeutics) and a matched sub-cohort from PfPWS sponsored by Foundation for Prader Willi Research, NCT03718416) ($n=229$) who did not receive experimental treatment.
Methods
C601/C602 and PfPWS studies were conducted concurrently. The creation of the PfPWS sub-cohort was conducted prospectively by an independent group prior to receiving the results from either study. Participants from both groups had genetically confirmed PWS and their caregivers completed the HQ-CT and PWS-P questionnaires prior to enrollment. Availability of participant-level data in PfPWS allowed for the creation of a propensity matched control cohort ($n=195$) similar to the C601/C602 study population by applying the defined inclusion criteria (age, gender, baseline HQ-CT score, baseline weight, and data collection time points).
Results
Statistically significant reductions in HQ-CT score for C601/C602 compared to PfPWS sub-cohort at Week 26 were observed for propensity-adjusted [Difference (C601/C602 – PfPWS), Adjusted Least-Square means, SE (standard error), 2-sided 95% CI=-5.7 (-7.43, -3.95)] and non-propensity-adjusted analyses [Difference=-5.9 (-7.53, -4.34)] (all $P<0.001$), which were sustained at Week 52 [Difference (C601/C602 - PfPWS)=-5.5 (-7.39, -3.64) for propensity-adjusted;=-5.9 (-7.65, -4.23) for non-propensity-adjusted; (all $P<0.001$)]. The difference in HQ-CT score between the two cohorts was consistent across age, sex, baseline HQ-CT, PWS genotype, geographical subgroups and growth hormone use. Reduction of PWS-P scores for C601/C602 were statistically significant across all domains (aggression, anxiety, rigidity/irritability, compulsivity, depression, disordered thinking) in comparison to PfPWS sub-cohort ($P<$ 0.001 for all) at Week 26 and were maintained at Week 52 ($P<0.001$ to 0.03).
Conclusions
These data demonstrate that improvements in hyperphagia and other PWS-related behaviors achieved by 26 weeks and maintained through 52 weeks in subjects receiving DCCR were significantly greater than in matched controls from an untreated observational cohort, in line with previous results of C601/C602 studies. This further suggests that DCCR may be an effective treatment option for individuals with PWS.

Habit-intervention induces an amelioration of prediabetics cardiometabolic traits by lowering the miR-21/ROS/HNE damaging axis

Lucia La Sala[1,2], Elena Tagliabue[2], Simona Mrakic-Sposta[3], Pamela Senesi[1,4], Ileana Terruzzi[1,4], Livio Luzi[2,4] & Emilio Trabucchi[1]
[1]Multimedica, Milano, Italy; [2]IRCCS, Lab of Cardiovascular and Dysmetabolic Diseases, Italy; [3]National Research Council Research Area Milan, Milano, Italy; [4]University of Milan, Milano, Italy

The prevalence of prediabetes is increasing in the global population and its metabolic derangements may expose to a higher risk to develop type 2 diabetes (T2D) and its cardiovascular burden. Lifestyle modifications might have considerable benefits on ameliorating metabolic status. In light of this scenario, preventive programmes are focusing on the modification of lifestyle that notoriously decreases the incidence of T2D, to reduce the risk and delay T2D and its burden: Diabetes Prevention Program (DPP) recommended healthy habits (diet and physical activity), avoiding smoking, alcohol, and stress as hints to reduce the risk to develop T2D. Intensive lifestyle intervention was able to reduce the incidence of T2D by 58% over 3 years Alternative biomarkers, such as circulating miR-21, has been recently discovered associated with dysglycemia. Here we evaluated, in a longitudinal cohort of dysglycemic population the relation between the circulating miR-21/ROS/HNE levels and the habit-intervention (HI) after 1 year of follow-up.
Methods
1506 subjects from DIAPASON study were screened based on the Findrisc score. 531 subjects with Findrisc ≥ 9 were selected for dysglycemia (ADA criteria) and tested for circulating miR-21, ROS and HNE levels, as damaging-axis. 207 dysglycemic subjects were re-evaluated after a habit intervention (HI), 1-year later. Repeated measures tests were used to evaluate changes from baseline to 1-year of follow-up. Furthermore, linear regression and logistic regression models were implemented to evaluate the association between glycemic parameters and miR-21/ROS/HNE.
Results
We observed, after HI, a significant reduction of miR-21/ROS/HNE axis in dysglycemic subjects, concomitantly with ameliorating of metabolic parameters, including insulin resistance, BMI, microalbuminuria, reactive hyperemia index and skin fluorescence. Significant positive interaction was observed between miR-21 axis with glycaemic parameters after HI. Lower miR-21 levels after HI, strongly associated with a reduction of glycemic damaging-axis, in particular, within-subjects with values of 2hPG <200 mg/dL.
Conclusions
Our findings demonstrated that HI influenced the epigenetic changes related to miR-21 axis, and sustain the concept of reversibility from dysglycemia. These data support the usefulness of novel biological approaches for monitoring glycemia as well as provide a screening tool for preventive programmes.

Non-invasive quantification of pancreatic islet beta-cell function in people with type 1 diabetes mellitus

Shruti Joshi[1], Trisha Singh[1], Lucy Kershaw[1], Fraser Gibb[1,2], Marc R Dweck[1], Michelle Williams[1], Scott Semple[1,3], Shareen Forbes[1], Rebecca Reynolds[1] & David Newby[1]
[1]University of Edinburgh, Department of Cardiovascular Science, Edinburgh, United Kingdom; [2]NHS Lothian, Edinburgh Centre for Endocrinology, Edinburgh, United Kingdom; [3]University of Edinburgh, Edinburgh Imaging, Edinburgh, United Kingdom

Background and Aims
Type 1 diabetes mellitus (T1DM) is characterised by autoimmune destruction of pancreatic beta-cells resulting in insulin deficiency. Evaluation of novel therapies for T1DM requires reliable methods to measure beta-cell function, which is unattainable using traditional non-invasive imaging techniques. A new approach is manganese-enhanced magnetic resonance imaging (MEMRI). As a calcium analogue, manganese is taken up into pancreatic beta-cells during insulin secretion, serving as intracellular contrast. We conducted a proof-of-concept study to investigate whether MEMRI can be used as a measure of beta-cell function in people with T1DM.
Methods
In a prospective case-control study, 20 people with T1DM (age 52 [44-61] years, 6 female; 10 with very low [<50 pmol/l], and 10 with reduced [>50pmol/l] C-peptide concentrations) and 15 healthy volunteers (age 32 [23-36] years, 6 female) underwent MEMRI of the pancreas following a standardised oral glucose load (Fortisip Compact, 125 mL). MEMRI was performed using intravenous manganese dipyridoxyl diphosphate administered over 10 minutes. Pancreatic T1 mapping was performed prior to and every 2.5 min for 30 min after manganese infusion. Quantitative manganese uptake analysis was performed by measuring T1 relaxation times in regions of interest drawn within the pancreas and compared with the left ventricular blood pool. The rate of pancreatic manganese uptake was determined by Patlak modelling [1]. Scan-rescan reproducibility was performed in 10 participants at least 8 weeks apart.
Results
People with T1DM had impaired pancreatic manganese uptake (Ki) in those with reduced (median Ki 24 [interquartile range 21-25] ml/100 g of tissue/min) or very low (15 [8-16] ml/100 g of tissue/min) C-peptide concentrations compared to healthy volunteers (30 [27-34] ml/100 g of tissue/min; $p\leq 0.002$ for both). Compared to healthy volunteers, participants with T1DM had visibly lower pancreatic enhancement 30 min after manganese infusion, especially in those with very low C-peptide concentrations. Ki correlated with C-peptide levels in people with T1DM ($r=0.73$,$P=0.0002$) but not in healthy volunteers ($r=$-0.054, $P=0.88$). There were no correlations between Ki and age, body-mass index or glycated haemoglobin. We found strong intra-observer (0.98[0.96-0.99]) and inter-observer (0.84[0.51-0.95]) repeatability and scan-rescan reproducibility (0.73[0.23-0.92]) for Ki.
Conclsions
MEMRI can provide a non-invasive imaging technique to assess beta-cell function in people with T1DM. This has important implications for investigation of the pathophysiology of T1DM, monitoring disease progression and assessment of novel immunomodulatory interventions.

The COVID-19 in patients with diabetes mellitus in tashkent: a retrospective cohort study

Anna Alieva[1], Abdulaziz Djalilov[2], Feruza Khaydarova[1], Anvar Alimov[3], Dilovar Khalilova[1], Nasiba Alimova[1], Iroda Tajieva[1] & Vasila Talenova[1]

[1]Republican Specialized Scientific-and-Practical Medical Centre of Endocrinology, Tashkent, Uzbekistan; [2]Westminster International University in Tashkent, Uzbekistan; [3]Tashkent City Health Department, Uzbekistan

Background
Since the very first outbreak, scientists have been trying to determine the most critical pathogenetic mechanisms for the development of COVID-19 and related complications, analyze individual subpopulations of patients with chronic diseases and develop optimal tactics to combat not only the infection itself but also its acute and chronic complications.
Aim
to identify and analyze factors influencing the severity of the COVID-19 course among patients with Type 1 and Type 2 DM, including the glucose-lowering therapy effects.
Materials and Methods
A retrospective cohort study of 5023 Tashkent inhabitants, who had COVID-19 from April to December 2020, was performed. The data were obtained from the single electronic database of registered cases of COVID-19. All data were analyzed by univariate and multivariate logistic regression models using STATA 17.0 software. Further, the matched case-control study was performed for patients with type 2 DM and no DM based on age, gender, and BMI.
Results
Of the 5023 analyzed subjects, 72.63% had no diabetes mellitus (DM), 4.24% had type 1 DM, 15.19% had type 2 DM, and 7.94% was diagnosed with DM during the COVID-19 infection. DM, overweight, and obesity were associated with severe COVID-19; the most significant risk of a severe course was found in persons with type 2 DM. The risk of a lethal outcome and the need for prescription of glucocorticoids did not show a significant association with diabetes in Tashkent. The clinical features of COVID-19 were more common in patients with type 2 DM, especially for shortness of breath, chest pain, and arrhythmia. The persons receiving SU have complained of dyspnea significantly more often than matched patients without DM. Metformin and DPP4i were the groups of drugs that were not associated with significantly increased risk of hospitalization of patients because of COVID-19. The matched case-control study did not reveal statistically significant differences in the disease course severity, need for hospitalization and glucocorticoids, and death depending on the glucose-lowering therapy preceding the onset of COVID-19.
Conclusion
Diabetes, age and overweight/obesity were associated with severe course of COVID-19 in Tashkent. There was no statistical difference in COVID-19 severity depending on initial glucose-lowering therapy.

Adipocytokines profile in patients with Graves' orbitopathy and the effect of high-dose corticosteroids

Jan Schovanek[1], Michal Krupka[2], Lubica Cibickova[1] & David Karasek[1]
[1]Faculty of Medicine and Dentistry, Palacky University Olomouc and University Hospital Olomouc, Department of Internal Medicine III – Nephrology, Rheumatology and Endocrinology, Olomouc, Czech Republic; [2]Faculty of Medicine and Dentistry, Palacky University Olomouc and University Hospital Olomouc, Department of Immunology, Olomouc, Czech Republic

Graves' orbitopathy (GO) is a serious, progressive eye condition seen in patients with autoimmune thyroid disease. GO is characterized by inflammation and swelling of soft orbital tissues. Adipose tissue produces cytokine mediators called adipokines. The present study focuses on the relationship between serum levels of selected adipokines in patients with GO, comparing them with the control group, and uniquely describes the effect of high-dose systemic corticosteroids (HDSC) on their levels. For the purposes of this study, we collected blood samples before and after the treatment with HDSC from 60 GO patients and 34 control subjects and measured serum levels of adiponectin, AIF-1, A-FABP and FGF-21. Levels of adiponectin significantly differed among the three study groups (ANOVA $P = 0.03$). AIF-1 levels were also highly significantly different among the study groups (ANOVA $p < 0.0001$) with the highest value in GO patients after HDSC treatment, which was, however, not statistically different to the value in patients before HDSC treatment ($P = 0.82$). We did not observe any statistically significant difference in the levels of A-FABP or FGF-21 between controls and our patients, nor did HDSC treatment have an effect (ANOVA $P = 0.19$; $P = 0.11$). AIF-1 was in a multivariate analysis significantly associated with the presence/absence of GO after adjusting for clinical factors (age, sex, smoking and BMI) and level of TSH (Odds ratio 1.003, $p < 0.01$). No other adipokine showed this association. This finding could enforce targeting macrophages in treatment strategies for GO since AIF-1 is considered as a marker of their activation. This work was supported by the Ministry of Health of the Czech Republic – Conceptual development of research organization (FNOL, 00098892) and grant no. NU21J-01-00017.

Irisin in pediatric patients with Prader Willi Syndrome: the role of body composition and glucose metabolism

Stefania Mai[1], Danilo Fintini[2], Chiara Mele[3], Alessio Convertino[2], Sarah Bocchini[2], Graziano Grugni[4], Gianluca Aimaretti[3], Roberta Vietti[1], Massimo Scacchi[1,5], Antonino Crinò[2] & Paolo Marzullo[1,3]
[1]Istituto Auxologico Italiano IRCCS, Laboratory of Metabolic Research, San Giuseppe Hospital, Verbania, Italy; [2]Bambino Gesù Children's Hospital, Reference Center for Prader Willi Syndrome, Rome, Italy; [3]University of Piemonte Orientale, Division of Endocrinology, Department of Translational Medicine, Novara, Italy; [4]Istituto Auxologico Italiano IRCCS, Division of Auxology, San Giuseppe Hospital, Verbania, Italy; [5]University of Milan, Department of Clinical Sciences and Community Health, Milan, Italy

Irisin is a myokine involved in the browning of white adipose tissue and in the regulation of energy expenditure, glucose tolerance and insulin sensitivity. It was previously demonstrated that obese adults with Prader-Willi syndrome (PWS) harbor lower irisin levels than individuals with common obesity. Significant associations seem to relate irisin to muscle mass, REE, insulin resistance and triglycerides and also the strongest independent predictors of irisin levels were PWS status, %FM and triglycerides (Mai S et al., 2020). The divergent models of obesity herein studied suggest a potential link between circulating irisin and muscle mass and metabolic dysfunction relating to adiposity. Scanty and debated information exists on the role played by irisin in obese children. In this context, the obese phenotype of children with PWS markedly differs from that of BMI-matched subjects with common obesity. Based on these considerations, the present study aimed at exploring circulating irisin in relation to body composition and metabolic profile in obese children with and without PWS. For this purpose, 25 PWS children and adolescents (15 DEL15/10 UPD15, 16 M/9 F; age 6.6-17.8y; BMI SDs 2.5 ± 0.3) and 25 age, and BMI-matched control subjects (11 M/14 F; age 6.8-18.0y; BMI SDs, 2.8 ± 0.1) underwent analysis of irisin levels, body composition and metabolic profile, in particular glucose homeostasis assessed by OGTT. Expected differences in body composition and metabolic profile existed between study groups. PWS displayed lower FFM ($P < 0.05$), as well as lower fasting insulin level ($P < 0.0001$), 2h post-OGTT insulin ($P < 0.05$) and C-peptide levels ($P < 0.0001$), together with better insulin resistance, expressed as HOMA-IR ($P < 0.0001$). Irisin levels were significantly lower in PWS group than in controls with common obesity ($P < 0.05$): more specifically, irisin levels of PWS patients with DEL15 were reduced compared to controls with common obesity ($P < 0.05$). Exploring the relation between irisin and glucose metabolism in obesity, univariate correlation analysis in our obese population as a whole showed positive associations between irisin, insulin $OGTT_0$ ($P < 0.05$), insulin $OGTT_{120}$ ($P < 0.005$), HOMA-IR ($P < 0.05$) and C-peptide ($P < 0.05$). In stepwise multivariable regression analysis on merged data, irisin levels were independently predicted by insulin $OGTT_{120}$. Overall, current results show that irisin levels are lower in obese PWS compared to matched children, possibly due to differences in body composition and insulin resistance. A strong association links irisin to measures of insulin resistance, particularly post-OGTT insulin levels, suggesting a link between this myokine and insulin sensitivity in our two divergent models of obesity.

Menstrual cycle abnormalities as distinctive sign of type 1 diabetes mellitus: results from a meta-analysis

Rossella Corleto[1,2], Carla Greco[1,2], Marta Cacciani[1,2], Giorgia Spaggiari[2], Manuela Simoni[1,2] & Daniele Santi[1,2]
[1]Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy., Modena, Italy; [2]Unit of Endocrinology, Department of Medical Specialties, Azienda Ospedaliero-Universitaria di Modena, Ospedale Civile di Baggiovara, Modena, Italy., Modena, Italy

Background
Type 1 diabetes mellitus (T1DM) management profoundly changed across years, with increasing emphasis on stringent glycaemic control. While it is well demonstrated that the progressive improvement of glycaemic control allows a tighter command of diabetes-related complications, the positive implications thereof on reproductive functions are still unclear. Indeed, it is well known that oligomenorrhea and amenorrhea are more frequently detected in young women with T1DM compared to healthy age-matched controls. However, whether the menstrual abnormalities incidence changed across years is still matter of debate.
Aim of the study
To evaluate the menstrual cycle abnormalities rate in T1DM young women, compared to healthy subjects, and to search for potential T1DM-related factors influencing female reproductive system. Secondary aim was the evaluation of the possible effects of the change in T1DM management, occurred in the late 90's, on menstrual cycle dysfunction.
Methods
A meta-analysis was performed considering all clinical trials in which menstrual cycle abnormalities in T1DM young women were reported, compared to healthy age-matched subjects. Primary endpoint was the rate of oligomenorrhea/amenorrhea and secondary objective was age at menarche. Sensitivity analysis was conducted dividing studies into two groups, i.e. before and after 2000, according to the change in T1DM management. Three meta-regression analyses were performed, considering the influence of diabetes duration, body mass index (BMI) and glycated haemoglobin (HbA1c) serum levels on menstrual irregularities.
Results
From 623 papers initially identified, 12 studies were finally included. Menstrual cycle dysfunction rate was significantly higher in T1DM women compared to controls, also considering only studies published after 2000 (OR:2.08; 95%CI: 1.43,3.03, $P<0.001$). Age at menarche was significantly higher in T1DM women compared to controls ($P<0.001$) also when studies published after 2000 were evaluated separately (mean difference:0.53; 95%CI: 0.32,0.74 years, $P<0.001$). In meta-regression analyses, the menstrual abnormalities rate in T1DM women were inversely related to diabetes duration ($R^2=0.396$,$P=0.023$), but not to BMI ($R^2=0.134$,$P=0.373$) and HbA1c serum levels ($R^2=0.083$,$P=0.409$).
Conclusion
The meta-analytic approach confirmed the high incidence of menstrual cycle dysfunction in T1DM young women. The improvement in T1DM management, introduced after 2000, seems not able to influence this rate, leaving menstrual cycle abnormalities one of the distinctive signs of this chronic condition. Indeed, T1DM-related menstrual dysfunction is associated neither to anthropometrical variables, nor glycemic control. Although actual pathogenetic mechanisms are not fully understood, here we demonstrate a potential association with T1DM duration, suggesting that the process of disease acceptance could underlie these irregularities.

DOI: 10.1530/endoabs.81.P83

Vitamin D supplementation lowers the serum levels of branched chain amino acids in a cohort of patients with type two diabetes mellitus

Mahmoud A. Alfaqih[1], Samir Al Bashir[2] & Nebras Melhem[1]
[1]Jordan University of Science and Technology, Physiology and Biochemistry, Irbid, Jordan; [2]Jordan University of Science and Technology, Pathology and Microbiology, Irbid, Jordan

Background
Type two Diabetes Mellitus (T2DM) is a rapidly growing crisis. Data from several T2DM cohorts demonstrate that elevated levels of serum branched chain amino acids (BCAAs) increase the risk of the disease. BCAAs levels correlate with parameters that reflect glycemic control. Elevated levels of BCAAs in T2DM is associated with a higher risk of complications. Vitamin D plays an important role in regulating insulin action on target tissues. Normalization of serum vitamin D levels in T2DM patients with vitamin D deficiency was shown to improve their glycemic control.
Aim
To determine whether the positive effect of vitamin D on insulin sensitivity in T2DM could be partially mediated through the ability of vitamin D to reduce BCAAs.
Methods
A case-control design was used followed by a therapeutic intervention cohort for 3 months. In the case control part, 231 subjects were recruited, 137 subjects had a confirmed diagnosis with T2DM and 93 subjects were disease free. Patients were frequency matched with the controls by age and body mass index. The serum levels of 25(OH) vitamin D, glucose, total cholesterol, triglycerides, and BCAAs were measured from the serum samples of all subjects while HbA1c levels were measured from whole blood samples. Of the 137 subjects with T2DM, 26 subjects had 25(OH) vitamin D deficiency. These patients were recruited to a therapeutic intervention where they received 50,000 IU of vitamin D_3 tablets weekly for 3 months while maintaining standard treatment of care. Following the intervention; 25(OH) vitamin D, glucose, HbA1c, total cholesterol, triglycerides and BCAAs were measured.
Results
T2DM subjects had significantly higher levels of glucose, HbA1c, triglycerides and BCAAs ($P<0.05$) but significantly lower levels of 25(OH) vitamin D. Serum levels of BCAAs negatively correlated with serum 25(OH) vitamin D ($P=0.043$, $r=-0.173$). In the intervention cohort, vitamin D supplementation significantly lowered the serum levels of glucose, triglycerides, BCAAs ($P<0.05$) and the whole blood levels of HbA1c ($P<0.05$) compared to baseline levels measured a day prior to the intervention.
Conclusion
Normalization of 25(OH) vitamin D using clinically approved supplementation protocols significantly reduces circulating levels of BCAAs in T2DM patients; an effect that may reduce T2DM patient risk of future complications.

Ramadan fasting without the doctor's consent: which patient, and what impact? Results of a prospective study

Ali Halouache[1], Errahali Yassine[1], Chakdoufi Sanae[1,1], Isouani Jad[1] & Guerboub Anas[1]
[1]Hopital Militaire d'Instruction Mohammed V, Endocrinology and Metabolic Diseases, Rabat, Morocco

Background and aims
The objective of our study is to evaluate the respect of Muslim diabetics for the contraindication of fasting and the control metabolic impact of fasting during the month of Ramadan.
Materials and methods
This analytical cross-sectional study was conducted during the period from Mars to June of the year 2021, within the department of endocrinology and metabolic diseases of the Military Hospital of Instruction Mohamed V of Rabat.
Results
Among the 89 patients included in our study, 54 (60%) fasted against their physician's advice, among whom 77.77% had a low level of education (versus 71.4%) ($P=0.498$), the age of diabetes ($P=0,004$), the presence of degenerative complications($P<0,001$), and the degree of glycemic control($P=0,018$) were the main predictors of fasting against medical advice. The mean HbA1C level in the patients who decided to fast was 7.77+/-1.6% before Ramadan and 7.79+/-1.56% after Ramadan, while that in the non-fasting group was 8.84+/-2.34% before Ramadan and 8.58+/- 1.89% after Ramadan. Hypoglycemia concerned 37% of the patients who fasted(versus 0%) ($P<0.001$).
Discussion
Of the 89 patients who were not allowed to fast, more than half(60%) fasted during the month of Ramadan. This result is similar to that of the study by Meriem Bencharif and al, in which 58.5% of patients with type 2 diabetes fasted during the holy month, The EPIDIAR study, found that among type 2 diabetics, 78.7% fasted for more than 15 days of the holy month. In our study, patients with long-standing diabetes tend to comply with their doctor's instructions; this can be explained by the improvement of the knowledge of diabetics regarding their disease with time as proved by the study of C. Bel Hadj Sliman and al . The presence of degenerative complications, and the glycated hemoglobin level, also influence, the attitude of diabetic patients during the month of Ramadan ($P<0.001$). The EPIDIAR study showed a significant increase in hypoglycemic events during Ramadan in diabetic patients, the same finding was noted in our study, Nevertheless, no change in the incidence of hypoglycemia was found in diabetic who fasted and were well controlled at baseline in several studies
Conclusion
Our study proves that a large Muslim diabetic population does not respect the doctor's instructions when it comes to fasting during Ramadan

Effect of an extract of the Andean plant Lampaya on insulin signaling and proinflammatory markers in human adipocytes treated with palmitic acid

Paulina Ormazabal[1,2], Gabriela Yuri[1,2], Isidora Villagran[1], Alexis Cerda[2], Mariana Cifuentes[2], Adrian Paredes[3] & Glauco Morales[3]
[1]Institute of Health Sciences, Universidad de O'Higgins, Rancagua, Chile; [2]Laboratory of Obesity and Metabolism in Geriatrics and Adults (OMEGA), Institute of Nutrition and Food Technology (INTA), Universidad de Chile, Santiago, Chile; [3]Laboratorio de Química Biológica, Instituto Antofagasta (IA) and Departamento de Química, Facultad de Ciencias Básicas, Universidad de Antofagasta, Antofagasta, Chile

Background
Obesity is strongly associated with a state of chronic low grade systemic inflammation and insulin resistance (IR). IR at the molecular level may be defined as a diminished activation of the metabolic phosphatidylinositol-3-kinase (PI3K) /Akt pathway of insulin. On the other hand, inflammatory response may be activated by NF-κB. Subject with obesity have elevated plasma levels of saturated fatty acids, such as palmitic acid (PA), which triggers insulin and inflammatory signaling disruption *in vivo* and *in vitro*. Additionally, protein phosphorylation is an important regulatory mechanism to activate intracellular signaling. The protein tyrosine phosphatase 1B (PTP1B) is well known to regulate PI3K/Akt route and NF-κB inflammatory signaling. Infusions of *Lampaya medicinalis* Phil. (*Verbenaceae*) are used in folk medicine of Northern Chile to counteract inflammatory diseases. Hydroethanolic extracts of lampaya (HEL) contain considerable amounts of flavonoids that may explain the biological activity of the plant. The aim of this study was to assess whether HEL exposure protects against PA- induced inflammation and disruption of PI3K/Akt signaling in human adipose cells.
Methods
Cytotoxicity of a range of HEL concentrations (0.01– 10 μg/ml) was evaluated by MTS assay in *in vitro* differentiated adipocytes from the adipose cell line SW872. Adipocytes were incubated or not with PA for 24 h in the presence or not of HEL (2-h preincubation), and thereafter stimulated with insulin or vehicle. Thereby, experimental conditions were: control (untreated cells), 0.4 mM PA, 0.01 μg/ml of HEL, 0.01 μg/ml of HEL (2 h before) + 0.4 mM PA for 24 h, in insulin-stimulated (100 nM, 10 min) or basal conditions. Phosphorylation of Tyr-IRS-1, Ser-Akt, Ser-NF-κB and protein expression of PTP1B were evaluated by Western blot.
Results
In SW872 adipocytes, HEL was not cytotoxic at any concentration assessed. Insulin-stimulated phosphorylation of IRS-1 and Akt as well as phosphorylation of NF-κB and PTP1B protein content were not affected by treatment with 0.01 μg/ml HEL compared with vehicle-treated cells. PA-treated adipocytes showed a reduction in insulin-stimulated phosphorylation of IRS-1 and Akt compared to control ($P<0.05$), while the phosphorylation of NF-κB and PTP1B protein expression were elevated compared to untreated cells ($P<0.05$). Interestingly, these effects were prevented by HEL treatment.
Conclusion
These findings give new insights about the effect of HEL ameliorating PA-impaired insulin signaling and inflammatory markers in adipocytes. More studies should focus on lampaya, since might represent a preventive approach in individuals whose circulating PA levels contribute to inflammation and IR.

COVID-19 and Steroids- How well are we monitoring blood glucose levels?

Aye Me-Me-Ko, Ashutosh Kapoor, Fatima Riaz, Stuart Wightman & Prasanna Rao-Balakrishna
Manchester University NHS FT, Manchester, United Kingdom

Background
The Covid-19 pandemic has led to various unprecedented challenges and obstacles, especially in the field of Diabetes and Metabolism, many of which are as novel as the pandemic itself. Discovering efficacious therapeutic options resulting in positive outcomes has been a challenge. Dexamethasone has been shown to reduce mortality in patients with Covid-19 pneumonitis who require oxygen therapy and/or ventilation. Exogenous steroid therapy is renowned to cause adverse metabolic side effects, including Hyperglycemia. In addition to this, concurrent Covid-19 infection further exacerbates the issue at hand.
Aims
The main aim of the Quality Improvement Project (QIP) was to improve adherence and compliance of capillary blood glucose (CBG) monitoring in patients with Covid-19 pneumonitis treated with steroid therapy by implementation of educational tools. Our results were compared with the standard of care guidance as set out by the Joint British Diabetes Societies (JBDS) Specific emphasis was placed upon early recognition of Hyperglycaemia, leading to improved Glycaemic control and patient outcomes.
Methods
Phase one of the project involved data collection on a retrospective basis of patients admitted to both the medical and COVID wards. This involved obtaining relevant information from the patient's medical, nursing, and electronic notes. Changes were implemented in the form of teaching and educational sessions for the nursing staff. Posters focusing on the important of Blood Glucose monitoring were circulated on the medical wards including the COVID wards. This was followed by discussions emphasising the importance of Blood Glucose monitoring on the board rounds.
Results
Data collection prior to changes showed that out of the cohort of 23 patients, only 5 patients (21.74 %) met the desired standard of care as per the guidance set out by the JBDS**.** Following implementation of changes, data collection revealed an improvement of compliance from 21.74 % to 56.52 %. Out of 23 patients, the desired level of care was now met in 10 of the patients. The project was carried out over a period of 3 months, commencing in October 2020, and concluded in January 2021
Conclsions
Hyperglycaemia was associated with worse outcomes. Our QIP improved rates of blood glucose monitoring, followed by early recognition of hyperglycaemic states. This was also reflected in the fact that early recognition led to early therapeutic measures and prevention of diabetic emergencies. Despite significant changes, we aim to instigate further improvement by reinforcing learning among the frontline staff to achieve 100% compliance with the guidelines.

Sodium glucose cotransporter 2 inhibitors treatment in acromegalic patients with diabetes

Adnan Zaina[1], Yuval Grober[2], Ali Abid[3], Eldad Arad[4], Elena Golden[4] & Samih Badarny[5]
[1]Bar-Ilan University, Azrieli Faculty of Medicine, Division of Endocrinology and Metabolism, Zvulon Medical Center, Clalit Medical Health Care Services, Safed, Israel; [2]Bar-Ilan University, Azrieli Faculty of Medicine, Division of Neurosurgery, Galilee Medical Center, Nahariya, Safed, Israel; [3]Clalit Health Services, Division of Endocrinology and Metabolism, Zvulon Medical Center, Clalit Medical Health Care Services, Israel; [4]Clalit Health Services, Division of Endocrinology and Metabolism, Zvulon Medical Center, Israel; [5]Bar-Ilan University, Azrieli Faculty of Medicine, Department of Neurology, Galilee Medical Center., Safed, Israel

Introduction
Acromegaly is a chronic disease generally caused by a GH-secreting pituitary adenoma. GH excess causes insulin resistance and impair β cell function, predisposing patients with acromegaly to develop DM. Treatment of diabetes has been revolutionized since the introduction of sodium-glucose cotransporter inhibitors (SGLT2i). This novel class is widely used in type 2 diabetes mellitus (T2DM) and recently was approved for patients with heart failure with reduced ejection fraction and patients with chronic kidney disease (CKD) without diabetes. Taking into consideration the cardiorenal protection aspects, SGLT2i seems to be also attractive for diabetes management in acromegalic patients with already known increased cardiovascular risk. However, despite the known favorable aspects, SGLT2i is less recommended for acromegalic patients with diabetes due to the increased risk of diabetic ketoacidosis (DKA).
This study aims
To report data regarding the use of SGLT2i in patients with acromegaly and diabetes.
Methods
In the present case series, data was collected using an electronic computerized registry at Clalit Medical Health (CMH) Services from Western Galilee and Haifa district between the years 2000-2020. Charts of patients with acromegaly and diabetes were reviewed thoroughly for current and previous anti-diabetic and acromegaly medications. Notably, electronic computerized files enable health care practitioners to follow the monthly treatment dispensing and report drug side effects. Laboratory results for fasting plasm glucose (FPG), hemoglobin A1c, IGF-1, and GH were reported before SGLT2i administration. In addition, actual hemoglobin A1c, body mass index (BMI), duration of diabetes, tumor size was reported for patients with and without SGLT2i treatment.
Results
34 acromegalic patients with diabetes were identified. Treatment with SGLT-2i was documented in nine patients, out of them 5 females and 4 males with a mean

age (SD) of 61 ± 12 yr. The mean (SD) duration of treatment with SGLT2i was 27.5 ± 7.3 months. Mean HbA1c before and after SGLT-2i initiation was 8.1 ± 1.1% and 7.0 ± 0.9% respectively. Mean IGF-1 level (SD) before SGLT-2i initiation was 177 ± 68 ng/ml and the mean GH level (SD) was 0.7 ± 0.5 µg/l. All nine patients are still under treatment with SGLT2i and none of them had reported any adverse reaction related to SGLT2i.

Conclsions

This study provides us for the first time with new data regarding the use of SGLT2i among acromegalic patients with diabetes. The use of SGLT2i among patients with already treated acromegaly and diabetes seems to be attractive.

Predictors of persistant abnormal glucose tolerance in post partum in women with gestational diabetes mellitus

Rahma Khalaf, Yosra Htira, Zohra Hadj Ali, Chaima Jemai, Imen Hedfi & Faika Ben Mami

National Institute of Nutrition, Department C, Tunisia

Background and aim

To determine clinical and metabolic predictors of persistant abnormal glucose tolerance in post partum after gestational diabetes mellitus (GDM).

Methods

This was a prospective study including 150 patients with GDM who underwent 75 g oral glucose tolerance test (OGTT) at 4-12 weeks after delivery.

Resulats

The prevalence of abnormal glucose tolerance in post partum after GDM was 32,8 %, inclusive of 3.3% type 2 diabetes and 29.5% pre-diabetes. After univariate analysis, persistent carbohydrate tolerance disorders in post partum were statistically associated with age (34,77 ± 4,02 vs 32,07 ± 6,29 years ;p = 0.015) and AB blood group (10.3% vs 0% ;p = 0.012). Family history of type 2 diabetes in a first degree relative, personal history of GDM, fetal macrosomia, pre-gestational Body Mass Index and parity did not statiscally differ between the two groups. Thirty minutes of moderate physical activity five times per week was a protective factor ($P = 0.004$) while sedentary lifestyle was associated with impaired carbohydrate tolerance in post partum ($P = 0.004$). Fasting blood glucose, glycemia at 2 hour in 75 g oral glucose tolerance test (OGTT) > 1.6 g/l and insulin use according to a full basal bolus regimen were significantly associated with the persistence of carbohydrate tolerance disorders (respectively $P = 0.005$, $P = 0.02$, $P = 0.03$). After multivariate analysis, the independent factor associated with abnormal glucose tolerance in post partum was glycemia at 2 hour (OGTT) (OR 5.18, 95% CI 1.27- 21.16, $P = 0.02$).

Conclsion

Antenatal caracteristics may predict abnormal glucose tolerance in post partum after GDM. High prevalence of persistent carbohydrate tolerance disorders highlights the importance of ongoing screening for all women with previous GDM in order to delay the onset of type 2 diabetes in this high risk population.

Evening chronotype is associated with hormonal and metabolic disorders in Polycystic Ovary Syndrome

Ludovica Verde[1], Luigi Barrea[2], Claudia Vetrani[1], Annamaria Docimo[1], Giulia De Alteriis[1], Silvia Savastano[1], Annamaria Colao[1] & Giovanna Muscogiuri[1]

[1]Federico II University, Department of Clinical Medicine and Surgery, Endocrinology Unit, Naples, Italy; [2]Pegaso Telematic University, Department of Humanities, Naples, Italy

Objective

Polycystic ovary syndrome (PCOS) is the most common female endocrine disorder. Recently in the context of obesity, which often coexists with PCOS, it has been highlighted the role of chronotype as risk factor for obesity-related cardiometabolic complications. Given the importance of chronotype categories in the context of metabolic diseases and being PCOS characterized by metabolic derangements, we aimed to investigate the prevalence of chronotype categories in women with PCOS compared to healthy controls and their role in determining hormonal and metabolic aspects of PCOS.

Design and methods

In this case-control study, we investigated the chronotype categories in 112 women with PCOS and in 112 age and Body Mass Index (BMI) matched healthy women. Anthropometric (weight, height, BMI, and waist circumference), clinical [Ferriman-Gallwey (FG) score], biochemical [fasting plasma glucose (FPG), insulin levels and Homeostasis Model Assessment (HoMA-IR)], inflammatory [C-reactive Protein (CRP)] and hormonal (testosterone levels) parameters were assessed.

Results

Women with PCOS had a lower chronotype score ($P < 0.001$) and thus a higher prevalence of evening chronotype category ($P = 0.037$) than controls. Women with PCOS and evening chronotype had significantly higher levels of FPG, insulin levels and therefore HoMA-IR, CRP, testosterone levels and FG score than women with PCOS with neither and morning chronotype. After adjusting for BMI, chronotype score showed significant negative correlations with CPR, testosterone levels and FG score. Linear regression analysis showed that high testosterone levels were among the factors most associated with a lower chronotype score ($P < 0.001$), followed by BMI ($P < 0.001$) and HoMA-IR ($P < 0.05$).

Conclsions

In summary, the current study reports the first evidence that women with PCOS had a higher prevalence of evening chronotype than women without PCOS. In women with PCOS evening chronotype has been associated with a worse hormonal and metabolic profile. Thus, given the importance of chronotype in women with PCOS emerging in our study, the assessment of chronotype should be included in the clinic evaluation of women with PCOS Moreover, a chronotype-driven lifestyle approach could potentially improve the treatment of women with PCOS thus increasing the number of women with PCOS achieving their therapeutical goals.

PCSK-9 inhibitors and the reduction of serum lipoprotein (a) levels: experience of the reference center

Dunja Leskovar, Drazen Perica, Nediljko Sucur, Ana Godan Hauptman & Ivan Pečin

University Hospital Centre Zagreb, Divison for Metabolic Diseases, Zagreb, Croatia

Introduction

PCSK-9 (proprotein convertase subtilisin/kexin type 9) inhibitors are monoclonal antibodies that affect metabolism of low-density lipoprotein (LDL) by binding to the LDL receptor and promoting lysosomal degradation. There are two pcsk-9 inhibitors currently available: alirocumab (Praulent) and evolocumab (Repatha) which are administered subcutaneously every 14 days. Two large randomized studies (FOURIER, ODYSSEY) have shown that pcsk-9 inhibitors reduce LDL-cholesterol levels by 50-60% and additionally lipoprotein (a) levels by 25-30%. Such results broadened the indications for the usage of pcsk-9 inhibitors. Since serum levels of lp (a) is exclusively genetically determined, the possibility of its reduction is very important as high serum lp(a) levels increase cardiovascular risk by up to three-fold. Lowering of lp(a) levels is especially important for younger patients with cardiovascular incident in history Although the mechanism how pcsk-9 inhibitors reduce lp (a) levels is unclear, some studies show that at lower LDL-cholesterol levels, lp (a) levels decrease more with the assumption of better competence for LDL-receptor site.

Methods and results

Polyclinic of Reference Center for Rare and Metabolic Diseases has a total of 51 patients on PCSK-9 inhibitor therapy which was indicated due to elevated lp (a) concentration (> 75 nmol/l, > 0.5 g/l). The average age of patients is 52.74 years with almost equal distribution of male and female gender (53%, 47%). The overall percentage in reduction of lp(a) levels during 3 months of PCSK-9 inhibitor therapy was 30.78%, with a maximum reduction of 72% and a minimum of 5%. T-test of paired samples for the effect of pcsk-9 inhibitors on the reduction of lp(a) concentration revealed a statistically significant difference ($t = 5{,}2015$; $P = 0.00000156$, < 0.0001) at serum lp(a) concentrations before (M = 127.05, SD = 133.93) and after pcsk-9 inhibitor therapy (M = 82.29, SD = 81.06). The strength of the test is 0.982. The maximum observed reduction of 72% was observed in a patient who was previously on the statin therapy at the maximum dosage.

Conclusion

The experience of our Center confirms previous research on the effect of pcsk-9 inhibitors on the reduction of lp (a) concentration by 30%. Comparing targeted concomitant therapy, we have observed a trend of greater reduction in lp (a) levels with pcsk-9 inhibitor therapy in patients who are previously on the maximum

statin dose, suggesting possible metabolism of the particle itself via the LDL receptor by the mechanism of competition.

Transforming growth factor beta 1: a new factor reducing hepatic sex hormone binding globulin production during liver fibrosis development

Laura Briansó Llort[1], Lidia Fuertes Rioja[1], Lorena Ramos Perez[1], Maria Teresa Salcedo Allende[2], Cristina Hernandez[1], Rafael Simo Canonge[1] & David Martinez[1]
[1]VHIR - Vall d'Hebron Institut de Recerca, Diabetes and Metabolism, Barcelona, Spain; [2]Hospital Universitari Vall d'Hebron, Pathology, Barcelona, Spain

Low plasma sex hormone-binding globulin (SHBG) levels are present in fatty liver disease, which represent a spectrum of diseases ranging from hepatocellular steatosis through steatohepatitis to fibrosis and irreversible cirrhosis. We have previously determined that fat accumulation reduces SHBG production in different non-alcoholic fatty liver disease (NAFLD) mouse models and that SHBG plays an active role in the development of this disease. In the present work, we are interested in elucidating the molecular mechanisms reducing SHBG plasma levels in liver fibrosis development. To do so, *in vivo* studies were performed using the human *SHBG*transgenic mice developing liver fibrosis induced by carbon tetrachloride (CCl_4). Our results showed that CCl_4 induced liver fibrosis and decreased SHBG production by reducing hepatocyte nuclear factor 4 alpha (HNF-4α). The SHBG reduction could be influenced by the increase in TGF-β1 levels, which were elevated in mice developing liver fibrosis. Results obtained in human *SHBG* transgenic mice showed that TGF-β1 reduced significantly SHBG mRNA and protein levels through TGF-β1 receptor I via STAT3 signaling pathway, resulting in a transcriptional repression of the *SHBG* gene. Overall, TGF-β1 is a new factor downregulating hepatic SHBG production in liver fibrosis development.

Determination of serum and cord blood vitamin D status in women in twin pregnancies using liquid chromatography-tandem mass spectrometry – a preliminary results

Magdalena Zgliczynska[1], Iwona Szymusik[2], Konrad Kowalski[3], Magdalena Ostrowska[4] & Katarzyna Kosinska-Kaczynska[1]
[1]The Center of Postgraduate Medical Education, Second Department of Obstetrics and Gynecology, Warsaw, Poland; [2]Medical University of Warsaw, First Department of Obstetrics and Gynecology, Warsaw, Poland; [3]Masdiag Sp. z o.o. Company, Warsaw, Poland; [4]The Center of Postgraduate Medical Education, Department of Endocrinology, Warsaw, Poland

Objective
Vitamin D has a pleiotropic effect on the human body. Besides its classical function as a regulator of calcium and phosphorus metabolism, it influences the secretion of other hormones, modulates the immune response and regulates cell proliferation and differentiation. Because women in twin pregnancies have higher metabolic needs, it can be expected that they might have higher risk of vitamin D deficiency.
Aim of the study and method
The aim is to analyze the serum and cord blood concentrations of vitamin D metabolites in women in twin pregnancies with the use of liquid chromatography-tandem mass spectrometry (LC-MS). Until the submission of this abstract (January 2022) 15 maternal and 30 cord blood samples were tested. We have collected data on supplementation and dietary intake questionnaires.
Results
The mean maternal age was 34.1 years (±3.5). The delivery took place at an average 34.8 week of pregnancy (±3.3). All patients supplemented vitamin D in doses ranging from 200-4000 international units per day. The median concentration of total 25-hydroxyvitamin D (25(OH)D) in maternal serum was 43.9 ng/ml (interquartile range [IQR] 42.0-54.1). Its deficiency was found in one patient. Elevated vitamin D levels were found in 36.4% of the mothers (maximum 73.6 ng/ml). The median concentration of 25(OH)D in cord blood was 25.2 ng/ml (IQR 20.1-28.8). Maternal and cord blood levels were highly correlated ($r=0.58$). However, in each case, 25(OH)D level in the cord blood was lower than in the serum of corresponding mother (difference ranging from 7.1-48.2 ng/ml). In each pair of twins cord blood 25(OH)D concentrations were similar (differences: minimum 0.2, maximum 5.8, mean 2.2 ng/ml). In the described group, 25(OH)D levels in mothers were also determined by the commonly used in clinical practice chemiluminescent immunoassay (CLIA). The 25(OH)D levels obtained using the LC-MS method were significantly higher (median 43.9 ng/ml, IQR 42.0-54.1), than in case of CLIA (median 31.3 ng/ml, IQR 23.4-40.2;$P=0.003$). The differences in individual patients ranged from 5.4 ng/ml up to 36.7 ng/ml. These finding seem particularly important in terms of clinical decision making.
Conclusions
In the studied group of women in twin gestation that supplemented vitamin D, low prevalence of its deficiency determined by LC-MS was found. Maternal and cord blood levels of 25(OH)D were highly correlated. There are large discrepancies in the 25(OH)D concentrations obtained with LC-MS compared to CLIA in maternal samples.

The prevalence of non alcoholic fatty liver disease among diabetic patients attending the diabetic clinic in a tertiary care institute in colombo

Ishara Ranathunga, J P Naveenkumar, T G Athukorala, Manilka Sumanatilleke & Noel Somasundaram
NHSL, Colombo, Sri Lanka

Background and Objectives
Non-alcoholic fatty liver disease (NAFLD) is the presence of hepatic steatosis in the absence of other causes for secondary hepatic fat accumulation. The incidence and the prevalence of the NAFLD has risen exponentially in the recent past especially in the patients with diabetes. We have studied the prevalence of NAFLD in patients with diabetes attending the diabetes clinic based on the biochemical and ultrasonic criteria, the risk factors for disease development and associated comorbidities.
Methods
A descriptive cross sectional study was conducted from August 2020 to March 2021 at the Diabetes Unit of the National Hospital of Sri Lanka. Systematic sampling was done recruiting participants who are attending the diabetic clinic for annual end organ screening. After obtaining informed written consent, the data was collected using an interviewer administered questionnaire. The diagnosis of NAFLD is made according to the NHANES III criteria and the USS criteria. Categorical and numerical variables were analyzed using Chi-square and independent sample t-tests respectively. Multiple linear regression was used to determine the predictors of NAFLD diagnosis.
Results
The study enrolled hundred and one patients. The mean age was 58.3 years (range 23-80) and 69.3% were females. The mean weight was 65.7 (SD=12.5) kg and BMI was 26.8 (SD=4.7) kg/m^{-2} . The prevalence of NAFLD according to the biochemical and/or USS criteria was 72.3% ($n=73$). Out of that 34.7% met both biochemical and USS criteria. Furthermore, 7.9% ($n=8$) met only the biochemical criteria while 29.7% ($n=30$) met only the USS criteria. More females were diagnosed with NAFLD compared to males ($P=0.009$). Pioglitazone use was protective against the development of NAFLD ($P=0.000$). The younger age ($P=0.021$), higher HbA1c ($P=0.033$), higher Body mass index (BMI) ($P=0.014$) are other statistically significant factors contributing to the development of NAFLD. Multiple linear regression model identified BMI ($P=0.002$), pioglitazone use ($P=0.002$), gender ($P=0.000$) as predictors of diagnosis of NAFLD.
Conclsions
The prevalence of NAFLD is higher in the diabetes patients when compared to the general population. The use of biochemical criteria only identifies a proportion of patients with NAFLD. Early diagnosis with suitable tests will allow early intervention and prevention of long term deleterious complications. Optimization of modifiable factors such as high HbA1c, BMI is paramount in the prevention of the disease development. Further large scale studies including community studies are needed to recognize the current prevalence of NAFLD in the general as well as diabetic populations.

Perceived stigma in type 2 diabetes patients

Mehrez Achwak[1], Najoua Lassoued[2], Selma Mohsen[2], Khalil Chedly[3], Marwa Majdoub[4], Fedya Boubaker[4], Baha Zantour[4], Wafa Alaya[5] & Habib Sfar[6]
[1]Taher Sfar University Hospital, Endocrinology Department, Moknine, Tunisia; [2]Taher Sfar University Hospital, Endocrinology Department, Mahdia, Tunisia; [3]Taher Sfar University Hospital, Endocrinology Department, Mahdia, Tunisia; [4]Taher Sfar University Hospital, Endocrinology Department; [5]Taher Sfar University Hospital, Endocrinology Department, Moknine, Tunisia; [4]Taher Sfar University Hospital, Endocrinology Department, Tunisia

Introduction

Diabetes stigma (DS) refers to the experience of negative feelings such as exclusion, blame, rejection, or judgment due to having a chronic disease. The objective of this work was to measure the DS and its clinical determinants in type 2 diabetic patients.

Patients and methods

Cross-sectional study conducted on 84 type 2 diabetic patients who consulted on an outpatient basis between September and December 2021. DS was assessed using the arabic version of the type 2 Diabetes Stigma Assessment Scale (DSAS-2).

Results

Women represented 42% of the patients. The duration of diabetes was meanly 9.4 ± 6.4 years. The mean glycated hemoglobin was 9.9 % ± 2.4. The mean BMI was 27.7 Kg/m^2 ± 4.7. The mean Total Diabetes Stigma score was 46.9 ± 10.2 (range 19– 90). Subscale scores were as follows: Treated differently: 15.4 ± 4.2 (range 6– 30), Blame and Judgment: 17.5 ± 4.3 (range 7– 35), and Self stigma: 13.9 ± 2.3 (range 6– 30). A total of 26 (30%) respondents scored more than the mean total diabetes stigma score, suggestive of potentially problematic perceived diabetes stigma. Higher Total Diabetes Stigma Scores were associated with level of therapeutic education (P = 0,045), social coverage (P = 0,043), diabetes treatment (P = 0,044), HbA1c level (P = NS).

Discussion and conclusion

The results of this work highlights the importance of identifying DS in type 2 diabetics. High levels of DS have been associated with poor glycemic control, poor diabetes self-management and poor quality of life. These data support the need to focus on increasing awareness efforts to educate the public about type 2 diabetes and its management.

Increased haematocrit mediates lowering of blood glucose in mice exposed to hypoxia or treated with erythropoetin

Thomas Scherer[1], Matthaeus Metz[1], Marianna Beghini[1], Sabine Dürr[1], Andreea Corina Luca[1], Mairam Kaplanian[1], Sameer Abu Eid[1], Alexandra Kautzky-Willer[2] & Clemens Fürnsinn[1]
[1]Division of Endocrinology & Metabolism, Department of Medicine III, Medical University of Vienna, Vienna, Austria; [2]Medical University of Vienna, Department of Medicine III, Division of Endocrinology & Metabolism, Vienna, Austria

Introduction

Mountain dwellers show a lower prevalence of diabetes, which among countless other factors could be due to lower partial oxygen pressure at high altitude. The present study was to investigate in an experimental setting, if and how reduced oxygen availability affects blood glucose.

Methods

Male obese mice on high fat diet were continuously maintained under a normobaric hypoxic atmosphere (10% oxygen) for three months. To exclude indirect effects via blunted appetite and reduced weight gain, control groups kept on normal air were fed restrictedly, so to match the weight curves of their hypoxia-exposed counterparts. To track down involved mechanisms, wild type mice as well as mice, which expressed the erythropoetin receptor in the haematopoetic lineage only, were treated with erythropoetin (300 U/kg i.p., three injections per week for two months). The immediate response to infusion of donor erythrocytes was also examined. Treatment-induced effects on blood glucose and insulin sensitivity were studied.

Results

Life under hypoxia increased the haematocrit (44 ± 1 *vs.* 55 ± 1 %, P < 0.001) and lowered blood glucose of obese mice (166 ± 5 *vs.* 132 ± 3 mg/dl, P < 0.001), which went along with improved insulin sensitivity (HOMA: 1.4 ± 0.2 *vs.* 0.60. ± 0.1, P < 0.001; euglycaemic-hyperinsulinaemic clamp experiments, mg glucose/kg/min: rate of disappearance, 42 ± 2 *vs.* 50 ± 2,P = 0.03; rate of appearance, 9 ± 4 *vs.* -5 ± 1,P = 0.008). Parameters of lipid metabolism were unaffected by hypoxia. Similar effects were observed in wild type mice under regular injections of erythropoetin (haematocrit: 44 ± 2 *vs.* 69 ± 3 %, P < 0.001; blood glucose: 173 ± 7 *vs.* 108 ± 9 mg/dl, P < 0.001; HOMA: 1.8 ± 0.4 *vs.* 0.3 ± 0.1,P = 0.008). Absence of the erythropoetin receptor in all tissues except bone marrow and spleen did not impair the glucose lowering action of erythropoetin injections (haematocrit: 46 ± 2 *vs.* 63 ± 1 %, P < 0.001; blood glucose: 160 ± 4 *vs.* 97 ± 10 mg/dl, P < 0.001; HOMA: 2.6 ± 0.7 *vs.* 0.8 ± 0.3,P = 0.048). This excluded direct action of erythropoetin on non-haematopoetic organs as the cause of decreased blood glucose. In line with such evidence for haematopoesis-mediated lowering of blood glucose, an acute increase in the haematocrit from 46 ± 1 % to 60 ± 1 % (P < 0.001) by infusion of donor erythrocytes induced a significant reduction in blood glucose (169 ± 6 *vs.* 135 ± 4 mg/dl, P < 0.001).

Conclusion

Reduced blood glucose in mice living in a hypoxic environment is associated with improved insulin sensitivity and is obviously the direct consequence of an erythropoetin-mediated increase in the haematocrit. Elevated haematocrit thus likely explains lower blood glucose found in people living at high altitude as well as in patients under treatment with erythropoetin.

Chronotype: a tool to screen eating habits in Polycystic Ovary Syndrome?

Ludovica Verde[1], Luigi Barrea[2], Claudia Vetrani[1], Silvia Savastano[1], Annamaria Colao[1] & Giovanna Muscogiuri[1]
[1]Federico II University, Department of Clinical Medicine and Surgery, Endocrinology Unit, Naples, Italy; [2]Pegaso Telematic University, Department of Humanities, Italy

Background

Polycystic Ovary syndrome (PCOS) is the most common endocrine disorders in women of reproductive age whose lifestyle approach is an essential part of the treatment. Recently chronotype, i.e. a trait that determines individual's circadian preference in behavioral and biological rhythms, has been reported to play a role in determining nutrition preferences and the risk of developing chronic diseases. Thus, the aim of the study was to investigate if chronotype categories (morning, evening and neither) could be used as tool to screen eating habits in PCOS in order to drive the most appropriate nutritional approach.

Methods

In this observational cross-sectional study, we assessed anthropometric parameters, lifestyle habits, chronotype categories, adherence to MD, dietary pattern, and metabolic parameters in 112 women with PCOS.

Results

Chronotype was classified as morning in 27.7%, evening in 42.9% and neither in 29.5% of subjects. Women with PCOS with evening chronotype showed significantly higher percentages of grade I (P = 0.003) and grade II obesity (P = 0.001), did less regular exercise (P < 0.001) and most of them were smokers (P < 0.001) compared to those with neither and morning chronotype. In women with PCOS with evening chronotype there was a significantly higher prevalence of subjects with HoMA-IR cut off > 2.5 than neither and morning chronotype (P < 0.001). Women with PCOS with evening chronotype had the lowest PREDIMED score, consumed more calories (P < 0.001), total (P < 0.001) and simple carbohydrates (P < 0.001), total fat (P < 0.001) and SFA (P < 0.001), PUFA (P < 0.001) and n-6 PUFA (P < 0.001) and less fiber (P < 0.001) than women with PCOS with other chronotype categories. In addition, women with PCOS with evening chronotype consumed less EVOO (P = 0.001), legumes (P = 0.038), fish/seafood (P < 0.001) and tree nuts (P = 0.041) than women with PCOS with other two chronotype categories and less red wine (P < 0.001) and more red/processed meat (P < 0.001) than women with PCOS with morning chronotype.

Conclsion
In women with PCOS evening chronotype has been associated with a most severe IR and unhealthiest eating habits. Thus, chronotype assessment could be effective tool to screen the eating habits, and more generally the lifestyle, of women with PCOS.

VLCKD: a real time safety study in obesity

Ludovica Verde[1], Luigi Barrea[1,2], Claudia Vetrani[1], Francesca Marino[1], Sara Aprano[1], Silvia Savastano[1], Annamaria Colao[1] & Giovanna Muscogiuri[1]
[1]Federico II University, Department of Clinical Medicine and Surgery, Endocrinology Unit, Naples, Italy; [2]Pegaso Telematic University, Department of Humanities, Naples, Italy

Very Low-Calorie Ketogenic Diet (VLCKD) is currently a promising approach for the treatment of obesity. However, little is known about the side effects since most of the studies reporting them were carried out in normal weight subjects following ketogenic diet for other purposes than obesity. Thus, the aims of the study were: 1) to investigate the safety of VLCKD in subjects with obesity; 2) if VLCKD-related side effects could have an impact on its efficacy. In this prospective study we consecutively enrolled 106 subjects with obesity (12 males and 94 females, BMI 34,98 $\pm$ 5,43 kg/m^2) that underwent to VLCKD. In all subjects we recorded side effects at the end of ketogenic phase and assessed anthropometric parameters at the baseline and at the end of ketogenic phase. In a subgroup of 25 subjects, we also assessed biochemical parameters. Ninety-nine (93,4%) of the subjects enrolled experienced at least one mild side effect but none of the most severe ones. From the most to the less frequent, the percentages of occurrence of the mild side effects were as follows: 49 (46,2%) lethargy, 49 (46,2%) halitosis, 48 (45,3%) headache, 41 (43,5%) dry mouth, 30 (28%) constipation, 19 (17,9%) hypotension, 17 (16%) dizziness, 16 (15,1%) vomiting/nausea, 16 (15,1%) hair loss, 13 (12,3%) diarrhoea, 11 (10,4%) hyperuricemia, 5 (4,7%) visual disturbances, 1 (0,9%) low blood sugar. No one experienced urolithiasis and gallbladder disease. In addition, 9 (8.5%) subjects stopped VLCKD before the end of the protocol for the following reasons: 2 (1.9%) due to palatability and 7 (6,1%) due to excessive costs. Finally, there were no differences in terms of weight loss percentage (13,5 $\pm$ 10,9 % vs 18,2 $\pm$ 8,9 %; P = 0.318) in subjects that developed side effects and subjects that did not developed side effects. Our study 2 demonstrated that VLCKD is a safe and effective nutritional tool in the management of subject with obesity.

A novel successful therapeutic option after a journey of treatment failures in a patient with heterozygous melanocortin-4 receptor deficiency

Mila Welling[1,2], Mostafa Mohseni[1,2] & Elisabeth van Rossum[1,2]
[1]Erasmus MC, University Medical Center, Obesity Center CGG, Rotterdam, Netherlands; [2]Erasmus MC, University Medical Center, Dept. of Internal Medicine, division of Endocrinology, Rotterdam, Netherlands

Introduction
Obesity is a complex and multifactorial disease with a chronic and relapsing nature, and is associated with over 200 co-morbidities. In a minority of patients, the obesity is caused by gene defects in the leptin-melanocortin pathway. As lifestyle interventions often fail in these patients, additional anti-obesity pharmacotherapy is needed. In this case report, we describe the therapeutic journey of a patient with early-onset obesity and hyperphagia due to heterozygous *melanocortin-4 receptor* deficiency.
Case presentation
A 33-year-old woman presented herself at our outpatient clinic with severe obesity, hyperphagia, and mild intellectual deficit. She developed obesity at the age of 6 years, resulting from hyperphagia. After regular lifestyle treatment without sufficient effect, a gastric bypass was performed at the age of 26 years leading to -40 kg weight loss, but eventually in greater weight regain. At the age of 27 years, genetic testing revealed a heterozygous pathogenic variant in the *melanocortin-4 receptor*gene, explaining her early-onset severe obesity and hyperphagia. Glucagon-like peptide-1 receptor agonist (GLP-1 RA) treatment, i.e. liraglutide 3 mg, was started which resulted in -7.3 kg of body weight (-3.8%, weight at start 193.5 kg), sustained hyperphagia (after a temporary, short term decrease), and increased fasting insulin after 5 months of treatment. GLP-1 RA treatment was therefore terminated and treatment with metformin was started at a dosage of 1500 per day, without any effects on weight or hyperphagia. Additionally, naltrexone-bupropion treatment was initiated after a 2.5 months wash-out period of liraglutide. In 6 months of naltrexone-bupropion treatment, she lost -29.5 kg of weight (-15.8%, weight at start 186.4 kg), of which -27.9 kg (-7.3%) was fat mass. Most importantly, her subjectively reported hyperphagia, satiety, and subsequently quality of life improved.
Discussion
To our knowledge, this case report is the first to describe that naltrexone-bupropion can effectively reduce weight and improve subjectively reported hyperphagia and quality of life in a patient with genetic obesity. This extensive journey learns us that in patients with genetic obesity various anti-obesity agents can be initiated and when ineffective terminated and substituted to another anti-obesity agent to find the most efficient treatment with regard to weight loss, hyperphagia, and quality of life. It also demonstrates that genetic screening should be considered in patients with early-onset obesity, hyperphagia, or other specific symptoms of monogenic obesity, prior to bariatric surgery as they are at higher risk for weight regain.

The trigliserid-glucose index shows a stronger correlation with serum adiponectin levels than HOMA-IR

Suleyman Nahit Sendur[1], Kubra Isgin Atici[2], Busra Turan Demirci[2], Incilay Lay[3], Zehra Buyuktuncer[2] & Tomris Erbas[1]
[1]Hacettepe University, Endocrinology and Metabolism, Ankara, Turkey; [2]Hacettepe University, Nutrition and Dietetics, Ankara, Turkey; [3]Hacettepe University, Medical Biochemistry, Ankara, Turkey

Objective
Different methods are used to identify individuals with insulin resistance. The gold standard is the euglycemic-hyperinsulinemic clamp. However, in clinical practice, clamp is not preferred because it is cumbersome, the HOMA-IR index is used more often. The Trigliserid-glucose (TyG) index is a new and practical way to identify individuals with insulin resistance (IR). When compared to HOMA-IR, this index has been shown to be more reliable in determining insulin resistance and more effective to predict common diseases related to IR. In this study, the relationship between TyG index/ HOMA-IR and adiponectin were investigated.
Method
A total of 400 individuals, aged 24-50, were included in the study. Two hundred of participants had normal (Group 1) body mass index (BMI) values (18.5-25 kg/m2), while 200 were either overweight or obese (Group 2) (BMI > 25 kg/m2). Demographic characteristics of all participants have been recorded. Height, weight and waist circumference were measured; BMI values were calculated. Body fat content was determined by the electrical impedance method. Glucose, insulin, triglyceride, total cholesterol, LDL, HDL and adiponectin were measured.
Results
There was no difference between groups in terms of gender distribution. Group 1 were younger (33.3 $\pm$ 6.8 years vs. 36.4 $\pm$ 7.0 years, P < 0.001). BMI, waist circumference, fat weight, fat ratio, plasma glucose levels, insulin, triglyceride, total cholesterol, LDL, HOMA-IR and TyG index values were higher in group 2 (TyG index; Group 1: 8.25 $\pm$ 0.51 vs Group 2: 8.58 $\pm$ 0.57). HDL cholesterol and adiponectin concentrations were found to be lower in Group 2. There was a stronger correlation between the TyG index and the adiponectin levels in Group 1, Group 2 and whole cohort compared to the HOMA-IR (Group 1, adiponectin-HOMA-IR, r = -0.19,P = 0.006, adiponectin-TyG index, r = -0.37, P < 0.001; Group 2, adiponectin-HOMA-IR, r = -0.26, P < 0.001, adiponectin-TyG index, r = -0.38, P < 0.001; Whole cohort adiponectin-HOMA-IR r = -0.27, P < 0.001, adiponectin-TyG index, r = -0.41, P < 0.001).
Conclusion
The TyG index is correlated with adiponectin levels better than HOMA-IR. This index could be an easy, practical and powerful method to predict unfavorable adipokine profile.

Hypothyroidism and obesity in a population of Italian women with lipedema and correlation with the clinical stage

Laura Patton[1] & Lorenzo Ricolfi[2]
[1]Rehabilitation Department, Valdobbiadene, Italy; [2]Lymphological Clinic, Bordighera, Italy

Aim
Lipedema is a painful fat disorder that affects ~11% of the female population, characterized by bilateral, disproportionate accumulation of subcutaneous adipose tissue predominantly in the lower body. The initial manifestations of lipedema arise in phases of hormonal change (puberty, pregnancy, menopause). The pathophysiology of lipedema is unclear. The putative causes proposed include altered adipogenesis, microangiopathy, and disturbed lymphatic microcirculation The diseases is diagnosed on the basis of its main manifestations: pain, a feeling of tension, and increased tendency to form hematomas in the affected areas. Treatment is symptomatically oriented and based on complex decongestive therapy and nutritional regimen, low carb or ketogenic. There are four stages of lipedema that refer primarily to changes in the skin, based on the progression of fat accumulation and changes to the skin. The fourth stage is a condition characterized by lymphological complications secondary to the failure of lymphatic system. A higher incidence of endocrinopathies, such as obesity and thyroid diseases, has been described in woman with lipedema, but no studies have been done in Italy. The aim of the study was to evaluate the prevalence of these endocrine diseases in an Italian population of women with lipedema
Materials and methods
Sixty-five women suffering from lipedema, who arrived consecutively at the lymphological clinic, underwent an endocrinological examination, with particular reference to the presence of obesity and thyroid diseases.
Results
The median age was 41.1 $\pm$ 13.5 years. Twenty-two women had stage 1 lipedema, twenty-five stage 2 lipedema, fifteen stage 3 lipedema and three stage 4 lipedema. Thirteen women (20%) were normal weght (BMI $<$25 kg/m2), twenty-two women (33.8 %) were overweight (BMI $\geq$ 25 $<$30), thirty women (46.2%) were obese (BMI $\geq$30.0). The prevalence of obesity increases with the lipedema stage ($P<0.001$): 9.1% in stage 1, 48 % in stage 2, 86.7 % in stage 3, 100 % in stage 4. Hypothyroidism was present in twenty-seven patients (41.5%). The prevalence of hypothyroidism (autoimmune and non-autoimmune hypothyroidism) increases with the lipedema stage ($P<0.001$): 18.2 % in stage 1, 40 % in stage 2, 66.7 % in stage 3, 100 % in stage 4.
Conclsion
The study confirms a high prevalence of obesity and hypothyroidism in patients with lipedema in Italian population and suggests a correlation between these diseases with the lipedema stage. Obesity and thyroid dysfunction should be evaluated in patients with lipedema, especially because for the possible worsening effect on the evolution of lipedema.

Design of a phase 2, double-Blind, placebo-controlled trial of setmelanotide in patients with genetic variants in the melanocortin-4 receptor pathway

Sadaf Farooqi[1], Martin Wabitsch[2], Wendy Chung[3], Olga Ohayon[4], Cecilia Scimia[4], Guojun Yuan[4] & Bhavik P. Shah[4]
[1]University of Cambridge, Wellcome-MRC Institute of Metabolic Science and NIHR Cambridge Biomedical Research Centre, Cambridge, United Kingdom; [2]Ulm University, Division of Pediatric Endocrinology and Diabetes, Department of Pediatrics and Adolescent Medicine, Ulm, Germany; [3]Columbia University, Division of Molecular Clinical Genetics, Department of Pediatrics, New York, United States; [4]Rhythm Pharmaceuticals, Boston, United States

Introduction
Rare genetic causes of obesity result from disruption of the melanocortin-4 receptor (MC4R) pathway, a regulator of energy balance. Patients with obesity due to variants in multiple genes, including *POMC, LEPR*, *SRC1*, and *SH2B1*, have shown weight and hunger reductions after treatment with setmelanotide, an MC4R agonist. DAYBREAK is a Phase 2 trial of setmelanotide in patients with additional gene variants with suggested relevance to the MC4R pathway (ClinicalTrials.gov identifier: NCT04963231).
Methods
This Phase 2, double-blind, placebo-controlled, 2-stage study will enroll ~500 patients in Stage 1 to achieve ~130 qualified patients in Stage 2. Patients (aged 6 to 65 years) with pathogenic, likely pathogenic, or uncertain significance genetic variants based on American College of Medical Genetics criteria in a preselected set ($n=31$) of MC4R pathway genes, including *LEP*, *SIM1*, *MRAP2*, and *KSR2*, and body mass index (BMI) $\geq$40 kg/m^2(aged $\geq$18 years) or BMI $\geq$97th percentile (aged $<$18 years) according to age and sex are eligible. Exclusion criteria include recent diet or exercise resulting in $>$3% weight loss, bariatric surgery within 6 months of enrollment, significant features or diagnosis of syndromic obesity, glycated hemoglobin $>$10.0%, and glomerular filtration rate $<$60 ml/min. Setmelanotide will be self-administered subcutaneously. Daily dosage will be age dependent: 2 mg will be administered for 14 days, then 3 mg thereafter in patients $\geq$12 years old or 1 mg will be administered for 7 days, 2 mg for 7 days, and 3 mg thereafter in patients 6–12 years old. Patients will be eligible to enter Stage 2 (randomized withdrawal period) if they have achieved $\geq$5% weight loss from baseline ($\geq$18 years old) or $\geq$0.1-point reduction from baseline in BMI Z score ($<$18 years old) at the end of Stage 1 (16-week open-label run-in). Eligible patients will be randomized 2:1 to daily setmelanotide or matching placebo for 24 weeks. Primary endpoints include proportion of patients achieving $\geq$10% weight loss (aged $\geq$18 years) or $\geq$0.3-point reduction from baseline in BMI Z score (aged $<$18 years) from baseline at Week 40. Secondary endpoints are initial response to open-label setmelanotide and changes in body weight, waist circumference, hunger, and quality of life. Safety will be assessed by severity and frequency of adverse events.
Results
Patient dosing has been initiated as of January 2022.
Conclusions
The Phase 2 DAYBREAK trial will evaluate setmelanotide for weight loss and hunger reduction in individuals with variants associated with the MC4R pathway.

The crosstalk between adiposity and bone: a potential role for SIRT1 and sclerostin

Rossella Tozzi[1], Davide Masi[2], Fiammetta Cipriani[2], Maria Elena Spoltore[2], Savina Contini[2], Mikiko Watanabe[2], Sabrina Basciani[2], Carla Lubrano[2], Lucio Gnessi[2] & Stefania Mariani[2]
[1]Sapienza University of Rome, Molecular Medicine, Roma, Italy; [2]Sapienza University of Rome, Department of Experimental Medicine, Section of Medical Physiopathology, Food Science and Endocrinology, Roma, Italy

Background and aim
Sirtuin1 (SIRT1) and sclerostin play important roles in adipose tissue and bone metabolism. SIRT1 pharmacological induction improves bone quality both in murine and human models and- as adiposity increases – its expression decreases both in peripheral tissues and blood. Sclerostin reduces osteoblasts' differentiation and mineralization and is associated with DMT2, obesity and cardiovascular risk. We evaluated the circulating SIRT1 and sclerostin relationship with mass and quality of bone considering the degree of adiposity.
Materials and methods
66 premenopausal women (16 underweight, 25 normal weight and 25 with obesity), aged $<$50 years, were enrolled. Plasma SIRT1, sclerostin, and DXA body composition [total-fat mass (FM), abdominal visceral adipose tissue, lean mass, trabecular bone score (TBS), lumbar spine and femoral neck-bone mineral density (BMD)] were assessed.
Results
The patients with obesity showed the lowest SIRT1 and TBS values and the highest sclerostin concentrations; BMD increased with FM and BMI and had an inverse association with SIRT1. Sclerostin was negatively correlated with SIRT1 ($P=$-0.37, $P=0.002$). When spine-BMD, femoral neck -BMD and TBS were standardized for BMI, a positive correlation with SIRT1 and a negative correlation with sclerostin were seen ($P<0.005$). In a regression analysis, sclerostin was the best independent, negative predictor for BMD and TBS, while SIRT1 directly predicted TBS ($P<0.05$).
Conclusion
Blood measurement of SIRT1 and sclerostin could represent a snapshot of the bone status that, taking into account the degree of adiposity, may reduce the interference of confounding factors in the interpretation of the bone health parameters.

Impact of basal bolus insulin therapy on glucose control and mortality in patients with type 2 diabetes hospitalized with COVID -19: a retrospective study

Elena Chertok Shacham[1], Nimra Maman[2] & Avraham Ishay[1]
[1]Endocrinology, Afula, Israel; [2]Statistics, Afula, Israel

Introduction
Previous studies have reported that SARS-CoV-2 infection is associated with a more severe disease and worse outcome in patients with diabetes mellitus. Insulin is the mainstay of diabetes therapy in the inpatient setting. However, the treatment of diabetes in patients with COVID-19 remains unclear. In this study we investigate the influence of different insulin regimens and other antidiabetic medications on glucose control and mortality in COVID-19 patients with type 2 diabetes.
Methods
We conducted a retrospective electronic medical record analysis of 359 type 2 diabetes patients hospitalized with COVID-19 between 01/04/2020 and 31/03/2021 in the Emek Medical Center. The following baseline characteristics included in the study are: gender, age, BMI, GFR, CRP, preadmission diabetes treatment regimens, and comorbidities. We divided the patients into two groups based on their diabetes treatment during hospitalization. The first group included patients treated only with insulin, and the second group of patients were treated with insulin and other classes of antidiabetic drugs. We recorded data of patients' 28-day mortality rates, preadmission diabetes treatment, average blood glucose, diabetes treatment regimens at discharge, and HbA1C levels 6 months before and after hospitalization in both groups.
Results
Of 359 patients, 82 were mechanically ventilated and 110 patients suffered a severe course of COVID-19. The mortality rate on day 28 after admission was similar in patients treated with insulin only and those treated with a combination of insulin and other treatment modalities ($P=0.29$) and remains non-significant after exclusion of mechanically ventilated patients from the statistical analysis. Patients who survived their hospital stay had lower CRP levels at admission (11.5 ± 8.2 vs 16.1 ± 9.7;$P=0.000$). During hospitalization, most of the patients in the combination therapy group received metformin on top of insulin (131 out of 162, 80%), 28 patients (17%) received SGLT-2 inhibitors, 12 (7%) were treated with DPP-IV or GLP-1 agonists, and seven patients (4%) with sulfonylureas. Regarding diabetes control, HbA1C levels improved after hospitalization in both groups of treatment, and overall: A1C levels before admission were 7.9 ± 1.9 mg% and after 7.5 ± 1.7 mg% ($P=0.002$).
Conclusion
Basal bolus insulin regimens, as well as a combination of insulin and other classes of antidiabetic medications, were not associated with dissimilar mortality rates in patients affected with *SARS-CoV-2*. Our study shows that new antidiabetic medications, such as incretin-based therapy and SGLT-2i, as well as metformin in combination with insulin may safe, and effectively control glucose levels in hospitalized COVID-19 patients.

Relationship between change in glycemic parameters and body weight with IDegLira in type 2 diabetes

Ivona Risovic[1], Mirjana Sumarac-Dumanovic[2], Mirjana Bojic[3] & Danijel Djekic[4]
[1]University Clinical Center of the Republic of Srpska, Faculty of Medicine, University of Banja Luka, Endocrinology, Banja Luka, Bosnia and Herzegovina; [2]School of Medicine, University of Belgrade, Clinic for Endocrinology, Diabetes and Diseases of Metabolism, Endocrinology, Belgrade, Serbia; [3]University Clinical Center of the Republic of Srpska, Endocrinology, Banja Luka, Bosnia and Herzegovina; [3]University Clinical Center of the Republic of Srpska, Endocrinology, Banja Luka, Bosnia and Herzegovina

Introduction
IDegLira is the first fixed ratio combination of a basal insulin degludec and a glucagon-like peptide-receptor analogue liraglutide. These combination producer-eduction in glycated hemoglobin A1c (HbA1c) and help to mitigate the weight gain. The aim of this study was to evaluate relationship between change in glycemic parameters and body weight in patients who began therapy with IDegLira.
Patients and Methods
Retrospective study included 86 patients with type 2 diabetes who began therapy with IDeg Lira, previously uncontrolled on basal insulin and metformin, and follow up for 6 months. Patients were devide in two groups according HbA1c: group I with HbA1c <9 ($n=50$) and group II with HbA1c ≥ 9 ($n=46$). We examined glycemic parameters (HbA1c, fasting plasma glucose, FPG) and antropomethric parameters (body weight and BMI).
Results
The analysis showed that patients in group II with higher HbA1c from baseline had higher reduction in HbA1c and FPG (0.9% vs. 0.6%, $P<0.05$ for HbA1c, 1.0 mmol/l vs. 0.6 mmol/l, $P<0.05$ for FPG). Patients in all groups had decreased body weight at the end of study. The higher decreased in HbA1c in group II didn't followed with significance higher weight loss (1.9 kg vs 1.8 kg, $P>0.05$) and higher reduced BMI (0.8 vs 0.7 kg/m^2, $P>0.05$). We founded in both groups a significant direct correlation between reduction HbA1c and BMI ($r=0.35$, $P<0.05$ vs. $r=0.42$, $P<0.05$), but with no significant difference between groups. At the end of study, no difference had showed in dosage of IDegLira between groups. Patients with poorer glycemic control from baseline were older and obese according BMI, but with no difference in duration of diabetes.
Conclusion
Our results showed that reduced glycemic parameters and weight loss depends on baseline value with IDegLira. The higher reduction glycemic parameters had no relationship with significantly higher weight loss.

Key words
insulin degludec, liraglutide, weight loss, type 2 diabetes.

Features of the level of amylinemia in patients with latent autoimmune diabetes in adults

Iryna Tsaryk[1] & Nataliia Pashkovska[2]
[1]Bukovinian State Medical University, Department of Clinical Immunology, Allergology and Endocrinology, Chernivtsi, Ukraine; [2]Bukovinian State Medical University, Clinical Immunology, Allergology and Endocrinology, Chernivtsi, Ukraine

Background
Among the heterogeneous types of diabetes mellitus (DM), latent autoimmune diabetes in adults (LADA) is the most common and attracts the attention of scientists, the pathogenesis of which combines the main mechanisms of classical type 1 (T1DM) and type 2 diabetes mellitus (T2DM). The role of hyperamylinemia in the development and progression of LADA remains out of the researchers' attention.
The objective
of the study was to determine the features of the level of amylinemia in patients with LADA compared to classical types of DM.
Methods
89 patients with diabetes and chronic kidney disease (CKD) were examined, as well as 15 representatives of the control group. The patients were divided into three groups by the types of DM (25 patients with classical T1DM, 36 patients with LADA, 28 patients with T2DM). The LADA group included patients with LADA1 phenotype (antiGAD ≥ 180 U/ml) and LADA2 phenotype. Serum amylin levels were measured using the ELISA method.
Results
In patients with classical T1DM, the level of amylinemia did not change, whereas in T2DM group it was 10.8 times significantly higher compared to the control and 8.3 times higher than in the group of patients with classical T1DM. In the group of patients with LADA, the amylin content was 9.0 times higher than in control and 6.8 times higher compared to classical T1DM. In the distribution of patients with LADA into phenotypes, in patients with LADA1, the serum level of amylin was 5.9 times higher relative to the control ($P<0.01$), 4.1 times higher relative to classical T1DM ($P<0.01$), but almost half as low as in T2DM ($P<0.01$). In LADA2 group, the above indicator exceeded that in the control group by 13.5 times ($P<0.01$), in the group of classical T1DM – by 9.3 times ($P<0.01$) and in patients with LADA1 – by 2.3 times ($P<0.05$). In patients with LADA, an interdependence was found between the content of amylin and insulin ($r=0.64$;$P=0.000$), C-peptide ($r=0.74$;$P=0.000$), the HOMA-IR index ($r=0.54$;$P=0.001$).
Conclusions
Serum amylin level significantly increase in patients with latent autoimmune diabetes in adults, especially in LADA2 phenotype compared to classical types of diabetes, which indicates the role of hyperamylinemia in the development and progression of this subtype of diabetes.

The relation between insulin resistance and both growth hormone and insulin-like growth factor (IGF-1) levels in a sample of Iraqi patients with type 2 diabetes

Hasanain Mohammed Alrubyae[1], Araz Al-Saffar[2] & Khalid Allehibi[3]
[1]The National Center for Diabetes / Al-Mustansirya University, Diabetes, Baghdad, Iraq; [2]Daisy Hill Hospital, Diabetes and Endocrinology, Newry, United Kingdom; [3]Specialised Center of Endocrinology and Diabetes SCED, Baghdad, Iraq

Introduction Background
Over the last decade, scientific attention has been drawn to the potential role of Growth hormone (GH) and Insulin Like Growth Factor-1 (IGF-1) in the pathogenesis and progression of T2DM. Both hormones are interrelated but exert variable effect on glucose homeostasis. While GH increases blood glucose level, IGF-1 maintain insulin secretion and enhance insulin sensitivity.
Methods
A cross sectional study conducted in the National Diabetes Centre, Baghdad, Iraq, from May 2020 to May 2021. Sixty patients with types 2 diabetes were investigated for fasting plasma glucose (FPG), GH, lGF-1 HbA1c, HOMA-IR, HOMA-B and anthropometric measures. Patients with Type 1 diabetes mellitus, thyroid disease, pituitary disease, chronic kidney disease, hepatic disease and Pregnancy were excluded from the study.
Results
There was no significant difference between gender and other variables of studied sample. There was association between HOMA-IR with HbA1c, IGF-1, fasting insulin, HOMA-B, and with QUICKI. A significant association between IGF-1 and body mass index (BMI), glycated haemoglobin (HbA1c), the duration of type 2 diabetes, quantitative insulin sensitivity index (QUICKI), and the age of patients was found. IGF-1 showed a significant negative correlation with BMI and a significant positive correlation with HbA1c and QUICKI. fasting GH correlated negatively with waist hip ratio (WHR), fasting insulin, HOMA-IR and positively with age and QUICKI. HbA1c was significant positive correlations with duration of T2DM, WHR, FPG, fasting TG, IGF-1, HOMA-IR and negatively correlated with QUICKI. There was a significant negative correlation between QUICKI index and BMI, WHR, FPG, HbA1c, fasting TG, fasting GH, Fasting insulin, and HOMA-IR. While HOMA-IR was significantly positive correlated with BMI, Fasting Plasma Glucose, HbA1c, Fasting TG and fasting insulin.
Discussion
GH and IGF-1 play a complex role in type 2 Diabetes Mellitus. In this study, IGF-1 in obese patient was low while in uncontrolled diabetes was high. GH decreased upon increased insulin resistance. Targeting IGF-1 in type 2 diabetes can be utilized as a potential therapy in the near feature. However, this needs further well designed randomized controlled trials. Conduct larger scale study to specify the cut off value of HOMA-IR for Iraq.
Conclusion
GH and IGF-1 play a complex role in type 2 Diabetes Mellitus. In this study, IGF-1 in obese patient was low, while in uncontrolled diabetes was high. GH decreased upon increased insulin resistance.
Keywords
Growth Hormone, IGF-1, Type two diabetes, insulin resistance, HOMA, QUICKE.

Prevalence of autosomal dominant mutations of Familial hypercholesterolemia in Finnish patients with premature coronary artery disease and elevated LDL-C levels

Antti Jokiniitty[1,2], Markku Eskola[2,3], Tanja Saarela[2,4] & Saara Metso[1,2]
[1]Tampere University Hospital, Department of Internal Medicine, Tampere, Finland; [2]Tampere University, Faculty of Medicine and Health Technology, Tampere, Finland; [3]Tampere University Hospital, Heart Hospital, Tampere, Finland; [4]Kuopio University, Department of Clinical Genetics, Finland

Background and aims
To assess the prevalence and variability of pathogenic or likely pathogenic autosomal dominant mutations (ADM) of Familial Hypercholesterolemia (FH) in a Finnish cohort of patients with premature coronary artery disease (CAD) and elevated LDL-C levels.
Methods
Study population was enrolled from 162 patients diagnosed with premature CAD (men $<$ 55 years and women $<$ 60 years) and history of high LDL-C ($\geq$ 5 mmol/l) levels, without apparent secondary reason for hypercholesterolemia, treated in the Heart Hospital at Tampere University Hospital between 2007 and 2017. A total of 80 patients were available for genetic testing for FH, 21 patients were studied during standard treatment and 59 patients were recruited for genetic testing retrospectively. Clinical probability of FH was assessed using the Dutch Lipid Clinic Network (DLCN) – Criteria: possible (DLCNC = 5), probable (DLCNC 6-8), definite (DLCNC $\geq$ 9). All patients were studied for Finnish *LDLR* gene founder mutations (FH-Helsinki (9,5 kb deletion including exons 1–18), FH-North-Karelia (c.925_931delCCCATCA, p.(Pro309Lysfs*59)), FH-Pori (c.1202T$>$A, p.(Leu401His)), FH-Turku (c.2531G$>$A, p.(Gly844Asp)). Further testing of the genes *LDLR* (Sanger sequencing and MLPA), *PCSK9* (Sanger sequencing) and *APOB* (Sanger sequencing for mutations affecting codon 3527 in exon 26) was conducted to 62 (78%) patients if a founder mutation was not discovered.
Results
Out of 80 patients four (5%) had definite FH, 54 (68%) had probable FH and 22 (27%) had possible FH based on DLCN - criteria. Pathogenic ADM of FH was found in five patients (6%). Four founder mutations and one additional *LDLR*-mutation were discovered. Based on clinical criteria three patients had definite FH and two patients had probable FH. ADM's of FH weren't discovered in 91% (53/58) of patients with probable/definite FH and in none of the patients with possible FH.
Conclusions
Despite possible selection bias, proportion of patients with ADM's of FH was lower than expected in a population with elevated LDL-C levels, premature CAD and clinical phenotype of FH. Only a minority of patients with clinically defined FH, studied for genetic mutations, had monogenic FH. Further studies in our area are required to identify the population where genetic testing of FH is likely to offer the greatest clinical advantages.

Maternal triglyceride levels, and not fructosamine, in early pregnancy are associated with birth weight

Isabel Clinck[1,2], Faro Verelst[1,2], Marcel Twickler[2,3] & Tanja Vrijkotte[4]
[1]University of Antwerp, Internal medicine, Antwerp, Belgium; [2]AZ Monica, Antwerp, Department of Endocrinology, Diabetology and Metabolism, Deurne, Belgium; [3]University of Antwerp, Faculty of Medicine and Health Sciences, Antwerp, Belgium; [4]Amsterdam University Medical Centers, University of Amsterdam, Department of Public and Occupational Health, Amsterdam Public Health Research Institute, Amsterdam, Netherlands

Objectives
Maternal metabolism has a major impact on foetal growth, and the risk of developing obesity, cardiovascular disease and diabetes in later life. Identification of maternal metabolic parameters in early pregnancy that predict birth weight (BW), is pivotal in the prevention of these diseases. We evaluated whether maternal triglyceride (TG) or fructosamine levels in early pregnancy, as possible reflectors of maternal insulin resistance (IR), could predominantly contribute to BW and whether this is sex dependent.
Study design
The data were obtained from the Amsterdam Born Children and their Development cohort study. Non-fasting TG and fructosamine levels were determined in early gestation (median 13 weeks). Associations between maternal TG and fructosamine levels, and BW - small for gestational age (SGA) - large for gestational age (LGA), were analysed for each sex separately.
Results
In total 3514 pregnant women were included. With every increase of 1 mmol/l TG, the BW increased significantly by 81.7 g. This increase was larger with boys (107.3 g, 95% CI 66.0-148) compared to girls (60.5 g, 95% CI 23.6-97.4). However, no association was found with fructosamine. The results were adjusted for gestational age at blood sampling, total duration of pregnancy, maternal height, age, parity, ethnicity, educational level, smoking, alcohol and pre-pregnancy BMI. These covariates were also used in a different statistical test (R-squared), and explained 29.2% of the variance in BW. Adding fructosamine to this model, had no added value in predicting BW (R^2 stayed 0.292). Contrary, TG levels raised the R^2 from 0.292 to 0.299 ($P<0.001$). In total 8.3% children in our population were LGA. The odds of a new-born LGA with higher maternal TG levels were increased (OR 1.6, 95% CI 1.3-2.0). No increased odds were found for fructosamine levels (OR 1.0, 95% CI 1.0-1.0).
Conclusions
This study shows that fructosamine levels, measured in the first trimester of a physiological pregnancy, are not significantly associated with BW, in contrast to maternal TG levels. This association is more prominent with boys. Our data suggest that the lipid profile in early pregnancy is more predictive for pregnancy outcomes, like LGA, than glycaemic metabolic parameters, such as fructosamine. This may give a different focus on metabolic variables (TG vs fructosamine) involved in early patterns of maternal IR during a physiologic pregnancy. Additional studies could show whether maternal TG levels should be included in the screening or follow-up of pregnancies with a pronounced IR (e.g. in gestational diabetes).

Evaluation of a new transition organization for young adults with endocrine or metabolic diseases

Enora Le Roux[1] & Philippe Touraine[2]
[1]INSERM, Université de Paris, ECEVE UMR 1123, Paris, France; [2]AP-HP. Sorbonne Université, Hôpital Universitaire Pitié Salpêtrière, Service d'Endocrinologie et Médecine de la Reproduction HCP-ENDO European Reference Network, Paris, France

Objective
To evaluate the effect of a new care organisation on multiple outcomes of transition success and its cost-effectiveness in patients with any endocrine or metabolic disease diagnosed during childhood and transferred to adult care.
Design
Non-randomized controlled trial in a French University Hospital.
Methods
Patients transferred to adult care during the control period (04/2014-08/2016) and the intervention period (09/2016-06/2018) were included. The intervention is based on case management involving liaising with pediatric services, personalising care pathways, and liaising with structures outside hospital (general practitioner, educational and social sector). The primary endpoint was the percentage of patients lost to follow-up at 24 months post transfer. Other outcomes were collected from medical files, consultation software, and questionnaires. A cost analysis was performed.
Results
202 patients were included (101 per period), the most represented pathologies were congenital and non-congenital hypopituitarism (respectively $n=34$ (17%) and $n=45$ (22%)) and thyroid diseases ($n=21$, 10%). Patients were aged 22.5 in median at 24 months post transfer where 12 were lost to follow up in the control group vs 9 with the intervention ($P=0.49$). The percentage of honoured consultation among those planned during 24 months was higher with intervention ($P=0.0065$). Patient satisfaction, physician trust, transfer delay did not differ between the groups. The incremental cost-effectiveness ratio was €179 per patient not lost to follow-up.
Conclusions
At 24 months post transfer the rate of lost to follow-up does not differ significantly, but indicators of a steadier follow-up are increased and the intervention appears to be cost-effective.

Analysis of the nutritional status of women in twin pregnancies in terms of key vitamins and microelements – preliminary results

Magdalena Zgliczynska[1], Iwona Szymusik[2], Magdalena Ostrowska[3] & Katarzyna Kosinska-Kaczynska[1]
[1]The Center of Postgraduate Medical Education, Second Department of Obstetrics and Gynecology, Warsaw, Poland; [2]Medical University of Warsaw, First Department of Obstetrics and Gynecology, Warsaw, Poland; [3]The Center of Postgraduate Medical Education, Department of Endocrinology, Warsaw, Poland

Objective
Diet and nutritional status during pregnancy are critical for the health of both mothers and the neonates. Women in twin pregnancies have higher metabolic needs compared to women in single pregnancies and it can be expected that they have higher risk of key vitamins and micronutrients deficiencies. However, very scarce data are currently available on this topic.
Aim of the study and method
The main aim is to analyze the nutritional status of women in twin pregnancies in terms of selected vitamins and microelements: iodine, vitamin D, calcium, magnesium, iron, folic acid and vitamin B12. It will be achieved through analysis of the nutritional status of the mentioned nutrients in 100 women with twin pregnancies after 22 weeks of pregnancy. A comparison with a control group of women in single pregnancies is also planned.
Results
Until the submission of this abstract (January 2022) 69 women in twin pregnancies were recruited. The median age in this group was 34 years (interquartile range [IQR] 31-36), whereas median gestational age was 30.4 weeks (IQR 25-33.3). 52.2% women were in dichorionic diamniotic, 43.5% in monochorionic diamniotic and 4.3% in monochorionic monoamniotic pregnancies. Deficiency of at least one of the tested micronutrients or vitamins occurred in 72.5% of the respondents. Iron deficiency was the most common and affected 55.1% of the examined patients. The second most common was vitamin D deficiency, which concerned 44.4% of the group. Vitamin B12 deficiency turned out to be the third most common and it was found in 8.7% of women. Almost 1 in 4 patients had excess level of folic acid. Moreover, in 5.8% of patients the concentration of 25-hydroxyvitamin D was increased. In terms of the remaining tested vitamins and microelements, no laboratory features of significant excess or shortage were found.
Conclusions
Basing on the preliminary results, it can be concluded that women in twin pregnancies may constitute a high-risk group for the deficiencies of iron, vitamin D and vitamin B12 deficiency.

Expression of beta2 adrenergic receptors in pancreatic islets of metabolic syndrome induced C57BL/6J Mice

Vijayalakshmi Gangadhara & Asha Abraham
St Aloysius College, Department of Post Graduate Studies and Research in Biotechnology, Mangaluru, India

Background
The global prevalence of metabolic syndrome (MetS) characterized by type 2 Diabetes (T2D), obesity, and cardiovascular diseases, has reached alarming proportions worldwide. The prevalence is rapidly increasing among all the age groups due to calorie dense food intake and sedentary lifestyle. Beta adrenergic receptors (β ADRs), are known for its role in thermogenesis, lipolysis and glucose metabolism. Ceasrine *et al*., 2018, reported that pancreas-specific deletion of Adrb2 resulted in glucose intolerance and impaired insulin secretion in mice.
Objective
To develop an animal model by feeding high fat simple carbohydrate diet (HFSC) and to study the expression pattern of β2 ADRs in the pancreatic islets.
Methodology
The MetS was induced in male C57BL/6J mice ($n=10$) by feeding HFSC. The control animals were fed with standard diet. The MetS was confirmed by anthropometrical analysis, fasting blood glucose, total cholesterol, triglycerides, HDL and LDL. At the end of 5thmonth of feeding, the experimental animals were sacrificed, the pancreas was isolated. The morphology of the pancreas was studied by histology and SEM. The pancreatic islets were isolated by collagenase digestion. The quality of islet was accessed by Dithiozone staining. The total islet protein was extracted by RIPA lysis method and quantified by BCA assay. The protein was separated by SDS PAGE, immune blotted and probed with β2 ADR polyclonal antibody followed by Goat anti rabbit IgH(H+L) cross adsorbed DyLight488. The blots were quantified using Biorad Geldoc XR+ with *Imagelab* software.
Results
The metabolic syndrome was developed in male C57BL/6J mice by feeding HFSC diet up to 5thmonth. Blood glucose ($P>0.01$), triglyceride level ($P>0.001$), total cholesterol ($P>0.01$), LDL ($P>0.01$) of HFSC fed mice was significantly increased compared to control. The number of pancreatic islets was reduced in the HFSC fed mice compared to control. In comparison to control mice, HFSC-fed mice's islets were depleted and had higher lymphatic infiltrates. The expression of β2 ADRs were found to be altered in the HFSC fed mice.
Conclusion
Serving as a model, HFSC fed mice more closely resembled human obesity with altered blood glucose and lipid profile. The presence of lymphatic infiltration around the islets of HFSC-fed mice indicates that the inflammatory process may also contribute to islet destruction, which could lead to T2D. Additional changes associated with the β2 ADRs and its downstream signaling will be discussed during the congress.

DOI: 10.1530/endoabs.81.P112

Impact of hyperuricemia at metabolic syndrome and diabetic nephropathy, among patients with diabetes mellitus

Ergita Nelaj[1], Sonila Gozhita[2], Irida Kecaj[1], Ilir Gjermeni[1] & Mihal Tase[1]
[1]UHC 'Mother Teresa', Internal Medicine, Tirana, Albania; [2]Hygeia Hospital, Tirana, Albania

Hyperuricemia is a high risk factor for atherosclerotic diseases such as CVD and carotid atherosclerosis, hypertension, type 2 diabetes mellitus (T2DM), metabolic syndrome (MS). There are complex interrelationships between hyperuricemia,

T2DM, chronic kidney disease (CKD) and MS. The purpose of our study was to investigate the relationship between hyperuricemia, CKD, MS, and its components.
Materials and methods
179 patients with T2DM were included. The baseline presence of components of metabolic syndrome as defined by the World Health Organization was determined. CKD was defined according to the guidelines by reduction of GFR below 60 ml/min/1.73 m2, with a minimum duration of 3 months or renal impairment lasting more than 3 months. Hyperuricemia was determined as serum uric acid level above 7 mg/dl in men and 6 mg/dl in women.
Results
Following the analysis of the studied group, out of the 179 cases, 131 were identified with hyperuricemia and 48 with normo-uricemia. The prevalence of hyperuricemia was 73%. The average age of the patients was 73 years. In patients with hyperuricemia, the mean values of SBP and DBP were statistically significant higher than in patients with normo-uricemia ($P<0.003$). Triglycerides had statistically significant higher values in the hyperuricemia group ($P<0.005$). The mean HDL-cholesterol value being statistically significant lower in the hyperuricemia group ($P<0.01$). Renal function evidenced by creatinine, blood urea nitrogen and GFR, was statistically significant lower in patients with hyperuricemia ($P<0.001$). There was statistically significant relation between hyperuricemia and albuminuria ($P=0.008$), as predictor of diabetic nephropathy.
Conclsions
Among diabetic patients with hyperuricemia, the prevalence of CKD, obesity, hypertension, MS and its components are statistically significantly higher than in patients with normo-uricemia.

Management of patients with Diabetes Mellitus and concurrent Covid-19 infection at a centre in Manchester with tertiary diabetes services: A retrospective single-centre audit

Amr Mohammed, Ashutosh Kapoor, Asfand Yar Malik Ganjera & Prasanna Rao-Balakrishna
Manchester University NHS FT, Manchester, United Kingdom

Background
The prevalence rate of Diabetes within Manchester is higher than the national average of England. Association of British Clinical Diabetologists (ABCD) guidance highlights an increased risk of typical and atypical presentations of diabetic emergencies in patients with Diabetes and COVID-19. In the absence of early recognition and treatment, this could lead to adverse outcomes and poor prognosis, thus leading to increased mortality rates.
Aims
The aims involved evaluation of outcomes in patients with diabetes and concurrent Covid-19 infection followed by identification of compliance with the ABCD front door guidance for immediate management of these cohort of patients, in order to improve clinical care.
Methods
We collected clinical data on a retrospective basis from electronic records of patients admitted to our centre with a diagnosis of Covid-19 and Diabetes Mellitus between January and July 2020. Patients were identified using coding within Discharge Notification Forms (DNFs).
Results
Thirty-four (34) patients were selected to create our sample population. Thirty-one (91.2%) patients had a recorded blood glucose on admission. Two (5.9%) patients had blood ketone levels recorded on admission. The median and mean blood glucose on admission was Ten point one (10.1 mmol/l) and Twelve point four (12.4 mmol/l), respectively. Metformin was withheld in five (5) out of Sixteen (equating to 31.9%) patients taking on admission, pending review of the biochemical and hypoxic status. Sodium-Glucose Transport Protein 2 (SGLT-2) inhibitors were appropriately withheld in all Thirty-four (equating to 100%) patients on admission. Out of the entire cohort of patients, eleven (equating to 32.3%) did not survive admission.
Conclusions
Severe Covid-19 is associated with significant morbidity and mortality. Data from this single centre audit suggests that a large proportion of patients with diabetes and diagnosis of Covid-19 are at risk of hyperglycaemia with ketosis at time of admission, yet only a small number have a recorded ketone level. Steps should be taken to improve awareness and education of admitting clinicians to identify and reduce the risk of possible diabetic emergencies within this high-risk cohort of patients. In addition to this, it is also recommended that in this group of patients, health care professionals must consider additional safety measures, namely review of medications such as SGLT-2 inhibitors and Metformin on admission, which in turn is likely to improve outcomes and prognosis of these patients. Following the acute phase, Metformin needs to be reviewed on the basis of the biochemical and Respiratory status of the patient.

Immunotherapy-induced Diabetes Mellitus is not uncommon

Janessa Bell[1,2], Mahamud Bashir[1], Hassan Rehmani[1] & Gideon Mlawa[3]
[1]Queen's Hospital, Acute Medicine, United Kingdom; [2]American University of the Caribbean School of Medicine, Sint Maarten (Dutch Part); [3]Queen's Hospital, Diabetes and Endocrinology/Acute Medicine, London, United Kingdom

Background
Lung cancers are one of the leading causes of death worldwide which has resulted in an increase in immunotherapy, particularly immune checkpoint inhibitors (ICIs). Recent studies have shown induced endocrinopathies secondary to ICIs as a result of pancreatic beta cells, thyroid, and pituitary dysfunction.
Aim
We aim to present an interesting case of Type 1 Diabetes mellitus secondary to immunotherapy. Pembrolizumab is used to treat melanoma, non-small cell lung cancer, head and neck cancer, Hodgkin lymphoma, stomach cancer, and cervical cancer. Pembrolizumab is a human monoclonal IgG4 antibody that selectively binds to programmed cell death ligand-1 (PD1) receptor on the cell surface, thus blocking PD-1 (Programmed cell Death 1) which prevents T-cells from recognising and attacking cancer cells.
Case
In this case, a 62-year-old lady presented to hospital with polyuria, polydipsia, and weight loss after 8 months of immunotherapy. She was found to be hyperglycaemic and new of type 1 diabetes. Her background includes poorly differentiated adenocarcinoma of right lung diagnosed in March 2017, dermatomyositis, and an ex-smoker. She had received 4 cycles of chemotherapy (Cisplatin/Pemetrexed) between April 2017- June 2017 and then radical radiotherapy which completed August 2017 with good response and then she commenced Pembrolizumab in July 2020. Initial investigations were not consistent with DKA; pH 7.431, serum glucose 29.7 mmol/l, HCO3 26.2 mmol/l and urinary ketones 4+. She was commenced on NovoRapid 4 units 3 times a day and Levemir 10 units in the morning and 4 units in the evening. TSH was 0.90 mU/l and cortisol of 263 nmol/l excluded adrenal insufficiency. She was negative for Islets-cell antibodies, anti-GAD antibodies, and ZNT8.
Discussion
ICIs are commonly associated with endocrinopathies which are categorized as immune-related adverse events (Ruggeri 2019). New type 1 diabetes mellitus is a frequent toxicity of immunotherapy and can potentially be life-threatening if not diagnosed promptly. Therefore, during immunotherapy treatment, serum glucose should be regularly monitored. The UK National Institute of Health and Care Excellence (NICE) recommends developing an early plan of care, blood glucose management (periodic HbA1c and serum fasting glucose level tests), and managing long-term complications for adults diagnosed with Type 1 Diabetes mellitus. It is also recommended that patients started on ICIs have other endocrine toxicities testing. Current treatment is targeted to replace the specific hormone deficiency, e.g insulin in the case of new T1DM, as well as immunosuppression depending on the severity of the endocrinopathy (Ruggeri 2019).

Association of uric acid levels with diabetic retinopathy in filipino patients with type 2 diabetes mellitus at a tertiary government hospital: a cross-sectional analytic study

Irene Kei Bariuad-Garcia[1], Cecilia Jimeno[1] & Paul Siopongco[2]
[1]East Avenue Medical Center, Internal Medicine, Section of Endocrinology, Quezon City, Philippines; [2]East Avenue Medical Center, Ophthalmology, Quezon City, Philippines

Objectives
Diabetic retinopathy, is the most frequent cause of new cases of blindness among adults aged 20–74 years in developed countries. In 15 of the 23 studies in developing countries and in ethnic minority groups within developed countries, the prevalence of diabetic retinopathy was over 35%. In developed countries, only 2 of 16 studies reported a prevalence of 35% or over. Variation in neither population demographics nor method of retinopathy assessment appeared to account for these differences in prevalence. Serum uric acid is one of the major

sources of oxidative stress thru generation of free radicals and exhibits pro-inflammatory actions. This study aims to investigate the association of serum uric acid levels and diabetic retinopathy.
Methodology
Consecutive patients at the Diabetes Clinic at East Avenue Medical Center, diagnosed with Type 2 Diabetes Mellitus by the ADA criteria for diabetes from August 2019 to May 2020 were recruited. We excluded patients with pre-diabetes, Type 1 DM, diabetes induced by steroid use and other endocrine diseases, gestational diabetes, significant co-morbidities (cancer, COPD, decompensated heart/liver failure, ESRD on HD), kidney transplanted patients, renal artery stenosis, autoimmune kidney diseases and patients who undergone cataract or any retinal surgeries. Demographic, medical and laboratory data were obtained. Blood examinations were performed in the same diagnostic center by the same device. All recruited patients were examined by one retina fellow to prevent inter-observer variability.
Results
117 (67 with DR and 50 no DR) patients were analyzed. The mean age of patients with diabetic retinopathy was younger (55.73 + 8.18) than those patients without diabetic retinopathy (56.34 + 11.31) however the difference between the two groups was not statistically significant (P= 0.736). The mean serum uric acid level was 6.44 + 1.54 mg/dl in patients with DR whereas it was 6.10 + 1.59 mg/dl in those without DR. The levels however were not statistically significant (P=0.249). Using the binary logistic regression, duration of DM, presence of anemia as well proteinuria and low estimated glomerular filtration rate (eGFR) were independently associated with DR (P=0.006, 0.008, 0.012 and 0.037, respectively).
Conclusion
Serum uric acid levels were not associated with diabetic retinopathy, but it was shown in this study that there was a higher concentration of uric acid levels in patients with more severe retinopathy. Duration of diabetes, anemia, lower eGFR and presence of proteinuria reflecting chronic kidney disease were independently associated with the presence of diabetic retinopathy.

Sound mind at the expense of diabetes: olanzapine induced hyper-osmolar hyperglycaemic state (HHS) in acute setting

Patricia Kessy[1], Gideon Mlawa[2], Kirtanya Ramachandran[3], Barney Low[1,3], Belayet Hossain[3], Hassan Rehmani[3], Muhammad Saleem[1] & Janessa Bell[1]
[1]Queen's Hospital, Acute Medicine, London, United Kingdom; [2]Queen's Hospital, Diabetes and Endocrinology/Acute Medicine, London, United Kingdom; [3]Queen's Hospital, London, United Kingdom

Background
Second generation antipsychotics (SGAs) are increasingly playing a bigger role in the treatment of schizophrenia and other psychiatric conditions due to their lower extra pyramidal side effect profile However, SGAs are known to cause clinically relevant metabolic derangements including hyperglycaemia
Case
A 70-year-old gentleman was admitted with generalised weakness and increased urinary frequency (polyuria) and polydipsia. His blood glucose was noted to be significantly elevated (72.6 mmol/l) and was diagnosed with hyperosmolar hyperglycaemic (HHS) and other blood test revealed acute kidney injury. He was not acidotic on venous blood gas analysis; blood ketones were negative with normal bicarbonate. His background includes pre-diabetes (diet controlled type 2 diabetes), which was diagnosed in May 2021 after about 2 years of olanzapine exposure, Paranoid schizophrenia, Bronchiectesis, Chronic kidney disease and abdominal aortic aneurysm. He was on olanzapine started in 2018. HHS was probably triggered by being on Olanzapine. He was started on IV fluid replacement followed by insulin infusion. His medications include aspirin 75 mg od, furosemide 20 mg od, atorvastatin 40 mg od, omeprazole 20 mg od, olanzapine 7.5 mg od He made improvement clinically and his renal function was better following which his oral metformin as well as Gliclazide. Olanzapine was continued.
Discussion
The prevalence of diabetes in bipolar/schizophrenic patients is 10-15%. This is 2-3 folds that of general population (3.5-5%-Holt *et al* 2005. Diabetes and other metabolic risk factors contribute to increase rate of CVD. Life expectancy is reduced by 10-15 years in people with schizophrenia (Brown *et al* 200). Postulated mechanism of olanzapine induced hyperglycaemia include: increased appetite(dopaminergic), induction of weight gain, possible direct beta cell toxicity and pancreatitis, increased insulin resistance and decreased insulin sensitivity, 2-3-fold increased risk of diabetes in mental health patients as well as the role of prolactin in dysregulation of glucose. Ethnicity, family or personal history of diabetes poverty, urbanisation, poor diet, physical inactivity also contribute to hyperglycaemia. The time taken for clinical manifestations of hyperglycaemia varies from a few days to a few years.
Conclsion
Managing diabetes in patients with mental health problems can be challenging. It has to be integrated, MDT team (psychiatry and diabetology teams), use of cognitive behavioural therapy (CBT), use of motivational interview. NICE recommends screening for diabetes at baseline, 3-4 months after initiation of anti-psychotic and then annually.

DOI: 10.1530/endoabs.81.P117

P118

Association between hyperuricemia and degenerative complications of type 2 diabetes

Meriam Dalhoum, Zohra Hadj Ali, Bani Ines, Htira Yosra & Ben Mami Faika
National Institute of Nutrition, Department C, Tunis, Tunisia

Introduction
Hyperuricemia is associated with increased cardiovascular mortality and morbidity hence the interest in screening for hyperuricemia in the type 2 diabetic population.
Objective
To investigate the association between hyperuricemia and degenerative complications in type 2 diabetics.
Patients and Methods
This is a retrospective study including 130 patients followed in the C department of the National Institute of Nutrition in Tunis.
Results
The mean age of our patients was 61 ± 11 years, with a sex ratio M/F = 0.63. The average duration of diabetes was 14 ± 8 years. Obesity was present in 63.2% of patients. The incidence of hyperuricemia was 47.1% with a higher incidence in women: 54.4% of these patients were women vs 45.6% of men. In this population, microangiopathic and macroangiopathic degenerative complications were noted in 80.8% and 45% of cases respectively. For macroangiopathic complications, coronary artery disease topped the list with a frequency of 43.1%, followed by obliterative arteriopathy of the lower limbs with a frequency of 25.5% and finally stroke with a frequency of 3.9%. For microangiopathic complications, diabetic retinopathy was noted in 56.9% of cases. The frequency of diabetic nephropathy was 50%, of which 26.3% were at the stage of renal failure. The frequency of diabetic neuropathy was 38.5%. This analysis showed that hyperuricemia was significantly associated with macroangiopathic complications (P=0.06) and microangiopathic complications (P=0.049).
Conclusion
Our study showed a significant association between hyperuricemia and degenerative complications of type 2 diabetes.

Spondylodiscitis after diagnostic lumbar puncture in a post COVID -19, diabetic patient

Marjeta Kermaj[1], Tea Shehu[1], Jona Troshani[1], Violeta Hoxha[1], Klodiana Poshi[1], Dorina Ylli[1], Jonida Kito[2], Ermira Muco[3] & Agron Ylli[1]
[1]UHC 'Mother Tereza', Endocrinology, Tirana, Albania; [2]UHC 'Mother Tereza', Emergency Unit, Tirana, Albania; [3]UHC 'Mother Tereza', Infectious Disease Department, Tirana, Albania

Background
During the COVID-19 outbreak, there are rising concerns about long-term complications of COVID-19. On the other hand, discitis is a rare neurologic diagnosis, often delayed or missed due to the rarity of the disease. Patients usually present at an average age of 69 years with a history of diabetes or with a systemic infection. The lumbar spine is the most frequent site of infection (54%), and the cervical is the least at 10%. This is a case of post-COVID-19, diabetic patient complicated by discitis after a lumbar puncture.
Case presentation
A 77 years old patient presented in our emergency unit with intermittent temperature, headache and nuchal rigidity. Medical history: Patient was diagnosed with Diabetes Mellitus and hypertension 5 years ago. He was being treated with Metformin and antihypertension drugs. He was diagnosed with COVID-19, two months ago, since then he has had temperature between 38-39°C. Laboratory analysis: hyperglycemia and hypoalbuminemia, in haemogram:

microcytic hypochromic anemia and neutrophilic leukocytosis. CRP(C Reactive Protein) and D-dimer were very high (22 mg/dl and 4 times normal range respectively). Kidney, liver and thyroid gland function resulted normal. In cranio-thoracal CT: Large multinodular thyroid gland with calcified nodules that slightly compressed trachea. Head and thorax normal. A diagnostic lumbar punction was obtained but the result excluded meningitis. Because of disequilibrated diabetes and need for thyroid exploration, the patient was hospitalized in Endocrinology Department where insulin, antibiotics (ceftriaxone and moxifloxacine), antic-oagulation therapy and human albumin were started. After being hospitalized he complained a severe lumbar pain. CRP firstly, started to fall but then started to raise (10 days later even on antibiotic therapy, CRP was 18 mg/dl again), and immediately CT and then MRI with contrast were performed and confirmed presence of L2-L3 spondylodiscitis. ASLO, C3, C4, RF, and tumoral markers were normal. Infectionist changed antibiotic therapy to Imipenem and Ciprofloxacine,10 days later, CPR level decreased to 6.6 mg/dl, but lumbar pain persisted even under painkiller. Sub febrile temperature kept persisting also. Our patient also achieved better glycemic control under basal-bolus insulin regimen but inflammatory parameters (PCR, D-dimer and Fibrinogen) remained high and actually he is transferred to local hospital for further treatment with intra venous antibiotics.

Conclusion

Post-covid-19 diabetic patients who are imunocompromised, are in higher risk of developing serious infections (like spondylodiscitis) even after diagnostic procedures like lumbar spine diagnostic puncture. Physicians must be careful to prevent.

P311

Oxidative stress decreased after six months testosterone treatment compared to placebo in ageing men – a randomized, double-blind trial

Louise Lehmann Christensen[1], Marianne Andersen[1], Henrik Enghusen Poulsen[2] & Dorte Glintborg[1]
[1]Odense University Hospital, Endocrinology, Odense, Denmark; [2]Rig-shospitalet, Pharmacology, Copenhagen, Denmark

Background

High oxidative stress is associated with increased morbidity. The effect of testosterone treatment (TT) on oxidative stress in ageing men with reduced bioavailable testosterone is undetermined.

Aim

To determine the effect of TT compared to placebo on oxidative stress biomarkers.

Methods

Double-blinded, placebo-controlled study in 38 men, aged 60–78 years, with bioavailable testosterone <7.3 nmol/l and waist circumference $\geq$ 94 cm, randomized to six-month testosterone gel therapy ($n=20$) or placebo ($n=18$). Whole body oxidative stress was assessed at baseline and after 6 months therapy by measuring 24-h urine oxidized derivatives of nucleic acids: 8-oxoguanosine (8-oxoGuo) and 8-oxo-2'-deoxyguanosine (8-oxodG) by ultra-performance liquid chromatography tandem mass-spectrometry. Fat and lean mass were measured by whole body dual x-ray absorptiometry. Changes between TT and placebo groups were compared using Mann-Whitney test. Δ-values for clinical and biochemical markers were calculated as 6 months minus pretreatment level. Bivariate associations of Δ-values of clinical and biochemical data were investigated by Spearman's Rho correlational analyses. Linear regression analysis was used to adjust for changes in body composition. P-value of < 0.05 was considered significant.

Results

At baseline, median (interquartile range) age was 67 (64-72) years, BMI 29.8 (26.6-33.3 kg/m2, total testosterone 12.6 (8.9-16.1) and bio-available testosterone 4.7 (3.7-5.9) nmol/l. Levels of 8-oxodG/24h decreased during TT compared to placebo ($P=0.038$). Δ8-oxoGuo/24h was inversely associated with Δ-total testosterone ($\rho=$-0.35, $P=0.04$) and Δ-bio-available testosterone ($\rho=$-0.37, $P=0.03$). Δ-8-oxoGuo/24h and Δ-8-oxodG/24h were associated with Δ-fat mass ($\rho=0.47$, $P=0.006$ and $\rho=0.40$, $P=0.02$, respectively). Δ-8-oxodG/24h was inversely associated with Δ-lean mass ($\rho=$-0.38, $P=0.03$). In linear regression analyses. The inverse association between Δ-oxidative stress biomarkers and Δ-total testosterone remained significant after adjustment for Δ-fat mass and Δ-lean mass.

Conclusion

Oxidative stress biomarkers decreased during six-month TT compared to placebo in ageing men.

DOI: 10.1530/endoabs.81.P311

Gastric dysmotility in diabetes

Irodakhon Inoyatkhodjaeva
Center of Endocrinology, Tashkent, Uzbekistan

The prevalence of diabetes is growing every year. One of the important complications of diabetes is the effect of diabetes on the gastrointestinal tract. Purpose of the study: to identify the frequency of delayed gastric emptying in patients with diabetes.

Materials and methods

122 patients with type 2 diabetes were examined for complaints from the upper gastrointestinal tract. For this, the GCSI questionnaire was used. After a thorough clinical, laboratory and instrumental examination, 34 patients were excluded. The remaining 88 patients underwent gastric scintigraphy to determine the motor-evacuation function of the stomach.

Results

A comprehensive examination was carried out of 88 patients with type 2 diabetes mellitus All patients were divided into three groups depending on the age of diabetes: the first group (up to 5 years) - 23 people (27.27%), the second (6-10 years) - 26 (29.5%), the third (more than 11 years) –39 people (43.2%). The average age was 52.8 $\pm$ 6.51 years. Clinical and metabolic compensation of diabetes (HbA1c $<7\%$) was observed in 12 people (13.6%), decompensation of carbohydrate metabolism - in 76 people (86.4%). A labile course of diabetes mellitus was observed in 19 people (11.36%). Dynamic scintigraphy revealed the following data. Accelerated intake of the first portions of Tc into the intestines was observed more often in 37 people (42.3%), in 27 people (30.76%) - there was a delayed intake, in 4 patients (3.84%) - normal. Gastroesophageal reflux was observed in 27 people (30.7%), and duodenogastric reflux in 4 patients (3.84%). The time of maximum accumulation of Tc in the stomach, was slow in most patients in all three groups. In 15.9% of patients there were no complaints from the organs of the gastroduodenal zone, while 80% of them had a delayed motor-evacuation function of the stomach (T1 / 2av = 81.2 min), in 20% - within normal limits. Mathematical modeling with the construction of 3D graphs made it possible to identify the relationship between the motor-evacuation function of the stomach, the duration of diabetes and the presence of hypoglycemia, namely, with an increase in T1 / 2 (stagnation of food in the stomach), the frequency of hypoglycemia increases, and with an increase in the duration of diabetes, evacuation is even more delayed test breakfast from the stomach.

Conclusion

A comprehensive and targeted examination of 88 patients with type 2 diabetes mellitus showed a high prevalence of pathology of the gastrointestinal tract.

Obesity and obesity-related diseases as a new clinical features in 3q27.3 microdeletion syndrome involving adipoq gene: a case study

Davide De Brasi[1], Vincenzo Novizio[1], Livia Barba[1], Elisabetta Scarano[1], Domenico Serino[1], Roberto Novizio[1], Matteo Della Monica[2], Roberta Petillo[2] & Francesco Scavuzzo[1]
[1]Azienda Ospedaliera di Rilievo Nazionale 'Antonio Cardarelli', Unit of Endocrinology and Diabetes, Naples, Italy; [2]Azienda Ospedaliera di Rilievo Nazionale 'Antonio Cardarelli', Genetics, Naples, Italy

Introduction

Adipose tissue is recognized as an important endocrine organ, secreting many endocrine factors. Adiponectin is the most abundant peptide released into circulation, encoded by ADIPOQ gene localized in chromosome 3q27.3. Adiponectin decreases intracellular ceramide, implicated in insulin resistance, inflammation and atherosclerosis. It stimulates fatty acid oxidation in skeletal muscle and inhibits glucose production in the liver. Hypo-adiponectinemia plays a central role in obesity and obesity-related disease. Since the advent of Comparative Genomic Hybridization Array (CGH-Array), numerous new microdeletional syndromes have been described. Few cases of autosomal dominant 3q27.3 microdeletion syndrome have been described, mostly characterized by intrauterine growth retardation, marfanoid habitus, cranio-facial

dysmorphism, intellectual disability, psychosis and mood disorder. We describe a family affected by 3q27.3 microdeletion involving ADIPOQ gene, adding obesity and obesity-related disease to constellation of major clinical findings reported in 3q27.3 microdeletion syndrome.
Case Study
A 21-year-old Caucasian male underwent genetic investigation by CGH-Array during a diagnostic study for familiar schizoid-type personality disorder, cognitive delay, macrocephaly and thickening of skull cap. Array analysis revealed a 1.43-Mb deletion in the long arm of chromosome 3 (3q27.3), including ADIPOQ gene and other two OMIM disease genes (KNG1 and BCL6). The analysis was then extended to parental couple, demonstrating the paternal origin of the rearrangement. Afterwards, same microdeletion was demonstrated in his 26-year-old sister. Deletions were confirmed by fluorescent *in situ* hybridization. All family members shared a complex syndromic clinical spectrum consisting of severe neuropsychiatric impairment, schizoid-type personality disorder, cognitive delay and thickening of skull cap, signs compatible with other clinical findings reported in literature for 3q27.3 microdeletion. No marfanoid habitus was reported, even though all had history of ligament laxity-related disorders. All three members of the family shared moderate-severe hyperphagia, early central obesity, marked hyperinsulinemia, obstructive sleep apnea syndrome, arterial hypertension, dyslipidemia and hepatosplenomegaly with hepatic steatosis, composing a new syndromic frame in the context of 3q27.3 microdeletion syndrome.
Discussion
This new clinical spectrum associated with 3q27.3 microdeletion involving ADIPOQ gene reinforce a suggested role of adiponectin haploinsufficiency in central obesity, atherogenic metabolic status, fat accumulation in the liver and dyslipidemia. A possible role of adiponectin on food intake at hypothalamic level is also suggested. The involvement of adjacent loci and genes, such as OMIM genes, may contribute to these novel features in 3q27.3 microdeletion syndrome. The fewer number of bases involved, 1.43-Mb vs >5-Mb described in literature, could explain the absence of some syndromic features.

Diabetes and cervical pathologies: The phenotype and genotype connection

Prakhar Gupta[1,2], Shivani Bhadauria[3] & Bushra Khanam[4]
[4]L.N. Medical College, Internal Medicine, Bhopal, India; [2]William Harvey Research Institute, Endocrinology, United Kingdom; [3]Government Medical College, Ratlam, India; [4]Index Medical College, Hospital & Research Center, Indore, India

Cervical cancer is the fourth most common cancer among women globally and second most common in India. As per WHO, almost 90% of new cases and deaths worldwide, occurred in low to middle income countries in 2020. More than 95% of cervical cancers are associated with chronic Human papilloma virus infection (HPV), particularly of the types 16 and 18. High income countries have vaccination and screening programs that are in place for young girls but low-and middle-income countries usually do not have access to such facilities. Another disease that is increasing in incidence and prevalence in such populations is diabetes mellitus. Diabetes is known to be associated with increased incidence of various cancers like endometrial, cervical, breast, stomach and pancreas. It is also observed that cancer patients with diabetes have an overall reduced survival as compared to non-diabetics. We undertook this study to observe frequency and pattern of cervical pathologies (using routine pap smear) among diabetic females from reproductive age group and compared them with non-diabetic females. The idea was to observe if diabetic females have higher prevalence of cervical pathologies which might progress to cervical cancer in future. We found that diabetes was associated with higher occurrence of cervical pathologies like cervicitis (Odd's Ratio 10.9), vaginitis (OR 1.23), HPV infection (OR 1.4) and malignant changes (OR 1.52). We then attempted to find genetic association between diabetes and cervical pathologies to determine if there are overlapping predisposing genes that can explain higher preponderance of diabetics towards cervical pathologies. This was done by applying gaussian mixture modelling on available genetic data for diabetes mellitus (types 1 and 2), chronic HPV infection, cervical intra-epithelial neoplasia (CIN) and cervical cancer. Some MHC loci like HLA-DQA1, HLA DQB1 were found to be overlapping, which was expected. Apart from MHC genes, certain genes showed positive association with both spectrums (diabetes and cervical pathologies) like INS-IGF2, TTC7B, SILC1. The genetic association may help in understanding the connection between the two diseases in a better way and may also help in predicting higher chances of cervical pathologies in populations with higher preponderance towards upregulation of such genes.

Participation in Diabefly® digital therapeutics program leads to significant improvement in glycemic control and reduction in weight and BMI among people with T2D

Ritika Verma[1], Mohammed Khader[2], Tejal Lathia[3], Snehal Tanna[4], Amit Saraf[4], Piya Ballani Thakkar[5], Vivek Raskar[6], Chitra Selvan[7], Saimala Guntur[8] & Arbinder Singal[9]
[1]Fitterfly Healthtech Pvt Ltd, Scientific writing and Research, Navi Mumbai, India; [2]Fitterfly Healthtech Pvt Ltd, Department of Scientific Writing and Research, Navi Mumbai, India; [3]Apollo Hospital, Department of Endocrinology and Diabetology, Navi Mumbai, India; [4]Jupiter Hospital, Department of Endocrinology and Diabetology, Mumbai, India; [5]Bombay Hospital, Department of Endocrinology and Diabetology, Mumbai, India; [6]Dr Raskar's Diabetes Clinic, Department of Endocrinology and Diabetology, Mumbai, India; [7]MS Ramaiah Memorial Hospital, Department of Endocrinology and Diabetology, Bangalore, India; [8]Fitterfly Healthtech Pvt Ltd, Department of Operations, Navi Mumbai, India; [9]Fitterfly Healthtech Pvt Ltd, Chief Executive Officer, Navi Mumbai, India

Background
People with chronic metabolic conditions such as type 2 diabetes (T2D) encounter challenges with self-management regimens to improve their glycemic control, weight and as well as to reduce complications associated with diabetes. Optimal management of T2D requires regular monitoring by physician, access to multidisciplinary care and achieving target HbA1c without hypoglycemia. Digital therapeutics (DTx) provide highly accessible, cost-effective, evidence-based solutions for better management of T2D using high-quality software. This study explores the real-world effectiveness of the Diabefly® DTx program in improving glycemic control among people with T2D.
Methodology
The 90 days Diabefly® program offers mobile application enabled real-time digital logging of daily meals, physical activity, and provides access to remote lifestyle coaching from health coaches and experts (psychologist, physiotherapist, and nutritionist). The aim of the study was to evaluate the changes in HbA1c, weight, body mass index (BMI) and waist circumference at the beginning and at the end of the program. All the outcomes were evaluated using paired t-test with $P < 0.05$ considered as significant.
Results
De-identified data of 205 participants (Mean age: 47.14 $\pm$ 12.67 years, Gender: 55.60% female) was analyzed. After the completion of the Diabefly® program, a significant mean reduction in HbA1c by 1.55 $\pm$ 1.88% ($P < 0.001$) from the baseline of 8.59 $\pm$ 2.01 % was observed. HbA1c levels were reduced in 87.80 % (180/205) participants while reduction of >1% in HbA1c levels was observed in 56.11 % (101/180) participants. A significant mean reduction in body weight and BMI by 2.39 $\pm$ 3.25 kg and 0.82 $\pm$ 1.14 kg/m^{2}from the baseline of 75.33 $\pm$ 15.43 kg and 27.41 $\pm$ 4.68 kg/m^{2}was observed respectively ($P < 0.001$ for both). Reduction in body weight was observed in 68.29 % (140/205) participants and a reduction of >5 kg body weight was observed among 20.71 % (29/140) participants. Furthermore, complete data on waist circumference was available for 109 participants which showed a significant mean reduction by 3.49 $\pm$ 8.24 cm from the baseline of 98.80 $\pm$ 14.08 cm ($P < 0.001$).
Conclusion
At the end of the program, a significant improvement in glycemic control and reduction in weight and BMI was observed. Thus, the study showed that usage of the Diabefly®program along with standard medical care by a physician can be effective in better management of T2D by providing multidisciplinary care and continuous support to people with diabetes.

Simultaneous pancreas-kidney transplantation: long-term survival and metabolic profile analysis among functioning pancreatic graft patients – A 20 year experience from a center in Portugal

Ariana Maia[1], Miguel Saraiva[1], Inês Sala[2], Daniela Soares[1], Diana Borges Soares[1], Sílvia Monteiro[1], Joana Vilaverde[1], Lia Ferreira[1], La Salete Martins[2] & Jorge Dores[1]
[1]Centro Hospitalar Universitário do Porto, Serviço de Endocrinologia, Diabetes e Metabolismo, Porto, Portugal; [2]Centro Hospitalar Universitário do Porto, Serviço de Nefrologia, Porto, Portugal

Introduction
Simultaneous pancreas-kidney transplantation (SPKT) is the treatment of choice for type 1 diabetic patients with advanced kidney chronic disease (CKD), restoring normoglycemia, insulin independence and improving survival. The

present study aims to analyse survival of patients undergoing SPKT and the post-SPKT metabolic profile of patients with a functioning pancreatic graft.
Methods
Retrospective observational study. T1DM patients with CKD stages 4-5 KDIGO undergoing SPKT at Centro Hospitalar Universitário do Porto from May 2000 to November 2020 were included. Pre-SPKT baseline data collection. Survival analyses were performed using Kaplan-Meier method. Metabolic profile of patients with a functioning pancreatic graft was secondarily investigated in the latest post-SPKT medical visit.
Results
242 patients were included with a mean age at SPKT of 35.4 ± 6.1 years, mean duration of DM and dialysis of 24.1±5.9 years and 25.8±19.5 months, respectively. Patients had mean values of HbA1c, total daily insulin dose (TDID) and BMI of 8.5±1.6 %, 38.8 ± 12.5 U/day and 22.4 ± 2.8 kg/m2 pre-SPKT. Cumulative patient survival was 96.3%, 94.4%, 90.1%, 83.4%, and 80.6% at 1, 5, 10, 15, and 20 years post-SPKT. Pancreatic graft survival of 85.5%, 79.4%, 74.5%, 65.0% and 61.8% at 1, 5, 10, 15 and 20 years. Renal graft survival of 93.8%, 88.6%, 80.1% and 73.5% at 1, 5, 10 and 20 years. The main causes of failure were graft rejection and thrombosis. The metabolic profile of the individuals analysed at the most recent post-SPKT consultation included 178 patients with functioning pancreatic graft, with a mean follow-up of 9.3±5.2 years post-SPKT, and of these, 94.4% with functioning renal graft. Mean BMI, creatinine clearance, C-peptide, HbA1c, LDL-cholesterol and non-HDL-cholesterol were 23.7±4.0 Kg/m2, 63.8±21.2 ml/min/1,73 m^2, 3.1±2.0 ng/ml, 5.6±0.7%, 89.0±35.3 mg/dl and 111.3±40.0 mg/dl. Intermediate hyperglycaemia was present in 29.8% of patients and 5.1% had HbA1c ≥ 6.5%.
Conclusion
Results of our center reinforce SPKT as a valid option in the treatment of T1DM, aiming to improve quality of life, with sustained maintenance of euglycemia, without the need for exogenous insulin, in the medium/long term within a selected group of patients with advanced diabetic kidney disease.
Keywords
Type 1 diabetes mellitus, simultaneous pancreas and kidney transplantation, transplant, transplantation, chronic complications of diabetes, metabolic profile.

Changing trends in the aetiology of diabetes-related ketoacidosis(DKA)-a blueprint to identify preventable causes

Dineshwaran Rajendran[1], Catherine Cooper[2], Wai Nga Alice Yip[3], Gobeka Ponniah[3], Anjitha Anilkumar[3], Dengyi Zhou[3], Shamanth Soghal[4], Parijat De[5] & Haaziq Sheikh[6]
[1]Good Hope Hospital, Acute Medicine, The Royal Town of Sutton Coldfield, United Kingdom; [2]Walsall Manor Hospital, Walsall, United Kingdom; [3]University of Birmingham Medical School, United Kingdom; [4]Queen Elizabeth Hospital Birmingham, United Kingdom; [5]Sandwell General Hospital, United Kingdom; [6]Haberdashers' Adams' Grammar School, United Kingdom

Introduction
Diabetes-related Ketoacidosis (DKA) is a commonly-encountered acute endocrine emergency requiring prompt recognition and treatment. DKA is triggered by risk factors that are often preventable. There are limited studies evaluating the precipitating causes of DKA and depicting their trends over the years. The latter is important in the prevention of DKA by ensuring appropriate education and interventions.
Aim
To study the trends of aetiologies that precipitate DKA over the years.
Methods
We conducted a retrospective analysis of all DKA related admissions across six regional hospitals in the United Kingdom between April 2014 to November 2021. DKA was diagnosed as serum glucose ≥11 mmol/l, ketones ≥ 3 mmol/l and pH ≤7.3 or bicarbonate ≤ 15 mmol/l. Precipitating factors were classified as Alcohol-related, COVID-19, Drug-induced, Intercurrent illness, New Diagnosis of type-1 diabetes, SGLT-2 inhibitor-associated, Sepsis, Suboptimal compliance to treatment and Trauma respectively. Statistical analysis was done using SPSS version 27. Results are expressed in percentage and proportion.
Results
A total of 1463 DKA episodes were included in the analysis. Intercurrent illness (34.8%, $n=509$) and Suboptimal compliance to treatment (28.2%, $n=413$) were the most common factors identified. Other notable causes of DKA were: New diagnosis of type 1 diabetes (8.9%$n=130$), Sepsis (4.2%, $n=62$), Alcohol-related (3.9%, $n=57$). The proportion of these aetiologies has remained consistent over the years. Newer varieties of precipitating causes such as SGLT2 inhibitor-associated (1.3%, $n=19$) and other Drug-induced (1.1%, $n=16$) had an increasing trend since 2019. COVID-19 accounted for 5% of the total episodes ($n=41$). Precipitating aetiology was unclear in 8%($n=187$) of the DKA admissions. However, the proportion of unclear causes as precipitating aetiology for DKA has been steadily down trending since 2016 (24.0% in 2016, 19.2% in 2017, 14.5% in 2018, 16.2% in 2019, 12.6% in 2020 and 8.0% in 2021)
Conclusion
Infections and Suboptimal compliance to treatment accounted for a majority of 63% of the DKA cases, suggesting more work needs to be done to minimize these preventable causes. A rise in medication-induced DKA prompts the need to educate patients and clinicians to be aware of the role of these contributory medications. Down trending seen in Unclear Causes of DKA is a welcome result as this can help us prevent recurrences in patients by educating them regarding the known or established precipitating factors so that they could be vigilant in regards to these in future.

Effect of treatment of gestational diabetes mellitus with insulin on pregnancy outcomes

Olfa Lajili, Aroua Temessek, Rim Rachdi, Yosra Htira & Feika Ben Mami
National Institute of nutrition of Tunis, The Research Unit of GDM (Department C), Tunis, Tunisia

Introduction
Gestational diabetes mellitus (GDM) complicates approximately 3% to 9% of pregnancies. Diagnosis and treatment of GDM remain essential to limit maternal and neonatal outcomes. The aim of the study was to evaluate the difference in pregnancy outcomes between insulin- and diet-treated tunisian women with gestational diabetes.
Methods
It was a prospective longitudinal study including 220 patients followed for GDM at the research unit of the C department of the national institute of nutrition in Tunis. The patients were followed during pregnancy and until post partum. Patients were divided into two groups: group 1 (G1): Insulin treated and insulin therapy and group 2 (G2): Patients treated by diet alone.
Results
At the end of our study, 68 patients were treated with insulin, 11 patients developed gestational hypertension or pre-eclampsia. Two thirds of the patients (68%) delivered by cesarean section. Neonatal outcomes were dominated by macrosomia (13.5%) and transient respiratory distress (11.4%). insulin-treated patients had a higher incidence of gestational hypertension (G1: 11.9% vs G2: 2.1%;$P=0.03$). insulin treatement did not reduces the rate of caesarean section (G1: 64.7% vs G2: 63.2%;$P=0.785$). Insulin therapy did not reduce fetal outcomes, including intrauterine growth retardation (G1: 0% vs G2: 1.3%;$P=0.326$), fetal death in utero (G1: 0% vs G2: 1.3%;$P=0.306$), neonatal hypoglycemia (G1: 0% vs G2: 1.3%;$P=0.333$), macrosomia (G1: 17.6% vs G2: 11.2%;$P=0.203$), hydramnios (G1: 13.2% vs G2: 6.6%;$P=0.111$), transient respiratory distress (G1: 11.8% vs G2: 10.5%;$P=0.781$), neonatal jaundice (G1: 5.9% vs G2: 3.3%;$P=0.787$) and prematurity (G1: 7.4% vs G2: 4.6%;$P=0.452$).
Conclsion
Our study showed that patients treated with insulin had a higher incidence of pregnancy induced-hypertension. However, treatment of gestational diabetes with insulin did not reduces the rate of caesarean section and noenatal morbidity.

Feeding and DKA resolution

Elaine Louise Fernandez & Maria Jocelyn Isidro
Makati Medical Center, Medicine, Makati, Philippines

Background
Diabetic ketoacidosis (DKA) is a complication of Diabetes Mellitus and is a life-threatening medical emergency usually requiring admission to an intensive care unit. There is no established guideline regarding timing of initiation of oral/enteral feeding in DKA patients.
Purpose
To determine if there is a difference in clinical outcomes for DKA patients whose oral/enteral feeding was started early vs patients whose feeding was started beyond 24 hours.
Methods
A 10-year retrospective observational cohort was conducted in a single medical center. Subjects consisted of DKA patients admitted in the Intensive Care Unit.

Clinical outcomes were compared among DKA patients who were fed within 24 hours of admission (early feeding) vs those fed beyond 24 hours (late feeding). Primary outcome was DKA resolution. Secondary outcomes were Anion gap closure, Length of hospital stay, Length of ICU stay, and inpatient Mortality.
Results
A total of 68 patients were included in the study – 39 in the early feeding group and 29 in the late feeding group. Baseline characteristics, classification of Diabetes, DKA severity, and complications were comparable among the two groups. The odds of early DKA resolution or resolution of DKA within 24H was 4.8x higher in early feeding group compared to the late feeding group (95% C.I.: 1.2 – 19.6). Time to DKA resolution, time to anion gap closure, and length of hospital stay were also significantly shorter for the early feeding group. There was no significant difference in the ICU length of stay and inpatient mortality between the two groups. The power of the study is 87.34%.
Conclusion
DKA patients benefit from early feeding because it significantly shortens time to DKA resolution and anion gap closure, also length of hospital stay, without significant increase in the rate of DKA complications. Early feeding is also associated with DKA resolution within 24 hours.

Differences in diabetic neuropathy in type 1 and type 2 diabetes mellitus

Laura Šiauliene[1,2], Ieva Sereike[3], Juozas Rimantas Lazutka[1] & Zydrune Visockiene[2,4]
[1]Life Sciences Center, Institute of Biosciences, Vilnius University, Vilnius, Lithuania; [2]Vilnius University Hospital Santaros Klinikos, Center of Endocrinology, Vilnius, Lithuania; [3]Vilnius University Hospital Santaros Klinikos, Center of Neurology, Vilnius,; [4]Institute of Clinical Medicine, Clinic of Internal Diseases, Family Medicine and Oncology, Vilnius University Faculty of Medicine, Vilnius, Lithuania

Background
Diabetic neuropathy (DN) is the most common chronic diabetes complication in type 1 (T1DM) and type 2 (T2DM) diabetes mellitus. Due to diagnostic issues, it is the least studied complication with limited and controversial data about the differences of various types of DN between T1DM and T2DM patients.
Aim
To evaluate the differences of diabetic polyneuropathy (DPN) and cardiac autonomic neuropathy (CAN) - between T1DM and T2DM patients.
Materials and Methods
Three methods were used to evaluate DPN: clinical examination was done using neuropathy symptom score (NSS) and neuropathy disability score (NDS); neurometry (NM) – using Neurometer NervScan™ LLC device; electroneurography (ENG) – using Nihon Kohden Neuropack M-1 Electromyogram Machine. CAN was assesed by performing cardiovascular autonomic reflex tests (CARTS) using Cardiosys Extra MDE diagnostic device.
Results
There were 53 T1DM and 63 T2DM patients enroled in to the study. T1DM patients were significantly ($P<0,05$ for all) younger (41,6 $\pm$ 15,9 vs 60,0 $\pm$ 11,7 years), had lower BMI (23,5$\pm$3,5 vs 36,0$\pm$6,32 kg/m2), systolic and diastolic blood pressure (124,5$\pm$16,3 vs 138,7$\pm$13,7 and 74,2$\pm$8,9 vs 80,5$\pm$8,3 mmHg respectively), incidence of arterial hypertension (35,8% vs 90,5%), heart failure (3,8% vs 20,6%) and coronary artery disease (5,7% vs 20,6%). T2DM patients had significantly higher scores of symptomatic neuropathy compared to T1DM (NSS 4,3 $\pm$ 3,3 vs 3,1$\pm$3,4; $P<0,049$), but the severity of pain, evaluted by self reported numerical rating scale did not differ (1,8 $\pm$ 2,5 vs 1,4 $\pm$2,5, $P=0,17$). The prevalenceof DPN did not differ between the groups, however the proportion of DPN depended on method used, being the highest diagnosed with NM (67,3% vs 61,3%, $P>0,05$), followed by ENG (40,9% vs 44,1%, $P>0,05$) and clinical examination (30,2% vs 35,5, $P>0,05$). Tuning fork vibration perception was the only test of clinical evaluation that showed significantly worse vibration perception in T2DM patients compared with T1DM (impaired in 78,3% vs 57,1%, $P=0,023$), CARTs showed significantly higher incidence of CAN in T2DM compared to T1DM patients (67,3% vs 32,7%, $P=0,011$).
Conclusions
There was no difference in the prevalence of DPN between T1DM and T2DM, however significant difference in diagnostic accuracy of different methods was observed. T2DM patients were more likely to have symptomatic polyneuropathy, large fiber damage and CAN.

Effect of a novel-app based strategy for carbohydrate counting on glucose control in type 1 diabetes

Silvia Irina Briganti[1], Rocky Strollo[2], Daria Maggi[2], Shadi Kyanvash[2], Oreste Lanza[2], Silvia Manfrini[2] & Paolo Pozzilli[2]
[1]Campus Bio-Medico of Rome, Metabolic Diseases, Rome, Italy; [2]Campus Bio-Medico of Rome, Metabolic Diseases, Rome, Italy

Background
carbohydrate counting is often performed inaccurately by patients with type 1 diabetes (T1D). We hypothesized that mobile App 'Dietrometro', that estimates CHO content of food figures, would ameliorate glucose control.
Aim
To study the effect of 'Dietometro' on glucose control.
Methods
54 T1D subjects (aged 18-60 years, 26 males), on multiple daily injections ($n=23$) or continuous subcutaneous insulin infusion ($n=31$), were randomly assigned to three groups: no counting (group 1; $n=19$), 'self-managed' counting (group 2; $n=19$) and App-assisted counting (group 3; $n=16$). Outcomes were one- and three months follow-up TIR (time in range), TAR (time above the range) and TBR (time below the range), estimated by flash or continuous glucose monitoring, and HbA1c.
Results
At the baseline TIR were similar between groups, while HbA1c was lower in group 3 compared to group 1 (6.9$\pm$1.06 vs. 7.8$\pm$0.85%; $P<0.05$). At one-month follow-up, TIR was higher in group 2 and 3 compared to group 1 (63.58 $\pm$ 11.55 vs. 52.32 $\pm$ 13.22%; $P=0.014$, and 71.25 $\pm$ 9.75 vs. 52.32 $\pm$ 13. 22%, respectively; $P<0.001$). TAR at one-month follow-up was significantly lower in group 3 (31.25 $\pm$ 19.18 vs. 22.31 $\pm$ 10.89%; $P<0.001$), while no differences were observed in TBR. At three-months follow-up, groups 2 and 3 had a lower HbA1c than group 1 (7.16 $\pm$ 0.647 vs. 6.56 $\pm$ 1.91 vs. 7.96 $\pm$ 1.0%; $P<0.05$).
Conclusions
App-assisted CHO counting might improve glucose control. Larger sample size and longer follow-up are needed to define the long-term effect of this system.

Higher levels of psychological stress are associated with lower levels of the insulin sensitizer FGF-21 in patients with obesity

Susanne Kuckuck[1,2], Robin Lengton[1,3], Eline S van der Valk[1,2], Anand M Iyer[1,2], Mostafa M Mohseni[1,2], Sjoerd A A van den Berg[2,3] & Elisabeth van Rossum[1,2]
[1]Erasmus Medical Center Rotterdam, Department of Internal Medicine, Division of Endocrinology, Rotterdam, Netherlands; [2]Erasmus Medical Center Rotterdam, Obesity Center CGG, Rotterdam, Netherlands; [3]Erasmus Medical Center Rotterdam, Department of Clinical Chemistry, Rotterdam, Netherlands

Background
Altered signaling of hormones regulating appetite and metabolism is often observed in individuals with obesity (BMI $\geq$ 30 kg/m^2) and related diseases, potentially resulting in increased hunger signaling and metabolic dysfunctions. Previous research indicates that such disturbances may be induced by weight gain itself, but also by other factors such as glucocorticoid excess (e.g. due to stress). However, knowledge regarding the associations between hormonal appetite signals and biological or psychological measures of stress is still limited, particularly in patients with obesity.
Methods
Data were collected from 68 patients with obesity (47 women). We assessed psychological stress perceived over the last month (via the Perceived Stress Scale (PSS)-14, ranging from 0 to 56) and biological stress (using the average of 24h urine cortisol levels of two consecutive days). In addition, we measured overnight-fasted serum levels of the hormonal appetite regulators leptin, insulin, adiponectin, FGF-21, PP, GIP, PYY, CCK and AgRP (pg/ml). To investigate cross-sectional associations between psychological/biological stress and hormonal appetite regulators, we used linear regression analysis with PSS-14 scores or urine cortisol levels as predictors, adjusted for pre-defined potential confounders (age and sex).

Results
There was a negative association between PSS-14 scores and log10-transformed FGF-21 levels (β = -0.015 (-0.028; -0.003 95% CI), $P < .05$) which persisted after adjustment for the potential confounders (β = -0.015 (-0.029; -0.001 95% CI), $P < .05$). We did not see any other associations of hormonal appetite regulators with PSS-14 scores, nor with 24h urine cortisol levels.
Conclusion
A 1-point increase on the PSS-14 score was associated with a 3.4% decrease in serum levels of the insulin sensitizer FGF-21. In patients with obesity, FGF-21 levels are often increased compared to normal weight controls, probably to compensate for metabolic challenges associated with the disease. We hypothesize that chronic stress may interfere with FGF-21 actions in these patients by decreasing FGF-21 levels; resulting in a failure to compensate for metabolic challenges. Future studies should further investigate the directionality of this association and its potential implications for eating behaviour and the development of metabolic disorders such as type 2 diabetes.

Sleep quality in patients with type 1 diabetes: a large cross-sectional study

Claudio Bongiorno[1], Simona Moscatiello[2], Gilberto Laffi[2], Danilo Ribichini[2], Valentina Lo Preiato[2], Michele Grimaldi[2], Uberto Pagotto[1] & Guido Di Dalmazi[1]
[1]Alma Mater Studiorum - Università di Bologna, Bologna, Italy; [2]S. Orsola-Malpighi Polyclinic, Bologna, Italy

Background
Altered sleep quality and duration have been reported in 26-67% of patients with type 1 diabetes (T1D). However, differences in study designs, populations, and methods of sleep quality assessment have led to heterogeneous results in terms of association with clinical data and blood glucose parameters.
Aims
To investigate the sleep quality of a large cohort of adult patients with autoimmune diabetes under insulin treatment, and to analyze the relationship with clinical and biochemical data.
Methods
We administered the Pittsburgh Sleep Quality Index (PSQI) questionnaire to 553 adult subjects (>18 years) with T1D or latent autoimmune diabetes of the adult (LADA). We excluded 44 patients without clinical data. Patients were also administered additional questionnaires: Diabetes Distress Scale (DDS), Diabetes-Related Quality Of Life (DRQOL), Diabetes Treatment Satisfaction Questionnaire (DTSQ), and Hypoglycemia Attitudes and Behavior Scale (HABS). We retrieved biochemical and clinical data at the time of the PSQI administration (+/- 4 months). Glucose metrics up to 3 months before PSQI administration were analyzed in 183/329 patients under continuous glucose monitoring (CGM).
Results
PSQI questionnaires had complete data in 465 patients. Altered sleep quality (PSQI score >5) was detected in 150/465 subjects (32.3%). Short sleep duration (< 7 hours) was detected in 181/465 patients (38.9%). PSQI score was higher in females *vs* males (5.3 ± 4.3 *vs* 4.7 ± 2.9; $P=0.031$), with higher values of sleep latency ($P=0.010$), sleep disturbances ($P=0.001$), and daytime dysfunction ($P<0.001$). No difference in PSQI score were detected between patients under multiple daily injections ($n=390$) and insulin pump ($n=75$; $P=0.412$), and among subjects under self-monitoring of blood glucose ($n=159$), intermittently-scanned CGM ($n=221$) and real-time CGM ($n=85$; $P=0.403$), even when analyzed separately by sex. When compared to those with normal values, patients with altered sleep quality had higher glycated hemoglobin (56.4 ± 12.1 *vs* 60.4 ± 11.5; $P=0.001$), higher distress (DDS scores 1.9 ± 0.9 *vs* 2.4 ± 1.1; $P<0.001$), lower treatment satisfaction (DTSQ scores 29.3 ± 5.4 vs 27.1 ± 5.7; $P<0.001$) and lower quality of life (DRQOL scores 1.7 ± 0.3 vs 2.0 ± 0.4; $P<0.001$), whereas duration of diabetes was not different ($P=0.751$). No correlation was found between glucose metrics derived from CGM and parameters of sleep quality.
Conclsion
Altered sleep quality was detected in one third of the patients with autoimmune diabetes and was associated with higher glycated hemoglobin levels, rather than altered parameters of glycemic variability, irrespective of the specific treatment for diabetes. Higher distress and lower quality of life were detected in patients with altered sleep quality.

Characterization of the somatostatin and ghrelin hormonal systems revealed their potential therapeutic role in chronic liver disease

Natalia Hermán Sánchez[1], Juan Luis López-Cánovas[1], Antonio Garcia-Estrada[1], Prudencio Sáez-Martínez[1], Victor Amado[2], Manuel de la Mata[2], Jose Cordoba-Chacon[3], Andrá Sarmento-Cabral[1], Manuel Rodriguez-Peralvarez[2], Raul M. Luque[1] & Manuel D. Gahete[1]
[1]University of Cordoba, Cell Biology, Physiology and Immunology, Spain; [2]Reina Sofia Hospital, Spain; [3]University of Illinois at Chicago, United States

Hormonal signalling plays a key role in the progression of metabolic (dysfunction)-associated fatty liver disease (MAFLD) to hepatocellular carcinoma (HCC). However, the role of somatostatin (SST), cortistatin (CORT), neuronostatin (NST) and ghrelin systems in MAFLD-HCC progression has not yet been elucidated. We characterized the role of SST/CORT/NST and ghrelin systems in chronic liver disease and evaluated their clinical potential. The expression of the components of the SST/CORT/NST/ghrelin systems (ligands, receptors and accessory proteins) was analysed in different mouse models of MAFLD/non-alcoholic steatohepatitis (NASH)/cirrhosis, in two retrospective human cohorts [cohort 1: HCC vs. adjacent ($n=93$); cohort 2: HCC vs. adjacent ($n=58$), cirrhosis ($n=39$), and healthy livers ($n=5$)], in different in silico MAFLD and HCC human cohorts (mRNA/protein), and in three liver-derived cell lines (HepG2, Hep3B and SNU-387). Proliferation after treatment with natural (SST/CORT/NST) and synthetic (Lanreotide, Ocreotide, Pasireotide) peptides was evaluated in cell lines and human liver primary cultures. Our results revealed that MAFLD mouse models showed a damage-dependent differential expression pattern of SST/CORT/NST components. Indeed, early MAFLD stages were characterized by a decreased expression of Cort, Sstr1, Sstr2, Sstr3 and the truncated Sstr5 md3 receptor, while there was a marked increase in the expression of Sstr3, Sstr4, Sstr5 and Sstr5 md3 in advanced stages. Some of these observations were validated in a human in silico cohort of MAFLD (i.e. SSTR5 overexpression and CORT downregulation), confirming CORT dysregulation as an early event in MAFLD. In tumoral stages, retrospective cohorts revealed a decreased expression of CORT, SSTR1, SSTR2 and ghrelin receptor and the overexpression of SSTR5 and the NST receptor (GPR107) in tumoral tissues. These alterations were validated in in silico cohorts of HCC. Besides, the decreased expression of CORT was associated with the dedifferenciation of the tissue while GPR107 overexpression was associated with key aggresiveness parameters (survival, recurrence, tumoral diameter, etc.) in the retrospective and in silico cohorts. In vitro assays revealed a decreased proliferation after treatment with SST, CORT, NST and the synthetic analogues, which was dependent on the expression of the receptors. Specifically, NST reduced proliferation of the most aggresive cell lines, Hep3B and SNU-387. Altogether, this study demonstrates an profound alteration in the expression levels of the SST/CORT/NST and ghrelin systems in human, animal, and cellular models of chronic liver disease, and suggests a potential prognostic and therapeutic role of certain components of these hormonal systems in chronic liver disease.

Association between the coefficient of glycemic variation and time in range, below and above range in continuous monitoring glucose systems in type 1 diabetes

Cristiana Gomes da Costa[1], Tânia Matos[1] & Sónia Vale[1,2]
[1]Hospital Santa Maria, Endocrinology, Lisbon, Portugal; [2]Faculdade de Medicina da Universidade de Lisboa, Lisbon, Portugal

Introduction
Glycemic variability (GV) is a major consideration when evaluating quality of glycemic control. Coefficient of glycemic variation (%CV) is the metric of choice to define GV. International consensus on continuous glucose monitoring (CGM) recommends a %CV <36. Additional studies suggest that low %CV minimize hypoglycemia events <54 mg/dl.
Aims
The aim of this analysis is to examine the expected relationship between the coefficient of glycemic variation and time in range (%TIR), time below range (%TBR) and time above range (%TAR) in continuous glucose monitoring systems.

Methods
We analysed a subset of 71 patients with type 1 diabetes followed at our endocrinology outpatient clinic using a continuous glucose monitor system that uploads data to a database accessible for clinicians. 16 out of 71 patients were excluded, 11 patients because they had less than 70% of data captured by the sensor in the previous 2 weeks and 5 patients because they had a diagnosis within the previous year. A bivariate analysis was performed to evaluate the relation between the %CV and %TIR, %TBR and %TAR in 55 patients. Time in range is defined as between 70 and 180 mg/dl. Furthermore, a bivariate analysis was performed to evaluate the relation between %CV and the subgroup time below 54 mg/dl (%TB 54).
Results
Patients were between 22 and 66 years old (mean 43, SD 12) and 42% were male. The %CV showed a strong positive correlation and statistically significant with %TBR ($r=0.708$, $P < 0.0001$) and a weak negative correlation, but statistically significant with %TIR ($r=-0.398$, $P=0.003$). There was no correlation between %CV and %TAR. Both correlations are independent of age and sex. Moreover, the %CV showed a strong positive correlation and statistically significant with %TB 54 ($r=0.664$, $P < 0.0001$).
Conclsions
The coefficient of glycemic variation is an important metric to evaluate the risk of hypoglycemia, in our analysis it is closely correlated with time below 70 mg/dl and also with time below 54 mg/dl. These results are consistent with results from other studies. Although weak it is important to note the negative correlation between coefficient of glycemic variation and time in range, as the latest is an indicator for evaluating the efficacy of glycemic control and predicting diabetic complications. Our analysis highlights the importance of %CV in the management of type 1 diabetic patients.

Personalized glycemic response based Diabefly-Pro® digital therapeutics improves dietary patterns, glycemic control and reduces postprandial hyperglycemia in real-world settings

Shilpa Joshi[1], Ritika Verma[2], Mohammed Khader[2], Sneha Nikte[3], Suresh Ade[4], Saifuddin Bandukwala[5], Mitali Joshi[6], Vinod Methil[7], Mangesh Tiwaskar[8] & Arbinder Singal[9]
[1]Fitterfly HealthTech Pvt Ltd, Department of Metabolic Nutrition, Navi Mumbai, India; [2]Fitterfly HealthTech Pvt Ltd, Department of Scientific Writing and Research, Navi Mumbai, India; [3]Dr Nikte Clinic, Department of Endocrinology and Diabetology, Mumbai, India; [4]Ayush Diabetes and Neurology clinic, Department of Diabetology and Neurology, Mumbai, India; [5]Advance Diabetes Care Clinic, Department of Internal Medicine, Mumbai, India; [6]The Clinic, Department of Diabetology, Mumbai, India; [7]Sweet Clinics, Department of Diabetology, Mumbai, India; [8]Shilpa Medical Research Center, Department of Diabetology, Mumbai, India; [9]Fitterfly HealthTech Pvt Ltd, Cheif Executive Officer, Navi Mumbai, India

Background
CGM based monitoring can help in development of personalized digital therapeutics programs based on the understanding of the effect of diet, physical activity and medications on everyday blood glucose excursions. The variation in intra-individual glycemic response to the same food has been reported in many studies. Thus, understanding of personalized glycemic response (PGR) of each individual becomes important for effective diabetes management.
Methods
De-identified data of 108 participants (Average Age: 40.86 $\pm$ 12.08 years, 36.11% females) with T2D in Diabefly-Pro®program was analyzed. The program provided 90 days PGR based lifestyle management support via digital meal logging through mobile application and remote health coaching. CGM data was collected in week 1 and week 2 with a modified lifestyle plan being introduced from week 2 of the program. All the parameters were analyzed for week 1 (baseline) and week 2 of the program. Net area under the curve (AUC) for 0-24h was calculated using trapezoidal rule. The incremental area under the curve (iAUC) was calculated at 1h-post breakfast. Paired t-test and spearman correlation method was used for statistical analysis with $P < 0.05$ considered as significant.
Results
A significant reduction in AUC by 44.71 $\pm$ 17.40 % was observed from an average week 1 AUC of 7328.59 $\pm$ 4265.79 mg/dl*h ($P < 0.0001$). iAUC post breakfast showed a significant reduction by 42.33 $\pm$ 22.90 % from a baseline average of 340.52 $\pm$ 202.19 mg/dl*h ($P < 0.0001$). The comparison of dietary recall in week 1 and week 2 showed that participants showed reduction in intake of calories (70.29 kcal; $P=0.04$) and carbohydrate (12.68 g; $P=0.002$). The percent reduction in AUC showed a significant correlation with the reduction in the amount of carbohydrate intake ($\rho = 0.24$, $P=0.01$). Time-in-range (TIR) improved significantly from a baseline of 67.35 $\pm$ 25.56 % to 70.05 $\pm$ 25.55 % ($P=0.03$) in week 2. Time-above-range (TAR) reduced significantly from a baseline of 27.13 $\pm$ 27.64 % to 22.13 $\pm$ 27.25 % ($P < 0.0001$). Reduction in TAR showed significant correlation with percent reduction in AUC ($\rho = 0.32$, $P < 0.001$).
Conclusion
Diabefly-Pro® program led to significant reduction in postprandial hyperglycemia while improving TIR and dietary behavior in people with diabetes after 7 days of modified lifestyle plan. PGR-based coaching can play an important role in achieving better glycemic control in the long-term.

Retrospective observational study of Italian patients with diabetes mellitus in Covid-19 era: a big data approach

Carla Greco[1,2], Tommaso Pirotti[3], Giulia Brigante[1,2], Tommaso Filippini[4], Chiara Pacchioni[2], Tommaso Trenti[3], Manuela Simoni[1,2] & Daniele Santi[1,2]
[1]University of Modena and Reggio Emilia, Modena, Italy, Unit of Endocrinology, Department of Biomedical, Metabolic and Neural Sciences, Modena, Italy; [2]Azienda Ospedaliero-Universitaria of Modena, Italy, Unit of Endocrinology, Department of Medical Specialties, Modena, Italy; [3]Azienda USL of Modena, Italy, Department of Laboratory Medicine and Anatomy Pathology; [4]University of Modena and Reggio Emilia, Modena, Italy., Environmental, Genetic and Nutritional Epidemiology Research Center (CREAGEN), Department of Biomedical, Metabolic and Neural Sciences, Modena, Italy

Introduction
The prevalence of diabetes mellitus (DM) in patients with coronavirus disease (COVID)-19 varies widely, depending on population characteristics, country, age and disease severity. Moreover, pre-existing DM seems to double the risk of both critical COVID-19 and mortality.
Aim
To evaluate incidence and mortality risk of COVID-19 in a large diabetic population in Northern Italy.
Methods
A retrospective, observational, big data cohort study was carried out, including subjects with type 1 and type 2 DM living in the Province of Modena, submitted to at least one swab for SARS-CoV-2 between March 2020 and March 2021. Data were extracted from the Hospital data warehouse.
Results
9553 diabetic patients were enrolled (age 68.8 + 14.1 years). COVID-19 was detected in 2302 patients (24.1%) with death in 8.9% of cases. No differences in COVID-19 prevalence were detected considering sex. Mean age (67.6 + 13.7 *vs* 69.8 + 14.1 years) was significantly lower in infected than uninfected patients and COVID-19 was more frequent in youngest people, according to quartile of age ($P<0.001$) and retirement age of 65 years ($P<0.001$). Moreover, DM duration was lower in infected than uninfected patients (11.2 + 6.6 vs 11.8 + 6.7 years, $P<0.001$), but higher HbA1c was found in infected compared to uninfected patients (58.7 + 16.7 vs 56.7 + 15.9 mmol/mol, $P<0.001$). Accordingly, COVID-19 was less frequent in patients treated with anti-diabetic drugs compared to those not treated ($P<0.001$). Logistic analysis confirms these results and identifies 3 risk factors for COVID-19: age (odds ratio-OR 1.013, 95% confidence interval-CI:1.008-1.017), DM duration (OR 1.007, 95%CI:1.001-1.013), and HbA1c (OR 1.009, 95%CI:1.002-1.016). As regards COVID-19 mortality, logistic analysis demonstrated that death was predicted by DM duration (OR 1.010, 95%CI: 1.005-1.015) and HbA1c (OR 1.005, 95%CI:1.002-1.009). Three ROC analyses were generated setting death as test variable, showing that the worse prognosis could be predicted by DM duration longer than 10.9 years (AUC = 0.639, 95%CI:0.601–0.676) and age older than 74.4 years (AUC = 0.797, 95%CI:0.767–0.827).
Conclsion
Our big data analysis confirms the correlation between COVID-19 mortality and DM. In particular, although COVID-19 was more frequently detected in youngest patients, a poor glycemic control worsens outcomes, confirming the importance of strict glyco-metabolic control, especially in older diabetic people with long DM duration. Thus, diabetic patients should undergo careful monitoring of blood

glucose. In particular, patients with DM and COVID-19 should be followed carefully when older than 74 years and with long DM duration.

DKA registry: A step towards harmonising management of diabetes-related ketoacidosis in the United Kingdom-initial findings

Catherine Cooper[1], Lakshmi Rengarajan[2], Amy Birchenough[3], Haaziq Sheikh[4], Meghnaa Hebbar[5], Carina Synn Cuen Pan[5], Parijat De[3], Parth Narendran[6] & Punith Kempegowda[6]

[1]Walsall Manor Hospital, Walsall, United Kingdom; [2]Birmingham Heartlands Hospital, Birmingham, United Kingdom; [3]Sandwell and West Birmingham Hospitals, Birmingham, United Kingdom; [4]Haberdashers' Adams' Grammar School, United Kingdom; [5]University of Birmingham Medical School, Birmingham, United Kingdom; [6]Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom

Background

Diabetes-related ketoacidosis (DKA) is a common and potentially life threatening complication in people with diabetes. Despite national and international guidelines, interhospital guideline variation and mismanagement during admission are important contributory factors to increased DKA duration and length of stay.

Aim

To establish a common DKA registry to identify gaps in management, assess outcomes and share best practises across centres.

Methods

Retrospective analysis of all DKA admissions between 1st January 2021 to 1st December 2021 across six hospitals in the United Kingdom was undertaken. People aged <18 years, admission pH >7.3 or self-discharged before treatment completion were excluded. Information on fluid and insulin prescriptions, glucose and ketone monitoring, DKA duration and length of hospitalisation was collected. Comparison between hospitals was performed using the Independent-Samples Kruskal-Wallis Test. Data was analysed using SPSS version 27.0 and presented in median interquartiles, frequencies and proportion as appropriate.

Results

Since the objective is to identify best practice and not to compare, hospital names are coded A to F to ensure anonymity. A total of 465 DKA episodes across the six hospitals were included. There were differences observed in the DKA duration (median in hours; A- 13.1, B-11, C-9.7, D-15.7, E-19.5, F-15.2; P value < 0.001) and length of hospitalisation (median in days;A-4.6, B-5.4, C-2, D-3.9, E-4.5, F-3.5; P value < 0.001) across hospitals. Similarly, variations were noticed in appropriateness of glucose monitoring(A- 110.9%, B- 86.3%, C- 95.9%, D-89.1%, E- 92.6%, F- 117.8%; P value <0.001), appropriateness of ketone monitoring (A- 61.3%, B- 83.6%, C- 91.5%, D- 67.3%, E- 62.6%, F- 69.6%; P value <0.001) and fluid prescription (A- 83.6%, B- 80.0%, C- 102.8%, D- 100%, E- 100%, F- 133.3%; P value <0.001). No significant differences were noted in the appropriateness of fixed rate intravenous insulin infusion (A- 100%, B-100%, C- 1008%, D- 98.8%, E- 98%, F- 100%; P value: 0.156).

Conclusion

With the exception of fixed rate intravenous insulin infusion, significant inter-hospital variation in other individual parameters were observed. A centralised DKA registry can abet identifying gaps in DKA management and dissemination of best practises across centres to aid improved patient outcomes.

The relationship between clinically significant neonatal hypoglycemia and cord blood c-peptide levels in neonates of mothers with type 1 diabetes

Genya Aharon-Hananel[1,2], Keren Levi[1], Rina Hemi[3], Ehud Barhod[3], Oshrit Kordi-Patimer[3], Shali Mazaki-Tovi[2,4], Rakefet Yoeli-Ullman[2,4] & Tali Cukierman-Yaffe[1,5]

[1]The Chaim Sheba Medical Center, Tel Hashomer, Division of Endocrinology, Diabetes and Metabolism, Ramat Gan, Israel; [2]Tel Aviv University, Sackler School of Medicine, Tel Aviv, Israel; [3]Chaim Sheba Medical Center, Tel-Hashomer, Israel, Endocrine Laboratory, Division of Endocrinology, Diabetes and Metabolism, Ramat Gan, Israel; [4]Sheba Medical Center, Tel-Hashomer, Department of Obstetrics and Gynecology, Israel; [5]Tel Aviv University, Epidemiology D., Sackler School of Medicine, Tel Aviv, Israel

Introduction

Neonate of patients with type I diabetes (T1D) are at increased risk for neonatal hypoglycemia. It is hypothesized that this is a result of maternal hyperglycemia and subsequent fetal hyperinsulinemia.

Aim

The aim of this study was to determine the relationship between clinically significant neonatal hypoglycemia (CS-hypo) and cord-blood c-peptide (CBCP) concentrations in patients with T1D.

Materials and methods

This was a prospective cohort study including patients with T1D followed at a single tertiary center. Clinical variables and glucose control data during pregnancy were prospectively recorded. Cord-blood of neonates was collected, and CBCP concentration was determined. The correlation between CS-hypo (neonatal hypoglycemia requiring IV glucose treatment) and CBCP concentrations was determined.

Results

This analysis pertains to 54 pregnancies. Mothers to neonates that experienced CS-hypo had longer diabetes duration (19 vs. 13 years, $P=0.023$), higher HbA1c at conception (7.3 [6.3–8.8] vs. 6.5 [6.0–7.0], $P=0.042$) and higher rates of caesarian section (73.3% vs. 28.2%, $P=0.005$) than mothers to neonates who did not. No differences were observed between the groups in BMI, age, and other maternal complications, nor in glucose control indices (Table 1). CBCP levels were significantly higher in neonates with CS-hypo than in those who did not (3.3 mg/l vs 1.9 mg/l, $P=0.002$). After adjustment for age at conception, BMI, diabetes duration, neonatal birth weight and 3rd trimester HbA1c, every 1 unit higher in CBCP level was associated with a 1.46 (1.02–2.09, $P=0.035$) fold greater risk CS-hypo.

Conclusion

In neonates of patients with T1D, higher CBCP levels are associated with a higher risk for neonatal hypoglycemia.

Table 1

	Neonatal – CS-hypo	No neonatal CS-hypo	P for comparison	Total
Maternal Age (Median, [IQR])	30.0 [26.0–34.0]	29.0 [25.7–35.2]	0.905	
BMI (Median, [IQR])	23.1 [21.2–30.1]	25.4 [23.1–27.8]	0.333

Time of gestational diabetes diagnosis and neonatal outcomes

Paola S. Morpurgo[1], Laura F. Peverelli[1], Andrea M. Bolla[1], Alessandra Gandolfi[1], Michele Vignali[2], Giovanna Spadaccini[2] & Paolo Fiorina[1]
[1]ASST Fatebenefratelli-Sacco, Milano, Italy, SSD Diabetologia, MILANO, Italy; [2]ASST Fatebenefratelli-Sacco, Milano, Italy, UOC Ginecologia e Ostetricia, P.O. Macedonio Melloni, MILANO, Italy

Background
The incidence of gestational diabetes mellitus (GDM) is increasing worldwide, with considerable impact on the health of both mother and newborn. There is no doubt that screening for GDM between 24 and 28 gestational weeks (GWks) is important to reduce the risk of adverse outcomes; however, there is no clear consensus about the diagnosis and treatment of GDM in early pregnancy.
Aims
To evaluate the effect of time of GDM diagnosis (early onset (EO, 16–18 GWks) vs late onset (LO, 24–28 GWks)) on fetal outcomes.
Materials and methods
We retrospectively evaluated 1369 women with GDM followed at our Center. Diagnosis of GDM was performed by an oral glucose tolerance test (OGTT) at 16–18 GWks ($n=321$) or at 24–28 GWks ($n=1048$). Neonatal outcomes were macrosomia, neonatal intensive care unit (NICU) admission, neonatal hypoglycemia and neonatal cardiac hypertrophy. Self-monitoring of blood glucose (SMBG) data and insulin therapy at last visit were also assessed.
Results
No differences between groups were found in the need for insulin therapy (EO 48,5% vs LO 33,4%, $P=$NS) or in SMBG parameters. Considering all pregnancies, 18,3% were complicated with macrosomia; 10,7% of newborns had neonatal hypoglycemia and 20,5% had cardiac hypertrophy, while no NICU admission was observed in either group. In both groups, neonatal hypoglycemia correlated with poor glucose control at the last visit (less than 50% of SMBG measurements in target). In the LO group, we found a higher risk to develop macrosomia ($+38.6\%$, $P<0.003$) or cardiac hypertrophy ($+31.4\%$, $P<0.01$) compared to EO group. Interestingly, we observed that 23% of women in LO group presented the risk factors suggesting to perform an early OGTT, that was lost for different reasons. In this subgroup, 63% of women had at least one neonatal adverse outcome.
Conclsions
High risk women should be screened as early as possible and an early treatment may have a significant effect to improve fetal outcomes.

Increasing overrepresentation of diabetes in non-traumatic lower limb amputations

Sindre Eik-Nes[1], Susanna Valland[1], Ove Talsnes[2], Kristin Østlie[3], Kristin Holvik[4] & Trine Elisabeth Finnes[1,2,5]
[1]Innlandet Hospital, trust. Hamar, Department of Internal Medicine, Hamar, Norway; [2]University of Oslo Faculty of Medicine, Institute of Health and Society Studies, Oslo, Norway; [3]Innlandet Hospital Trust, Department of Physical Medicine and Rehabilitation, Ottestad, Norway; [4]Norwegian Institute of Public Health, Department of Chronic Diseases and Ageing, Oslo, Norway; [5]Oslo University Hospital, Aker, Department of Endocrinology, Morbid Obesity and Preventive Medicine, Oslo, Norway

Background and Aim
Recent international studies indicate a secular decrease in the proportion of patients with diabetes who undergo lower limb amputations (LLA), and the same trend is observed in the national quality indicator. The validity of electronic databases and quality indicators are limited by multiple discharges and precision of coding. Furthermore, amputation codes included in the quality indicator do not include all amputations. We therefore aim to investigate the recent incidence of LLA in the catchment area of a middle-sized Norwegian hospital, and to compare it with data collected during 1990–99.
Methodes
Medical records for all patients identified with LLA by the electronic discharge registers at Innlandet Hospital, Elverum, from 2013 through 2019 were retrieved. All codes for amputations and exarticulations were included, and amputations were verified by manual review by two of the authors. Traumatic and cancer-related amputations were excluded. Both minor and major amputations were included in further analyses. Diabetes was defined by the WHO criteria. The prevalence of diabetes was calculated using data from the Norwegian Prescription Database and Statistics Norway.
Results
We identified 169 non-traumatic, non-cancer related amputations in 127 patients, of which 77 had diabetes. The proportion of amputees with diabetes had increased from 44% in the previous period to 61% in the recent data. Ten percent had type 1 diabetes compared to 4% during 1990–99. We estimated that 0.23% of individuals on antidiabetic drugs in the catchment area, underwent an amputation per year in the period 2013–19, compared to 0.31 % in 1990–99. The average absolute number of diabetics undergoing an LLA per year was 11 in both periods. Multiple amputations were common both in persons with and without diabetes and was present in 26% of the amputees, even though a high proportion in both groups underwent vascular surgery before amputation. Detailed information and further results will be provided.
Conclusion
Our findings suggest that the proportion of diabetics among patients undergoing non-traumatic, non-cancer related lower limb amputations has increased over the past decades. Multiple amputations are still common, despite comprehensive preoperative investigations and other surgical interventions.

COVID-19 pneumonia patients with 25(OH)D levels lower than 12 ng/ml are at increased risk of death

Juraj Smaha[1], Martin Kužma[2], Kristína Brázdilová[2], Samuel Nachtmann[2], Martin Jankovský[2], Katarína Pastírová[2], Andrea Gažová[3], Peter Jackuliak[2], Zdenko Killinger[2], Ján Kyselovič[2], Tomáš Koller[2], Neil Binkley[4] & Juraj Payer[2]
[1]Comenius University Faculty of Medicine, 5th Department of Internal Medicine University Hospital Bratislava, Bratislava, Slovakia; [1]Comenius University Faculty of Medicine, 5th Department of Internal Medicine University Hospital Bratislava, Bratislava, Slovakia; [3]Comenius University Faculty of Medicine, Institue of Pharmacology and Clinical Pharmacology, Bratislava, Slovakia; [4]University of Wisconsin Medical Sciences Center, Department of Medicine Geriatrics Faculty, Madison, Wisconsin, United States

Objectives
There is no consensus about specific serum 25(OH)D levels associated with higher risk of severe outcome in COVID-19 patients. According to the literature patients with serum 25(OH)D levels $<$ 12 ng/ml are clearly deficient at all ages.

Our aim was to assess COVID-19 mortality in the settings of severe 25(OH)D deficiency.
Methods
A cohort study of 357 COVID-19 patients was conducted. Subjects were monitored until discharge or in-hospital death. At admission, severity parameters (CRP, IL-6, Charlson Comorbidity Index etc.) were assessed. These parameters were compared regarding 25(OH)D levels threshold 12 ng/ml, where values below 12 ng/ml were considered absolute vitamin D deficiency.
Results
25(OH)D levels at the time of admission were independently associated with mortality ($P<0.05$). Non-survivors ($n=168$) had lower 25(OH)D levels, SO2, higher age, CRP, viral load, and Charlson Comorbidity Index in comparison to survivors. Patients with serum 25(OH)D levels $<$ 12 ng/ml had higher mortality (55% vs. 45 %), viral load (21.5 vs 23.1) and Charlson Comorbidity Index (5.3 vs 4.4) in comparison to those with serum 25(OH)D levels >12 ng/ml ($P<0.05$).
Conclusions
COVID-19 patients with serum 25(OH)D levels $<$ 12 ng/ml have higher mortality. Among other factors, severe vitamin D deficiency likely leads to poor outcome.

REAL Life study of SEMaglutide in Patients with Type 2 diabetes in SPain (REALSEM-SP): Retrospective clinical study on the efficacy, adherence, and safety with Semaglutide

Jersy Jair Cardenas Salas[1,2], Roberto Miguel Sierra Poyatos[3,4], Bogdana Luiza Luca[3], Begoña Sánchez Lechuga[3], Naiara Modroño Mostoles[2], Teresae Montoya Alvarez[2], María De La Paz GóMez Montes[2], Raquel Sanchez-Lopez[3], Carlos Casado[3] & Clotilde Vazquez Martinez[2,3,4]
[1]Hospital Universitario Fundación Jiménez Díaz, Endocrinology, Madrid, Spain; [2]Hospital Universitario Infanta Elena, Spain; [3]Hospital Universitario Fundación Jiménez Díaz, Madrid, Spain; [4]General Hospital Villalba, Spain

Introduction
Real-world data on glucose and weight control effectiveness in patients with Type 2 diabetes mellitus (T2DM) on treatment with semaglutide is scarce. We aim to assess it in a cohort of patients from a real-world setting in Spain.
Materials and methods
We identified 830 patients with T2DM that were prescribed Semaglutide once-weekly since May 2019 to December 2020, in 4 hospitals in Madrid-Spain. At 6 $\pm$ 3 months, 435 GPL1-naïve and 317 GLP1-experienced patients continued on treatment. Semaglutide withdrawal ocurred in 78 patients(9.4%), mainly due to gastrointestinal adverse events. At 12 $\pm$ 3 months, 317 GPL1-naïve and 265 GLP1-experienced patients continued on treatment. Semaglutide withdrawal ocurred in 24 patients (3.3%), mainly due to gastrointestinal adverse events. The changes in HbA_{1c}, weight, fat-mass and skeletal-muscle-mass at 6 and 12 months of follow up, adjusted by basal HbA_{1c}, age, T2DM duration, BMI, sex, and change in Metformin, DPP-4, SGLT-2, Sulfonylurea, Repaglinide, Insuline and Thiazolidinedione status was assessed (multiple linear regression model).
Results
Baseline characteristics and T2DM treatments are shown in Table 1. There was a significant reduction in HbA_{1c}, weight, and fat mass after Semaglutide treatment at 6 and 12 months of follow-up (Table 2). The proportion of patients that achieved a $HbA_{1c} \leq 7\%$ was significant higher in boths groups. After adjusment the baseline-HbA_{1c} was the only predictor for HbA_{1c} change at 6 and 12 months.
Conclusion
Treatment with semaglutide once-weekly is an effective glucose and weight lowering treatment in GLP1-naïve and GLP1-experienced patients with T2DM.

Health outcomes following engagement with a digital health tool GroHealth app amongst people with type 2 diabetes

Farah Abdelhameed[1], Elle Pearson[2], Petra Hanson[1], Thomas Barber[1], Arjun Panesar[3], Charlotte Summers[4] & Michaela de la Fosse[5]
[1]Warwickshire Institute for the Study of Diabetes, Warwick Medical School, University of Warwick, Endocrinology and Metabolism, University Hospitals Coventry and Warwickshire, Coventry, United Kingdom; [2]Warwick Medical School, University of Warwick, Coventry, United Kingdom; [3]Founding CEO and Head of AI, DDM Health Ltd, Coventry, United Kingdom; [4]Founding Chief Operations Officer, DDM Health Ltd., Coventry, United Kingdom; [5]Operations Manager, DDM Health Ltd., Coventry, United Kingdom

Introduction
Diabetes is a chronic condition causing morbidity and mortality globally, with a growing economic burden on healthcare systems. In the UK, 1 in 14 people have diabetes, with type 2 accounting for 90% of cases (1). Complications from poorly controlled diabetes are associated with increased socioeconomic costs and a reduced quality of life. Research has shown education and self-management are crucial in helping diabetic patients achieve metabolic control (1). Smartphones

have become an influential platform providing feasible tools such as health-apps to deliver tailored support to enhance diabetic patients' ability for self-management. GroHealth is a NHSX-certified digital health tool used to deliver educational and monitoring support to facilitate the development of skills and practices for maintaining good health.
Objectives
To assess self-reported outcomes of the GroHealth app amongst diabetic and prediabetic users.
Method
The EuroQol-5D (EQ-5D) questionnaire is a standardised tool used to measure health status for clinical and economic appraisal. GroHealth users completed the EQ-5D at baseline and 6 months after using the app. Users provided informed consent for use of their anonymised data for research purposes. Health index scores (HIS) and visual analogue scale (VAS) scores were calculated at baseline and 6 months for individuals with prediabetes and type 2 diabetes (T2DM). Descriptive statistics and multiple-regression models were utilised to assess changes in outcome measures and determine the driving variables for change in HIS.
Results
HIS are average values that reflect people's preferences about their health state (1 = full health, 0 = moribund). There was a significant and clinically meaningful increase in mean HIS amongst app users between baseline (0.746 [SD 0.234]) and follow-up (0.792 [SD 0.224], $P < 0.001$). The greatest change was observed in mean VAS score with percentage change of 18.3% improvement (*baseline*:(61.7 [SD 18.1]), *follow-up*:(73.0 [SD 18.8]), $P < 0.001$). These VAS score improvements remained significant across age, gender, ethnicity, income, and diagnosis (prediabetes/T2DM). Baseline HIS, ethnicity and education variables were associated with significant changes in follow-up HIS ($P < 0.001$).
Conclsion
This study provides evidence of significant positive effect on self-reported quality of life amongst people living with T2DM engaging with a digital health intervention. The improvements in the five dimensions of health, as described by the EQ-5D, are facilitated through access to education and monitoring support tools within the app. This provides an opportunity for healthcare professionals to incorporate NHS certified digital tools, such as GroHealth as part of the holistic management of patients.

Prevalence of amputation in a group of long-standing type 1 diabetic patients

Emna Bornaz, Haifa Abdesselem, Imene Sebai, Amal Meherzi, Kamilia Ounaissa, Fatma Boukhayatia, Asma Ben Brahim, Rim Yahiaoui & Chiraz Amrouche
National Institute of Nutrition, Outpatient Department and Functional Explorations, Tunis, Tunisia

Background
Amputation is the major complication of diabetic foot. The aims of our study were to assess prevalence of amputation in a group of long-standing type 1 diabetic patients and to determine its risk factors.
Methods
We conducted a cross-sectional study including type 1 diabetic patients followed at the National Institute of Nutrition of Tunis. All patients had a duration of diabetes $\geq$ 20 years. Clinical and biological data were collected from medical observation records.
Results
One hundred and fifty five patients with mean age 39.7 $\pm$ 9.8 years were included in the study. About 30% of them were male. Age at diagnosis of diabetes was 12.7 $\pm$ 7.47 years. Mean duration of diabetes was 27.33 $\pm$ 6.38 years. The average of the last four glycated hemglobin (A1c) was 9.45 $\pm$ 1.62%. The prevalence of amputation was 7.1%. It was associated with low socioeconomic status ($P = 0.002$), low level of education ($P = 0.045$), unemployment ($P = 0.012$), age at diagnosis of diabetes ($P = 0.039$) and anemia ($P = 0.031$).
Conclsion
Amputation is a serious complication of diabetes. It is more associated with socioeconomic factors than with diabetes-related factors.

Is there a relationship between nonalcoholic fatty liver disease (NAFLD) and atheroma disease?

Josep León Mengíbar[1,1], Carolina Lopez, Marta Zorzano, Ana Gloria Soler Beunza, Maricruz De La Fuente, Fernando Herrerias, Felip Vilardell, Maite Santamaria & Albert Lecube
Hospital Universitari Arnau de Vilanova, Lleida, Spain

Introduction
Over the last few years, there are some studies that suggests a close connection between Nonalcoholic Liver Disease (NAFLD) and increased cardiovascular (CV) risk in population with obesity. Indeed, these two conditions share common drivers, most notably insulin resistance and other elements of the metabolic syndrome. Notwithstanding the above, this affirmation does not have solid scientific evidence. The proliferation of Vasa Vasorum (VV) in the adventitial layer of the carotid is proposed as an early alteration of atheromatous disease, which precedes the intima-media thickness. However, there is not any study that evaluates the association between NAFLD and VV.
Methods
A cross-sectional study was performed with 54 subjects undergoing bariatric surgery. Before surgery, all patients were subjected to a contrast-enhanced ultrasound study to evaluate carotid density of VV, to measure the thickness of intima-media and to verify the presence of atheromatous plaque. Whilst surgery a liver biopsy was performed.
Results
From liver biopsy, we regarded that 42 subjects had simple steatosis and 12 had steatohepatitis. The mean density of VV was similar between subjects with steatosis and subjects with steatohepatitis (0.742 $\pm$ 0.173 vs. 0.781 $\pm$ 0.136 arbitrary units (AU), $P = 0.481$). In addition, there were no difference in carotid intima-media thickness (0.742 $\pm$ 0.173 vs. 0.781 $\pm$ 0.136 AU, $P = 0.481$). We did not find any significative lineal correlation between mean density of VV and the carotid intima-media thickness ($r = 0.036$, $P = 0.799$), as well as there was not correlation with clinical parameters such as age ($r = -0.128$, $P = 0.346$), BMI ($r = 0.066$, $P = 0.627$), fasting plasma glycaemia ($r = 0.118$, $P = 0.390$), HbA1c ($r = 134$, $P = 0.342$), the 'fatty liver index' ($r = 0.024$, $P = 0.863$) nor levels of GOT ($r = 0.067$, $P = 0.623$), GPT ($r = 0.009$, $P = 0.945$) and GGT ($r = -0.099$, $P = 0.467$). From the multivariate analysis, we did not observe any clinical or analytic variable that correlates with the adventitial VV density in an independent way. Nevertheless, when carotid intima-media thickness was the dependent variable, we found that age correlated independently in the multivariate study, whilst the other variables did not correlate.
Conclusion
NAFLD disease is a comorbidity associated with severe obesity almost inevitably. However, there is insufficient evidence to suggest that NAFLD plays a key role in the initial development of obesity-associated cardiovascular disease.

Roux-en-Y gastric bypass and vertical sleeve gastrectomy showed similar efficacy in achieving cardiometabolic composite target in subject with type 2 diabetes undergoing bariatric surgery

Lavinia Monte[1], Dario Tuccinardi[1], Giovanni Rossini[1], Mikiko Watanabe[2], Paolo Pozzilli[†], Nicola Napoli[2] & Silvia Manfrini[1]
[1]Campus Bio-Medico University of Rome, Rome, Italy., Unit of Endocrinology and Diabetes Department of Medicine, Rome, Italy; [2]Sapienza University of Rome, Rome, Italy., Department of Experimental Medicine, Section of Medical Pathophysiology, Food Science and Endocrinology, Rome, Italy

Introduction
The American Diabetes Association (ADA) produced a triple composite outcome that summarizes the therapeutic targets of the three most prevalent complications of obesity: type 2 diabetes (T2D), hypertension and dyslipidemia (HbA1c $< 7.0\%$; LDL cholesterol < 100 mg/dl and systolic blood pressure < 130 mmHg). The present study primarily investigates the difference between VSG and RYGB in achieving the composite target one year after the surgery. The secondary outcome assessed the success rate in achieving the separate components' target at months 6, 12 and 24 post-surgery, the 2-year remission of DT2 and postoperative adverse events.
Methods
This retrospective observational study evaluated 103 patients with obesity and T2D (75/28 F/M). Sixty-two (60%) underwent VSG and 41 (40%) RYGB. Patient data

were collected before surgery and subsequently during the follow-up visits at 6, 12 and 24 months post-surgery. At each visit, anthropometric measurements were recorded, and the metabolic and lipid profile was evaluated. Pharmacological therapies for diabetes, hypertension, dyslipidemia and any adverse events were also collected.

Results

Twelve months after surgery, patients undergoing RYGB did not show a significant difference compared to those undergoing VSG in achieving the composite target [RYGB vs VSG OR 2.21 (95% CI: 0.61–8.05), $P = .57$]. Patients undergoing RYGB showed greater LDL target achievement (< 100 mg/dl) at 6 months post-surgery than the VSG group ($P = .005$). Total cholesterol and LDL cholesterol were significantly reduced over time (months 6–12-24 post-surgery) in the RYGB compared to the VSG group ($P = .023$ and $P = .010$ respectively). No significant differences were observed in the T2D remission rate and the use of antidiabetic, cholesterol-lowering and antihypertensive drugs between the two groups at months 6–12-24 post-surgery. There was a significant increase in the frequency of constipation episodes in the VSG compared to the RYGB group ($P = .002$).

Conclusion

Roux-en-Y Gastric Bypass and Vertical Sleeve Gastrectomy showed similar efficacy in reaching the cardiometabolic ADA composite target in subject with T2D undergoing bariatric surgery. Patients undergoing RYGB showed a greater achievement of the LDL target < 100 mg/dl at 6 months after surgery and also a significant reduction over time in LDL and total cholesterol compared to the VSG group. More extended randomized studies are needed to evaluate the effectiveness of the two surgical procedures in the improvement and remission of cardiovascular risk factors associated with obesity.

Effect of dietary protein source on body composition and cardiometabolic risk in young adults with obesity during anti-inflammatory weight management program

Gordana Kendel Jovanovic[1], Sanja Klobučar Majanović[2,3], Ines Mrakovcic Sutic[4] & Dario Rahelic[5,6,7]

[1]Teaching Institute of Public Health of Primorsko-goranska County, Department of Health Ecology, Rijeka, Croatia; [2]Clinical Hospital Centre Rijeka, Department of Endocrinology, Diabetes and Metabolic Diseases, Rijeka, Croatia; [3]University of Rijeka, Faculty of Medicine, Rijeka, Croatia; [4]University of Rijeka, Faculty of Medicine, Department of Physiology, Immunology and Pathophysiology, Rijeka, Croatia; [5]Merkur University Hospital, Vuk Vrhovac University Clinic for Diabetes, Endocrinology and Metabolic Diseases, Zagreb, Croatia; [6]Croatian Catholic University, School of Medicine, Zagreb, Croatia; [7]Josip Juraj Strossmayer University, School of Medicine, Osijek, Croatia

Introduction

Many studies have shown that dietary protein content may play a role in weight management. Moreover, it has been found that diets high in protein (either animal or plant) significantly reduced markers of insulin resistance and hepatic necroinflammation independently of body weight change. This study aimed to examine the effect of dietary protein source on body composition and cardiometabolic risk factors in young adults with obesity during anti-inflammatory weight management program.

Methods

A total of 56 participants (93% female, mean age 44 years, mean BMI 35.4 kg/m2) were enrolled in the study, and 42 of them completed the 24-week anti-inflammatory weight management program in the Obesity Outpatient Clinic at the Clinical Hospital Centre Rijeka, Croatia. Dietary protein intake was estimated from six three-day food diaries. The inflammatory potential of diet was assessed with the Dietary Inflammatory Index (DII®). Body composition parameters were assessed by bioelectrical impedance analysis (Seca® mBCA 515, Hamburg, Germany). Serum concentrations of glucose, insulin, total cholesterol, HDL cholesterol, LDL cholesterol, triglycerides, and high sensitivity C-reactive protein from fasting blood samples were measured and their correlation with dietary protein intake from animal or plant origin was examined.

Results

On average, participants lost 7.1 kg ($P < 0.01$) over the 24-week period, and reduced high sensitivity C-reactive protein concentration by 30% ($P < 0.01$). The inflammatory potential of their diet was significantly improved toward more anti-inflammatory potential ($P < 0.01$). The total ($P < 0.01$), animal ($P < 0.01$) and plant ($P = 0.01$) protein intakes were significantly reduced, but its energy fraction was significantly increased ($P < 0.01$). The plant protein intake was strongly negatively correlated with serum triglycerides ($r = -0.99$, $P = 0.02$) at the beginning of the program, and total body fat mass ($r = -0.99$, $P = 0.02$) after its completion. There was no correlation between animal protein intake with any of the considered parameters.

Conclusion

The study results suggest that change of the dietary protein source toward plant origin can improve body composition and cardiometabolic risk profile in young adults with obesity.

Autoimmune thyroiditis: What impact on diabetic retinopathy ?

Emna Bornaz, Haifa Abdesselem, Ghofrane Hkiri, Kamilia Ounaissa, Fatma Boukhayatia, Imene Sebai, Asma Ben Brahim, Rim Yahiaoui & Chiraz Amrouche

National Institute of Nutrition, Outpatient Department and Functional Explorations, Tunis, Tunisia

Introduction

Data from literature suggest that combination of autoimmune diseases may have a major physical and psychological impact on type 1 diabetic patients. The aim of our study was to assess the impact of autoimmune thyroiditis on diabetic retinopathy.

Methods

We conducted a descriptive observational retrospective study of type 1 diabetic patients, followed at the National Institute of Nutrition and Food Technology of Tunis, between December 2019 and April 2021. All included patients had a diabetes duration of more than 20 years. Clinical and biological data were collected from medical observation records. The diagnosis of diabetic retinopathy was based on fundus examination, associated with retinal angiography in case of abnormality.

Results

The study included 155 patients. The mean age of patients was 39.7 ± 9.8 years. The sex ratio M/F was 0.49. Mean duration of diabetes was 27.33 ± 6.38 years with extremes ranging from 20 to 48 years. Autoimmune diseases associated with type 1 diabetes were dominated by autoimmune thyroiditis (22.4%) followed by celiac disease (6.8%) and adrenal insufficiency (4.3%). Diabetic retinopathy was present in 74.3% of the participants with a mean duration of 22 ± 5.9 years. The univariate study showed that autoimmune thyroiditis was present in 16.3% of patients with diabetic retinopathy compared with 35.1% of those with a normal fundus ($P = 0.016$).

Conclsion

Our study highlights the possible protective effect of autoimmune thyroiditis on diabetic retinopathy. Further research are needed to confirm this effect and determine the factors involved in this association.

Excellent disease control in Berardinelli Seip type 1 patient through dietary therapy alone: only an exception?

Carolina Cecchetti[1], Elisabetta Belardinelli[1], Paola Dionese[1], Rita Teglia[1], Ilaria Di Cintio[1], Maria Rosaria D'apice[2], Uberto Pagotto[1] & Alessandra Gambineri[1]

[1]IRCCS Azienda Ospedaliero - Universitaria di Bologna - Department of Medical and Surgical Sciences (DIMEC), Alma Mater Studiorum, University of Bologna, Division of Endocrinology and Diabetes prevention and Care, Bologna, Italy; [2]Azienda ospedaliera universitaria Policlinico Tor Vergata, Laboratory of Medical Genetics, Tor Vergata Hospital, Rome, Italy

Background and Objective

Severe metabolic complications generally manifest at an early age in Berardinelli – Seip congenital lipodystrophy (BSCL) and their management is especially

challenging, often requiring prompt pharmacological treatment with insulin-sensitizers, lipid lowering drugs, insulin and eventually metreleptin. Nutritional intervention with low lipid personalized diets is considered by experts a fundamental tool in handling the disease when associated with medical therapy, but little is known about the beneficial effect of diet intervention alone. This report aims to underline the importance of a well-structured low-fat diet in BSCL patients, by presenting a rare case of successful long-term disease control with the use of a low-fat diet only.
Methods and Results
A BSCL male patient strictly followed a personalized hypolipemic diet since clinical diagnosis at one year of age, with daily intake divided into 25 % lipids, 20% proteins and 55% carbohydrates. Interestingly, pharmacological intervention was not required at any point during follow up. At 16 – years old, age of transition from Paediatric to our Division, the patient weighed 40 kg and had a height of 162 cm (BMI 15,24 kg/m2), P5/B5 Tanner stage, 135/75 blood pressure, 12 % total body fat and normal BMD for age (evaluated by DEXA). Biochemistry, evaluation of thyroid function and sex hormones, 75 mg oral glucose tolerance test, cardiac evaluation and abdominal ultrasound were performed, revealing no abnormalities and therefore an excellent control of the syndrome by an exclusive dietary therapy. Genetic analysis and leptin dosage were carried out, confirming the diagnosis of BSCL type 1 (homozygosity for c.493–1G>C pathogenic variant in AGPAT2 gene) and showing undetectable circulating levels of leptin (< 0.2 mg/l).
Conclsions
This report proves how a personalized low-fat diet is of great help in the management of BSCL and its complications; furthermore, a specific hypolipemic diet may be used alone as an effective long-term treatment in selected cases with high compliance and, probably, a milder phenotype.

Impact of the mode of insulin delivery on the quality of life of type 1 diabetes patients

Lilian Tzivian[1], Jelizaveta Sokolovska[1], Anna E. Grike[2], Agate Kalcenaua[3,4], Abraham Seidmann[5,6], Arriel Benis[7,8], Martins Mednis[4], Ieva Danovska[4], Ugis Berzins[4], Arnolds Bogdanovs[4] & Emil Syundyukov[4,9]
[1]University of Latvia, Faculty of Medicine, Riga, Latvia; [2]University of Latvia, Faculty of Humanities, Riga, Latvia; [3]Riga Stradins University, Faculty of Medicine, Riga, Latvia; [4]Longenesis Ltd, Riga, Latvia; [5]Boston University, Questrom Business School, Boston, United States; [6]Boston University, Digital Business Institute, Health Analytics and Digital Health, Boston, United States; [7]Holon Institute of Technology, Faculty of Industrial Engineering and Technology Management, Holon, Israel; [8]Holon Institute of Technology, Faculty of Digital Technologies in Medicine, Holon, Israel; [9]University of Latvia, Faculty of Computing, Riga, Latvia

Background
Insulin pump therapy is an alternative to multiple daily injections and can improve glycemic control and quality of life (QoL) in Type 1 diabetes mellitus (T1DM) patients. The aim of this study was to assess the differences and factors related to the T1DM-specific QoL of T1DM patients in Latvia.
Methods
87 adult patients with T1DM were included. Of them, 20 were pump users and 67 were users of injections. All recruited patients participated in the quantitative part of the study; 8 pump users and 13 injection users participated in the qualitative part. Patients were invited to participate using a dedicated digital platform. Specially developed questionnaires adapted to Latvian conditions were used for assessment of QoL and self-management habits. Association between social and self-management factors and patients' QoL was investigated using multiple logistic regression models. Qualitative analysis of answers was performed according to major theme of transcripts.
Results
Compared to injection users, insulin pump users were younger (median age pump users 20.0 (18.2 – 22.0) years, injection users 31.0 (25.0 – 40.0) years, $P<0.01$) and reported higher T1DM expenses. There were no differences in self-management and HbA1c level between the groups; Total QoL differed at the 0.1 significance level. In fully adjusted multiple logistic regression models, the most important factor that increased Total QoL was lower T1DM-related expenses (odds ratio, Or=7.02 [95% confidence interval 1.29; 38.0]). Men and those with more years of living with T1DM had better QoL (Or=9.62 [2.20; 42.1] and Or=1.16 [1.05; 1.29], respectively), but the method of administration was not significantly associated with QoL (Or=7.38 [0.87; 62.9]). Qualitative data supported the results of quantitative analysis.
Conclsions
QoL was the main reason to use an insulin pump, while the expenses were the main reason to avoid the use of it or to stop using it. Reimbursement policies thus should be considered to enable patients to choose the more convenient method for themselves.

IGF1-zSDS in patients suffering from obesity with or without metabolic syndrome: a cross-sectional study in 2032 subject

Davide Masi[1], Renata Risi[1], Rossella Tozzi[2], Elena Gangitano[1], Mariaignazia Curreli[1], Mikiko Watanabe[1], Stefania Mariani[1], Lucio Gnessi[1] & Carla Lubrano[1]
[1]Sapienza University of Rome, Department of Experimental Medicine, Section of Medical Pathophysiology, Food Science and Endocrinology, Roma, Italy; [2]Sapienza University of Rome, Department of Molecular Medicine, Roma, Italy

Background
Metabolic syndrome (MS) is associated with increased mortality, and the key factors predictive of its development among patients with obesity are still unclear. We recently demonstrated with a machine learning approach that Insulin-like Growth Factor 1 (IGF-1) is a novel marker of metabolic health and that in individuals with obesity, lower IGF-1 levels are associated with increased metabolic deterioration. However, the interpretation of IGF-1 serum measurement is limited by a poor standardization of its normal values, as they vary significantly with sex, age and BMI.
Objective
To calculate a surrogate marker of serum IGF-1 concentration, normalized for age and sex, expressed as IGF-1 standard deviation score (IGF1-zSDS), in a cohort of 2032 individuals with obesity and to investigate its association with the presence of MS.
Methods
We conducted a cross-sectional study on adult Caucasian patients entering our third-tier obesity centre from 2010 to 2022. Anthropometric parameters, routine laboratory assessments, markers of glycolipid metabolism and serum IGF-1 levels were obtained. Adult treatment panel III criteria were adopted for the clinical diagnosis of MS. IGF1-zSDS was calculated both in men and in women age-grouped as follows: 18–22; 23–30; 31–50; 51–65; >65 years, according to the equation IGF-1 zSDS=(IGF-1 – mean)/SD. Student's t-test was used to assess differences between patients with MS and groups of obese patients without MS (noMS) matched for age. A multinomial logistic analysis (MLA) was performed to assess the association between IGF1-zSDS and the probability of being diagnosed with MS.
Results
A total of 2032 patients (1551 females and 481 males) were enrolled. IGF-1 means and SDs obtained were specific for the obese population. Overall, male subjects had both a higher BMI (39.1±7.2 vs 37.8±7.1, $P=0.001$) and a higher prevalence of MS (64.7% vs 45.7%, $P<0.0001$) than their female counterpart, suggesting that women may seek medical attention earlier or may be less likely to develop MS. The IGF1-zSDS in the overall population was 0.13±0.8 and was significantly lower in patients with MS than in noMS. A MLA showed that for each decrease in IGF1-zSDS units, the chance of having MUO increased by 30%.
Conclsion
In a large population with obesity, lower IGF1-zSDS is associated with a higher chance of suffering from MS. Our results obtained with classical statistical analysis confirm preliminary results proposed by artificial intelligence. We suggest to use specific IGF-1 reference values to calculate IGF1-zSDS in obese Caucasic patients

Prostate cancer (PCa) is one of the most common causes of cancer-related deaths in men worldwide. Therefore, more specific non-invasive diagnostic biomarkers as well as novel therapeutic targets are urgently needed. As miRNAs have been proposed as promising elements for the identification of novel diagnostic and therapeutic tools for different pathologies, including cancer, we investigated the miRNA landscape in PCa patients and explored their putative diagnostic/therapeutic utility. Specifically, the miRNome of plasma samples from healthy ($n=18$) and PCa patients ($n=19$) was initially determined using an Affymetrix-miRNA array. The main changes were validated in an independent cohort ($n=295$) by quantitative real-time PCR. Additionally, *in silico* and *in vitro* assays in normal and tumor prostate cell lines were performed. Results from the array revealed that the expression of 104 miRNAs was significantly altered ($P<0.01$) in plasma samples from PCa patients compared with healthy controls. Of note, 6 of these miRNAs also exhibited a significant ROC curve to distinguish between healthy and PCa patients with an AUC = 1. The validation using an independent cohort of patients demonstrated that miR-191–5p was one of the most profoundly altered miRNAs in PCa ($P<0.0001$) exhibiting an AUC = 0.67. Remarkably, miR-191–5p significantly outperformed the ability of prostate specific antigen (PSA) to distinguish between control and PCa patients, especially in the 'grey zone', which represents the range where PSA levels are less accurate to diagnose PCa. Interestingly, the diagnostic capacity of miR-191–5p was even stronger in obese patients (BMI > 30). Furthermore, we found that miR-191–5p levels were also dysregulated in PCa cells (compared to non-tumor cells). Moreover, *in vitro* overexpression of miR-191–5p significantly increased cell proliferation and migration in DU145 and PC-3, two of the most aggressive PCa cell models. Finally, these functional effects were associated with the alteration in key cellular elements that are critical in PCa and obesity pathophysiology. Altogether, our data demonstrate that miR-191–5p might represent a novel and useful personalized diagnostic biomarker in PCa, especially in patients with obesity, as well as a potential therapeutic tool in PCa.

Case Report: A triad of Diabetic Ketoacidosis, hypertriglyceridaemia and acute pancreatitis as a first presentation of diabetes mellitus

Ebo Dadey[1], Jesmith Perumbalath[1], David Leonard[1] & Gideon Mlawa[2]
[1]King George Hospital, United Kingdom; [2]Queen's Hospital, United Kingdom

Objective
We present a case of hypertriglyceridemia induced acute pancreatitis (HTG-AP) and concurrent diabetic ketoacidosis (DKA) as a first presentation of Diabetes Mellitus in an adult patient. This uncommon triad has been previously described in the literature, however, it is rare to be observed in a previously undiagnosed patient with diabetes. The purpose of this poster is to describe the potential mechanisms for this and discuss management strategies.
Case Presentation
A previously fit and well 30-year-old South Asian man presented to the emergency department with a 3-day history of vomiting and abdominal pain. He had a BMI of 36 kg/m^2 and there was a maternal history of Type 2 Diabetes Mellitus. His initial panel of investigations demonstrated severe metabolic acidosis with ketonaemia. Admission venous blood gas showed a pH of 7.152, glucose 20.4 mmol/l, lactate 1.3 mmol/l, bicarbonate (HCO_3^-) 5.8 mmol/l as well as blood ketones of 6 mmol/l. A subsequent CT scan showed acalculous acute pancreatitis (severity = Glasgow Score 2, Balthazar Score 2). Diabetic antibodies (GAD65, IA-2, ZnT8) were negative for Latent Autoimmune Diabetes of Adulthood (LADA). Triglycerides were 44.22 mmol/l and Haemoglobin A1C (HbA1C) was 118 mmoll/mol. He was treated in a high dependency unit with aggressive fluid resuscitation, intravenous and subcutaneous insulin as well as fibrates.
Conclusion
While acute pancreatitis (AP) and DKA are common presentations in the Emergency Department, it was unusual as a de novo diabetic presentation and required Multidisciplinary Team discussion with the Diabetology team as well as the Intensive Care team. AP is a complication in around 11% of patients with DKA and hypertriglyceridaemia (HTG) commonly occurs as a result of inhibition of lipoprotein lipase. It has been hypothesised that DKA could be the inciting event leading to HTG and ultimately AP. The correction of DKA is the crux of management, involving aggressive fluid repletion, intravenous insulin infusion and diligent monitoring of glucose, ketones and electrolytes. In the case of severe hypertriglyceridemia, clinicians should be aware of interventions such as fibrates or therapeutic plasma exchange.

Understanding and improving the management of hyperosmolar hyperglycaemic state

Carina Synn Cuen Pan[1], Emily Warmington[1], Lakshmi Rengarajan[2], Catherine Cooper[3], Megan Owen[3], Haaziq Sheikh[4], Anjitha Anilkumar[1], Ketan Dhatariya[5], Jonathan Webber[6] & Punith Kempegowda[6]
[1]University of Birmingham Medical School, College of Medical and Dental Sciences, Birmingham, United Kingdom; [2]Birmingham Heartlands Hospital, Birmingham, United Kingdom; [3]Walsall Manor Hospital, Walsall, United Kingdom; [4]Haberdashers' Adams' Grammar School, Newport, United Kingdom; [5]Norfolk and Norwich University Hospital, Norwich, United Kingdom; [6]Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom

Background
Hyperosmolar hyperglycaemic state (HHS) is an acute metabolic complication of diabetes that can lead to significant morbidity and mortality if managed incorrectly. With <1% prevalence, there is limited published literature available on HHS and most management guidelines worldwide are based solely on expert advice and opinions.
Aims
To study the precipitating causes and identify baseline practises of HHS management, to highlight areas for improvement.
Methods
This retrospective study included all patients who meet the diagnostic criteria of HHS from May to November 2021 in six hospitals across the West Midlands region of the United Kingdom. The criteria for HHS diagnosis was defined as serum osmolality >320 mOsmol/kg and glucose >25 mmol/l whereas HHS resolution was defined as either serum osmolality <300 mOsmol/kg, when fixed rate intravenous insulin infusion (FRIII) was stopped or when the clinical team documented resolution time, whichever came earliest. Osmolality was calculated using the formula: [(2x sodium) + (2x potassium) + glucose + urea, all values in mmol/l]. Data regarding precipitating causes, insulin and fluid administration, glucose and osmolality measurements, total duration of HHS and length of admission were collected. The data was then analysed using SPSS 28.0 and results were presented as frequencies, median and interquartile range (IQR) where appropriate.
Results
A total of 31 HHS episodes were identified. From these, 64.5% had the diagnosis of HHS documented in hospital records and 48.4% had serum osmolality measured. The most common precipitating causes were intercurrent illness (38.7%), suboptimal compliance to treatment (12.9%) and new onset of diabetes (9.7%). The median calculated serum osmolality at diagnosis was 343.2 mOs mol/kg (IQR: 330.1–363.9). Patients with HHS received a median of 4500 ml (IQR: 1825–8574) of fluid until resolution. 38.7% of patients had FRIII commenced within the first hour of diagnosis and 54.8% were given basal insulin alongside FRIII. The median duration of HHS was 26.7 hours (IQR: 6.7–46.8) and these people were admitted for a median of 9.0 days (IQR: 4.7–11.8). While the length of stay was similar for HHS across included hospitals, there was a significant difference in HHS duration between sites ($P<0.001$).
Conclusion
Our findings suggest there is an unmet need to improve the awareness of HHS identification and its management. With the difference in HHS duration between

hospitals, there is scope to identify and share best practises to provide improved, uniform clinical care for people with HHS across all centres.

Combination study of apoptosis gene polymorphisms in mitochondrial diabetes: Potential role in the pathogenesis of mitochondrial diabetes

Faten Haj Kacem Akid[1], Mohamed Abdellahi Mohamed Ahmed[1], Dhieb Nesrine[1], Youssef S[2], Mkaouar-Rebai E[2], Fakhfakh F[2], Mouna Mnif[1] & Mohamed Abid[1]
[1]Department of Endocrinology and Diabetology CHU Hedi Chaker Sfax, Tunisia; [2]Laboratory of Molecular and Functional Genetics, Faculty of Science, University of Sfax, Tunisia

Introduction
Mitochondrial diabetes (DM) is a monogenic form of maternal transmission diabetes that is caused by mutations in the mitochondrial genome. These mutations affecting mitochondrial function may be the cause of initiation of the phenomenon of apoptosis itself having an aggravating role of the phenotype in patients with mitochondrial diabetes.
Materials and Methods
This study involved 43 patients with mitochondrial diabetes (20 non-syndromic and 23 syndromic) for whom mutations were identified in the mitochondrial genome in addition to 100 controls of the general Tunisian population. An analysis of apoptosis was carried out on muscle biopsy using TUNEL, immunohistochemistry and western blot cytochrome C expression. The analysis of 11 SNPs in 10 apoptosis genes (TP53, BCL2, BAX, BAK1, FASL, CASP8, CASP10, CASP3, CASP7) was carried out by genotyping on the DNA of patients and controls.
Results
Our results confirmed the presence of apoptosis by the TUNEL approach on muscle biopsy and by the study of the expression of the cytochrome C protein by western blot. This apoptosis is most accentuated in patients with a severe phenotype suggesting possible involvement of genetic factors. To study this hypothesis, we carried out a genotyping analysis of 11 functional SNPs in 9 genes involved in the pathways of apoptosis to evaluate their association with the development of apotosis in patients with DM compared with controls. Results showed that mitochondrial (TP53) apoptosis and effector pathway (PSAP3) SNPs were significantly associated with a high risk of developing apoptosis (TP53 rs 1042522 OR 3.57, PSAP3 rs1405937 OR 4.33). In addition, this risk is increased (TP53 rs 1042522 OR 6.07, CASP3, rs1405937 OR 4.8) in patients with syndromic DM and pathogenic mitochondrial mutations.
Conclusion
apoptosis initiated by mtDNA mutations is aggravated by SNPs of the apoptosis genes in particular Tp53, and CASP3 in patients with DM in comparison with controls of the general population.

Uncommon side effect of a common drug: doxycycline induced hypoglycaemia

Elohor Ijete[1], Moustafa Hosni[1], Ebo Dadey[1], Khash Nikookam[1], Hassan Rehmani[1] & Gideon Mlawa[1]
[1]Queen's Hospital, London, United Kingdom

Introduction
Doxycycline is a broad-spectrum antibiotic that is used to treat gram negative, gram positive and atypical bacterial infections. It is a member of the second-generation tetracycline class of antibiotics.
Case
We describe a case of a (non-diabetic) male patient who developed hypoglycaemia following treatment with doxycycline. A 73-year-old male presented to the emergency department following a witnessed collapse at 9am on the 4thof September 2021. He was found to have a blood glucose level of 2.6 mmol/l with the London Ambulance Service. He had a past medical history of asthma, prostatic cancer, GORD and spondylosis. He had recently been prescribed doxycycline by his GP for treatment of a possible lower respiratory tract infection. He took an initial dose of 200 mg of doxycycline followed by 100 mg once daily for 11 days. It was on day 11 that he collapsed. During admission he received a Computed Tomography (CT) Head scan due to head injury which was reported as normal. His cortisol levels were normal at 346 nmol/l and he did not have any further episodes of hypoglycaemia after stopping doxycycline. Following discharge, he was reviewed at an endocrine clinic and endocrine causes of hypoglycaemia were investigated with a prolonged fasting glucose (15 hours) showed normal glucose and a repeat hormonal profile for IGF-1, IGF-2 and cortisol all of which were normal.
Discussion
Medications can frequently cause hypoglycaemia especially in the elderly. Anti-diabetic medications are usually the culprit however many other non-diabetic medications used routinely can also cause hypoglycaemia and the list of these medications is expanding. Doxycycline has a number of side effects. Commonly known side effects include gastrointestinal irritation such as vomiting, diarrhoea and oesophageal ulceration. It is also known to cause photosensitivity and photo-onycholysis. A rare side effect of doxycycline that is not well known is hypoglycaemia A Study of the FDA Adverse Event Reporting System (FAERS) on hypoglycaemia associated with antibiotics alone and in combination with sulfonylureas and meglitinides showed that many patients developed hypoglycaemia while on antibiotics with or with sulfonylureas and meglitinides.
Conclsion
Hypoglycaemia due to doxycycline is rare. The mechanism for doxycycline-induced hypoglycaemia is still unclear but it may be related to augmented insulin sensitivity, direct hepatotoxicity, inhibition of insulin degradation in the liver as well as inhibition of glycogenolysis. Paying attention to this potential adverse event is important as this medication is commonly prescribed antibiotic, especially in outpatient setting.

The effect of intermittently scanned continuous glucose monitoring on the glycemic control and treatment satisfaction in Korean type 2 diabetic patients

Junghoon Lee
Chuncheon Sacred Heart Hospital, Endocrinology and Metabolism, Chuncheon, Rep. of South Korea

Background
In recent years, continuous glucose monitoring (CGM) has emerged as a method for the assessment of glycemic control. Also CGM enables diabetic patients to understand their own blood glucose status and change their lifestyle.
Aims
We investigated the effect of CGM on the glycemic control in Korean type 2 diabetic patients.
Methods
We enrolled type 2 diabetic patients who met all the following criteria: 1) use of oral antidiabetic drug (OAD) or lifestyle change for diabetes control, 2) no change of OAD before the previous 3 months, 3) HbA1c levels, 7.0–8.9%, and 4) age, 30 to 75 years old. After informed consent, we applied the CGM (FreeStyle Libre) to the participants for 2 weeks. Participants were asked to record their diet and exercise while wearing the CGM on the apps. We educated the participants how to interpret the glucose profile and manage glucose. The participants were randomly assigned CGM or CGM + short message service (SMS) group. We sent educational feedback message for the each CGM glucose profile and lifestyle to the CGM + SMS group We compared the change of HbA1c, lifestyle, and diabetes treatment satisfaction questionnaire after 10 to 12 weeks.
Results
Fifty seven diabetic patients consented to the study. But 11 participants did not apply the CGM (no wearing CGM group). Twenty four were assigned to the CGM group. Twenty two were assigned to the CGM + SMS group. There were no differences in age (56.4 ± 7.8 vs 58.5 ± 7.3 years, $P = 0.429$), DM duration (12.5 ± 7.0 vs 12.4 ± 6.5 years, $P = 0.946$), baseline HbA1c (8.0 ± 0.5 vs 8.0 ± 0.3%, $P = 0.926$) between wearing CGM (CGM and CGM + SMS group) and no wearing CGM group. The deltaHbA1c of CGM, CGM + SMS, no wearing CGM group was -0.35 ± 0.65%, -0.32 ± 0.73%, and -0.04 ± 0.78% ($P = 0.478$). There was no difference in the scan frequency per day (11.2 ± 5.8 vs 10.9 ± 4.8, $P = 0.825$) and in walking time per week (219 ± 170 vs 302 ± 180 minutes, $P = 0.159$) between CGM and CGM + SMS group. The self-care for diabetes was improved in both CGM and CGM + SMS group, especially in diet, exercise, and glucose monitoring. The DTSQ score was also improved in CGM (delta 4.0 ± 7.6) and CGM + SMS group (delta 4.1 ± 5.6). In the logistic regression analysis, time in range in CGM results was related to the prediction of glycemic control in this study.
Conclusions
CGM can be used as a motivational tool for diabetes management when integrates with diabetes education. It is presumed that the intuitive ambulatory glucose profile had an effect on diet and diabetes management.

User acceptance and satisfaction with the eversense XL CGM in patients with type 1 diabetes

Francisco Javier Martinez Martin, Alba Hernandez-Lazaro, Ricardo de Leon-Durango, Agnieszka Kuzior, Claudia Arnas-Leon & Carmen Acosta-Calero
Hospital Universitario de Gran Canaria Dr. Negrin, Endocrinology and Nutrition, Las Palmas de Gran Canaria, Spain

Objectives
Eversense XL is a fully implantable sensor for continuous glucose monitoring (CGM) that lasts for up to 180 days. Our objective was to perform a survey on user acceptance and satisfaction among our type 1 diabetic patients who had been using the Eversense XL CGM for at least 3 months.
Methods
A questionnaire was devised in which the patients were asked about their experience with the Eversense XL CGM, including:
-Comparison with blood glucose strips and previously used glucose sensors if available
-Perceived accuracy, comfort and ease of use.
-Perceived changes in quality of life, and ability to perform their daily activities including sports
-Overall satisfaction with the device
Visual analogue scales were used for quantitative data. The questionnaires were collected anonymously and with informed consent from the patients. All our type 1 diabetic patients who had been using the Eversense XL monitor for at least 3 months gave their consent and fulfilled the questionnaire
Results
Thirteen patients were included in the survey, mean age 34 $\pm$ 5 years, 61.5% male. Five of them (38.5%) had previously used a glucose monitor (Abbott FreeStyle Libre in all cases). All patients were more satisfied with the Eversense XL than with blood glucose strips (by 49.3 $\pm$ 11.4%) and their previous glucose monitor (by 13.4 $\pm$ 2.5%) 9 patients (69.2%) perceived the Eversense XL as more accurate than blood glucose strips (change 13.6 $\pm$ 5.8%) and 3 patients (60%) as more accurate than the previous sensor (change 7.3 $\pm$4.7%). The Eversense XL increased the perceived overall quality of life of 11 patients (84.6%, change 23.2 $\pm$ 7.3%), and the perceived ability to perform their daily activities in all patients (change 32.7 $\pm$ 9.6%); all the 9 patients who regularly performed sports activities improved their ability to do so (by 63.7 $\pm$ 15.6%). The overall satisfaction with the device was rated 79.6 $\pm$ 12.8%. Comfort was rated 73.3 $\pm$ 15.5%, and ease of use 45.8 $\pm$ 29.7%.
Conclsions
The user acceptance and satisfaction with the Eversense XL CGM was high among our type 1 diabetic patients. The general impression was an improvement in their quality of life, and in their perceived ability to perform their daily activities. In particular, their ability to perform sport activities was markedly enhanced.

Prevalence of autoantibodies in paediatric and adult patients with type 1 diabetes mellitus – study of a Portuguese cohort

Ines Cosme[1], Catarina Silvestre[1], Daniel Nunes[2], Carlos Lemos[2], Maria João Bugalho[1] & Helena Proença[2]
[1]Centro Hospitalar Universitário Lisboa Norte, Serviço de Endocrinologia, Diabetes e Metabolismo, Portugal; [2]Centro Hospitalar Universitário Lisboa Norte, Serviço de Patologia Clínica, Portugal

Introduction
Almost all type 1 diabetes mellitus (T1DM) patients have autoantibodies (ab) at disease onset. These ab prevalence varies according to patients' age, origin and disease duration.
Aim
Determine diabetes mellitus ab prevalence in a paediatric and adult T1DM Portuguese according to their age on diagnosis, gender and diabetes duration.
Methods
Retrospective review of T1DM ab (glutamic acid decarboxylase 65 autoantibodies – GAD, islet cell autoantibodies – ICA, insulin autoantibodies - IAA, tyrosine phosphatase–like insulinoma antigen-2 antibodies - IA2) evaluated from 2018 to 2021. Considering the age at ab assessment, patients were divided into prepuberty (0–12 years) or postpuberty ($\geq$ 13 years) and further subdivided into G1 and G2 when the assessment was at diagnosis or during follow-up, respectively.
Results
Included 156 patients (56.4% men; mean age 21.9$\pm$15.5 years). Of these, 101 (64.7%) belonged to G1 and 55 (35.3%) to G2 (mean age at diagnosis 15.1$\pm$10 vs. 20.7$\pm$12.1 years;$P=0.004$). In G1, 65 (64.4%) were men and 45 (44.6%) were prepubertal. In G2, 23 (41.8%) were men and T1DM mean duration was 13.4$\pm$14.2 years. The overall prevalence of positive ab was 83.2% in G1 and 69.1% in G2 ($P=0.042$), without differences between genders. There was a higher prevalence of GAD ($P=0.23$), IA ($P=0.009$) and ICA ($P=0.006$) in G1 and IAA ($P=0.17$) in G2. In G1, the mean number of positive ab was 1.6 and in G2 was 1.1 ($P=0.017$). In prepubertal G1 patients, positive ab prevalence was 88.9% (highest rate between 6–12 years) and in postpubertal was 78.6%, without significant difference regarding each ab prevalence in pre or postpuberty. In G2, patients diagnosed in postpuberty had a higher prevalence of ab, with a significant difference for GAD ($P=0.011$) and ICA ($P=0.025$). Patients with all ab negative (30.9%) had a T1DM duration of 19.2$\pm$13.1 years, while patients with at least 1 positive ab (69.1%) had T1DM duration of 10.7$\pm$14 years ($P=0.039$). Spearman's correlation test indicated that there was a negative and moderate correlation between the number of positive ab and the diabetes duration (rs=-0.5, $P=0.001$).
Conclsions
In our cohort, more than 80% of T1DM patients had positive ab at diagnosis. GAD and IA were the most prevalent ab, contributing to T1DM diagnosis both in pre and postpubertal patients. There was no difference between genders and ab prevalence. The number of positive ab decreased with disease duration.

Glucokinase (GCK) diabetes

Mona Abouzaid, Jean MacLeod & Naveen Aggarwal
North Tees and Hartlepool NHS Foundation Trust, Diabetes & Endocrinology Department, Stockton on Tees, United Kingdom

Background
Glucokinase (GCK) is a gene which plays an important role in recognising how high the blood glucose is in the body. It acts as the glucose sensor for the pancreas. Changes in the GCK gene can lead to increases in blood glucose and affected people may be diagnosed with diabetes although this rise in blood glucose is mild and does not need treatment. Glucokinase diabetes is one of familial diabetes types that called MODY (maturity onset diabetes of the young). We report a case was diagnosed with type 1 diabetes during her second pregnancy in 2006 and she was on insulin since. However, her genetic test in 2021 confirmed Diabetes - MODY2 – Heterozygous mutation in GCK.
Case report
50-year-old female diagnosed with type 1 diabetes during her second pregnancy in 2006 and at that time her ketone levels were high and therefore she was started on insulin. She was commenced on a basal bolus regime during her pregnancy. After pregnancy, she was only on Insulatard twice a day. Her insulin requirements were low so the type of diabetes was revisited in 2010 and at that time the islet cells antibodies were positive and therefore it was agreed to continue to treat her as type 1 diabetes. She was on a small dose of Insulatard and still having hypos and therefore the insulin was stopped in January 2020. Before that she had another set of blood tests done in November 2019 and at that time her islet cell, IA2 and GAD antibodies were all negative. The C peptide level was still in the middle of the range at 0.76 nmol/l. Her HbA1c remained between 39 and 47 mmol/mol since 2009. When she was monitoring blood sugars for a few months after coming off insulin, they were always in the normal range. Her MODY probability score shows the probability of MODY being 15.1%. Her genetic test results show a pathogenic GCK missense variant consistent with MODY2. Her daughter genetic test also confirmed the same variant. It was explained to her that there is no need for any treatment.
Conclusion
Patients with GCK gene variants generally have a mildly raised fasting blood glucose (typically 5.5- 8 mmol/l) and small increment at 2 hours ($<$4.5 mmol/l) on 75g oral glucose tolerance test (OGTT). Clinicians need to be aware of GCK gene variant and its implications.

Objective
Treatment with metreleptin ameliorates hepatic steatosis in patients with lipodystrophy. The anti-steatotic effect of metreleptin is partially independent of its anorexic action, which suggests a direct effect of metreleptin on hepatic lipid metabolism. However, this mechanism is unknown. Based on previous findings in rodents, we hypothesized that metreleptin reduces hepatic lipid content by stimulating very-low density lipoprotein triglyceride (VLDL1-TG) secretion, a key mechanism that protects the liver from steatosis.
Methods
In this randomized, placebo-controlled, crossover trial we investigated the effects of a single acute subcutaneous metreleptin injection (0.1 mg/kg body weight) in overnight-fasted patients with lipodystrophy on VLDL1-TG secretion (primary outcome) and hepatocellular lipid content (HCL%, secondary outcome). VLDL1-TG secretion rate was assessed using an intralipid infusion test combined with density gradient ultracentrifugation. Changes in HCL% were measured by H^1-magnetic resonance spectroscopy before and 3hrs after metreleptin or placebo injection. Patients previously on metreleptin treatment suspended injections for 14 days prior to the study. A two-sided paired t-test and the Wilcoxon signed rank test were used to analyze the differences after placebo vs. metreleptin injection in VLDL1-TG secretion and HCL%, respectively (statistical significance $P < 0.05$).
Results
We recruited 5 patients with familial partial lipodystrophy: 4 females and 1 male; age range 27.9–58.6yrs; BMI 25.8 ± 2.8 kg/m^2 (mean ± SD); all Caucasian; LMNA mutations confirmed in 2 cases; 2 previously on metreleptin treatment. An HCL > 5% was detected in 3 patients. Hepatic VLDL1-TG secretion rate was higher after metreleptin in 5 out of 5 patients (mean ± SD: 366 ± 146 mg/h vs. 588 ± 108 mg/h; placebo vs. metreleptin;$P = 0.019$), whereas no statistically significant difference was observed in HCL% fold change within 3hrs post injection (median[IQR]: 1% [-7%;5%] vs. -6%[-11%;0%]; placebo vs. metreleptin;$P = 0.23$)
Conclusion
Metreleptin markedly increases hepatic VLDL1-TG secretion in patients with lipodystrophy. This effect may play a role in the longterm antisteatotic action of metreleptin.

Evaluating obesity among second and third age premature children

R K Jha[1] & A K Chandra[2]
[1]DMCH, Darbhanga, India; [2]Kurji Holi Family Hospital, Patna, India

Introduction
Premature newborns are defined as babies born before 37 weeks of pregnancy and after 22 weeks of pregnancy as a viability limit. This study aimed to analyse growth characteristics at the age of second and third age and the prevention of metabolic diseases that may occur in adult age at an early phase.
Methods
This study was conducted as a retrospective cohort study between May 2021 and October 2021 in 18 different Outpatient Clinics in Patna, Bihar. All participants were at least 3 years old and their follow-up visits were made by the same family physicians for 3 years.
Results
The findings showed that 55% of the babies were males and 46% of them were females i.e., 123 participants were males and 102 participants were females. The evaluation of the body mass index showed that 19.8% were overweight (43 babies), 16% of the participants were obese (36 babies) at the age of 2. 20% of the participants were overweight (45 babies), 13.33% of the participants were obese (30 babies) at the age of three. Mean Hb levels of the mothers showed that those mothers whose children were obese at the age of two were statistically low as compared to those who were not obese'.
Conclusion
The worldwide prevalence of childhood obesity and overweight was 6.70% in the year 2010. In 2020, it was expected to reach 9.10%. When reasons for high obesity and overweight were searched, not much significant difference had been seen between feeding patterns and maternal factors. A significant relationship was however seen between maternal anaemia and obesity or overweight.

Higher glucocorticoid receptor sensitivity is associated with less favorable body composition in patients with obesity

Robin Lengton[1,2], Anand Iyer[1,2], Eline van der Valk[1,2], Bibian van der Voorn[1,2] & Elisabeth van Rossum[1,2]
[1]Erasmus MC, University Medical Center Rotterdam, Department of Internal Medicine, Division of Endocrinology, Rotterdam, Netherlands; [2]Erasmus MC, University Medical Center Rotterdam, Obesity Center CGG, Rotterdam, Netherlands

Background
Mounting evidence points to an association between increased glucocorticoid (GC) action and weight gain. However, the response to GCs is not only determined by GC serum concentrations, but also by individual differences in tissue-specific sensitivity, influenced by genetic and acquired (e.g. disease-related) factors. The extent to which differences in GC sensitivity may influence development of (abdominal) obesity, or vice versa, is poorly understood. In this study we investigate the relation between GC sensitivity and (abdominal) obesity.
Methods
Anthropometric data (BMI, weight, waist circumference and dual-energy X-ray absorptiometry (DXA) scans) and peripheral blood mononuclear cells (PBMCs) were obtained at baseline (T0) and completion of 10 weeks of treatment (T1) from 16 patients with obesity (BMI $\geq$ 30 kg/m^2) undergoing a combined lifestyle intervention with cognitive behavioral therapy. The half maximal effective concentration of dexamethasone (DEX), mediating the transactivation (EC50) or transrepression (IC50) of responsive genes GC-induced leucine zipper (GILZ) or interleukin (IL)-2 and IL-6 respectively in PBMCs, was used as a measure of GC sensitivity. The associations of EC50 and IC50 with BMI, weight, waist circumference, DXA fat mass and DXA leans mass, were analysed using linear regressions.
Results
A lower IC50 of DEX-mediated transrepression of IL-6 at inclusion (higher sensitivity) was associated with higher DXA fat mass (% of total body mass) (β = -0.52, 95%CI = -0.86 to -0.19) and lower DXA lean mass (% of total body mass) (β = 0.52, 95%CI = 0.18 to 0.86). Interestingly, the lower the IC50 for DEX-mediated transrepression of IL-6 at inclusion, the higher was the weight loss in the first 10 weeks of lifestyle intervention (T1, β = 0.32, 95%CI = 0.04 to 0.60). Similar, but non-significant, associations were observed for IL-2. However, there were no associations between EC50 of DEX-mediated transactivation of GILZ and any of the above-mentioned anthropometrics variables.
Conclusion
This study suggests that increased GC sensitivity is associated with a less beneficial body composition in patients with obesity. Although, increased GC sensitivity at baseline was associated with weight loss at T1, further analysis of the data is in progress to determine whether this seeming contradiction is related to changes in GC sensitivity after lifestyle intervention.

GLP-1 receptor agonists and erectile dysfunction in diabetic men with and without hypogonadism: a 1- year retrospective observational study

Giuseppe Lisco[1], Maria Isabella Ramunni[2], Giovanni De Pergola[3], Emilio Jirillo[4], Edoardo Guastamacchia[1], Vincenzo Triggiani[1] & Vito Angelo Giagulli[1]

[1]University of Bari Aldo Moro, Interdisciplinary Department of Medicine-Section of Internal Medicine, Geriatrics, Endocrinology and Rare Diseases, University of Bari 'Aldo Moro', School of Medicine, Policlinico, Bari, Italy; [2]Local Health Bari, Outpatients Clinic of Endocrinology and Metabolic Disease, Conversano Hospital, Conversano, Italy; [3]Hospital Saverio De Bellis, Castellana Grotte, Italy

Background
Erectile dysfunction affects nearly half of men with type 2 diabetes (T2DM), and one-third of diabetic men have hypogonadism[1]. As an add-on to TRT in hypogonadal men with T2DM, Liraglutide may improve erectile function[2], and dulaglutide decreased the incidence of moderate and severe ED in T2DM[3].
Study aims
To assess the GLP-1RA effect in T2DM men complaining of ED treated with both liraglutide and dulaglutide as an add-on to metformin.
Design overview
This was a 1-year retrospective observational study. Patients with established type 2 diabetes mellitus, serum HbA1c $<$ 8.5%, two or more additional cardiovascular risk factors were included. Men with estimated glomerular filtration rate (eGFR) $<$ 60 ml/min per 1.73 m^2 were excluded. As per protocol, men with HbA_{1c} $<$7.2 % received metformin (2000 mg per day) while those with serum HbA1c $>$7.2% received a GLP-1RA as in add-on to metformin (52% liraglutide, 1.2 mg/day; 48% dulaglutide, 1.5 mg/week) for one year. ED was diagnosed and classified by the International Index of Erectile Function 5 (IIEF5) score. Hypogonadal men were identified according to standardized parameters from the European Male Aging Study (EMAS).
Results
Forty-eight men with hypogonadism (HP) and 62 eugonadal individuals (EP) complaining of ED were retrospectively eligible for analyses. Mean age ranged 51–64 years; T2DM evolution ranged from 5–10 years. Around 6% of participants had established cardiovascular disease. Twenty-eight HP were on metformin plus a GPL-1RA (HPs), and 20 HP were on metformin alone (HPc); thirty-eight EP received metformin plus a GPL-1RA (EPs), and 30 were on metformin alone (EPc). After 12 months of treatment, both HPs and EPs significantly reduced serum HbA_{1c} compared to baseline (-0.7 $\pm$ 0.3 %; $P<0.001$). HPc and EPc slightly increased HbA_{1c} (0.4 $\pm$ 0.2). IIEF 5 score increased from baseline (all $P<0.01$) in HPs and EPs.
Conclsione
Liraglutide and dulaglutide seem to have a favorable effect on ED in T2DM men with and without baseline hypogonadism. Further controlled studies are needed to confirm those preliminary results.

Prevalence and awareness of complications in type 2 diabetes mellitus : a hospital based comparative cross-sectional study

Uttar Kumar Mainali[1], Laxmi Narayan Kamat[1], Sanjeep Khatri[2] & Den Prasad Acharya[1]
[1]Koshi Hospital, Medicine, Biratnagar, Nepal; [2]Koshi Health Institute, Public Health, Biratnagar, Nepal

Introduction
Diabetes Mellitus appears to be globally pandemic and is drawing attention as a major public health concern. Chronic complications of this disease can lead to poor quality of life with significant financial burden to family and country as well. The current study aims to assess prevalence of such complications and its awareness in type 2 diabetes population.
Methods
This descriptive cross-sectional study was conducted during one year period in Endocrinology Outpatient Department of Koshi Hospital, Biratnagar, Nepal from 1st January 2021 to 31st December 2021. Consecutive sampling was applied and face to face interview was conducted to collect the information after informed verbal consent. Various factors related to awareness level were noted and compared.
Results
Out of 495 participants, 294 (59.4%) were male and 201 (40.6%) were female. The mean age of the participants was 52.07 $\pm$ 11.35 years. Of total patients 49.7 percent had diabetes related complications. Out of them 30.9 percent had one, 13.9 percent had two, 4.2 percent had three and 0.6 percent had four complications pertaining to their primary condition i.e. Diabetes Mellitus. Peripheral neuropathy was high (27.5%) followed by Diabetic retinopathy (17.6%), Diabetic Kidney Disease (16.2 %), Ischemic Heart Disease and/or Heart failure (4.8%), sexual problems (3.8 %) and Cerebrovascular disease (3.4%). Regarding awareness, only 45.5 percent had good awareness on microvascular and macrovascular complicatons related to Diabetes. Among the 49.7 percent patients who had complications, only 48.3 percent patients with retinopathy were aware that their retinopathy was secondary to Diabetes Mellitus. Similarly it was 75 percent awareness in case of cardiovascular complications, 52.9 percent with Cerebrovascular disease, 43.8 percent with Diabetic Kidney Disease, 43.4 percent with neuropathy and 31.6 percent with sexual problems. Participants of older age, male gender, longer duration of disease, higher literacy status and having other diabetic patient in family were more aware about the complications of type 2 diabetes than their counterparts.
Conclsion
This study revealed that there is lack of awareness in diabetic population on micro and macrovascular complications even them having considerable prevalence of such complications. The primary care physicians, diabetes educators and public health program implementers all have an important role in educating diabetics on chronic complications and measures to prevent them so that patients' morbidity and financial burden to family and country can be reduced or prevented.

Assessment of risk of foot ulceration in a group of long-standing type 1 diabetic patients

Emna Bornaz[1], Haifa Abdesselem[1], Manel Dridi[1], Yosra Hasni[2], Kamilia Ounaissa[1], Fatma Boukhayatia[1], Imene Sebai[1], Asma Ben Brahim[1], Rim Yahiaoui[1] & Chiraz Amrouche[1]
[1]National Institute of Nutrition, Outpatient Department and functional explorations, tunis, Tunisia; [2]Farhat Hached Hospital, Department of Endocrinology, Tunisia

Background
Diabetic foot represents a serious complication due to its prevalenceas well as its impact on functional and vital prognosis of the diabetic patient. The aim of our study was to assess the risk of foot ulceration in a group of long-standing type 1 diabetics.
Methods
We conducted a descriptive observational cross-sectional study including type 1 diabetic patients who had diabetes for more than 20 years, followed at the National Institute of Nutrition of Tunis. The risk of foot ulceration was determined according to the International Working Group of the Diabetic Foot (IWGDF) grading. Then, we devided patients into two groups: patients with low podiatric risk (grade 0 or 1) and patients with moderate to high podiatric risk (grade 2 or 3).
Results
Sixty patients were included in this study. The mean age was 38.92 $\pm$ 8.17 years. The mean duration of diabetes was 26.98 $\pm$5.95 years [ext : 20–48 years]. A history of amputation and plantar puncture was found in two patients. Foot deformity was noted in 31.7% of participants. Thirty-eight percent of the patients had sensory neuropathy. Obliterative arteriopathy of the lower limbs was diagnosed in 5% of the patients. According to the IWGDF classification; 53.3%, 23.3%, 20% and 3.4% of patients had grade 0,1,2 and 3 respectively. Univariate analysis showed that risk of foot ulceration was associated with age ($P=0.001$) and duration of diabetes ($P=0.004$). Only the association with age persisted after multivariate analysis ($P=0.013$).
Conclsion
Our study highlights the importance of screening of diabetic foot as well as prevention of foot abnormalities, particularly in long-standing type 1 diabetics.
DOI: 10.1530/endoabs.81.P357

Long-standing type 1 diabetes and female sexuality : Is there impact ?

Emna Bornaz, Haifa Abdesselem, Amal Salem, Kamilia Ounaissa, Fatma Boukhayatia, Imene Sebai, Asma Ben Brahim, Rim Yahiaoui & Chiraz Amrouche
National Institute of Nutrition, Outpatient Department and Functional Explorations, Tunis, Tunisia

Background
While sexual dysfunction in men with type 1 diabetes is well known, sexual dysfunction in women remains a neglected issue. The aim of this study was to

assess the sexual quality of life (SQOL) of women with long-standing type 1 diabetes.
Methods
We conducted a cross-sectional study of women followed at the National Institute of Nutrition and Food Technology of Tunis. We included women with type 1 diabetes for 20 years or more. Women who were not sexually active and those who were pregnant or breastfeeding were not included. The Audit Diabetes Dependent Quality of Life score was used to assess quality of life. This scale assesses overall quality of life, quality of life without diabetes and 19 life domains, includingsexual life. SQOL was impaired if its relative score was less than (-3).
Results
We included 39 patients with mean age 40.77 ± 7.9 years [ext :29–60 years]. Participants had been sexually active for a mean of 11 ± 8.9 years. All women included had only one partner. The mean glycated hemoglobin (A1c) was 9.3 ± 1.3%. The mean QOL score was (-3) ± 3 with extremes ranging from (-9) to 0. SQOL was impaired in 64.1% of the population. Univariate study showed that impaired SQOL was associated with history of in utero fetal death ($P = 0.012$) and number of abortions ($P = 0.015$). SQOL was associated with quality of life without diabetes ($P = 0.012$). Overall quality of life, glycaemic control, and chronic complications of diabetes were not associated with SQOL.
Conclsion
The results of our study highlight the impact of previous pregnancies on the SQOL of long-standing type 1 diabetic patients. Hence the importance of psychological support for all these women, especially those who has experienced an early or late abortion.

New insights into obesity treatment provided by smart technologies and telemedicine

Iva Jakubíková[1], Kristýna Štolbová[2], Peter Novodvorský[1], Iveta Dvořáková[3], Barbora Doležalová[1], Szabolcs Kalina[4], Petr Raška[4], Josef Kautzner[2] & Martin Haluzík[1]
[1]Institute for Clinical and Experimental Medicine, Diabetes Centre, Prague, Czech Republic; [2]Institute for Clinical and Experimental Medicine, Department of Cardiology, Prague, Czech Republic; [3]Institute for Clinical and Experimental Medicine, Centre for Experimental Medicine, Prague, Czech Republic; [4]Institute for Clinical and Experimental Medicine, Information Technologies Department, Prague, Czech Republic

Introduction
Obesity represents a major public health challenge and is linked with increased risk of multiple medical conditions including atrial fibrillation (AF). We have recently published the study protocol of the '*The Effect of complex weigHt-reducing interventiOns on rhythm control in oBese subjects wITh Atrial Fibrillation*' (HOBIT-AF) trial. Here we communicate the preliminary results with the focus on the use of smart technologies and telemedicine.
Methods
HOBIT-AF is a single-blinded, parallel-group, randomised controlled trial with 18-month follow-up to assess the effect of complex weight-reducing interventions supported by the use of smart technologies on the arrhythmia burden in obese individuals following catheter ablation for AF. Participants are randomised in a 1:1 fashion to undergo a structured weight reduction programme and optional sleeve gastrectomy aiming to achieve greater than 10% weight reduction (intervention group) or standard post-ablation medical care (control group). All participants are provided with the Apple Watch Series 5 and iPhone (Apple Inc, Cuppertino, CA, USA). Daily initial settings for the intervention group are as follows: 5000 steps, 30 minutes of physical activity, energy expenditure of 300 kCal, home self-monitoring of blood pressure, heart rhythm, body weight, waist circumference etc. Control group have no goals set and use smart technologies solely for the heart rhythm monitoring. Individual patient goals and settings are monitored by healthcare team by a custom made software IKEMOnlineFit.
Results
Thus far 75 patients have been enrolled into the trial of which 50 are male. Mean baseline characteristics are as follows: age 56 years, weight 118 kg, BMI 37 kg/m2, waist circumference 128 cm. 69 % patients suffer from paroxysmal AF, the rest of persistent. No statistically significant differences in baseline characteristics were detected between the groups at randomization time. Thus far, participants in the intervention group lost 6 % in weight, walked on average 8300 steps per day, performs 32 active minutes daily, energy expenditure of 900 kCal daily. Control group have lost 0,4% in weight so far, walked 3700 steps per day, and had energy expenditure of 600 kCal daily. In intervention group,1 patient underwent sleeve gastrectomy, the rest cut down on weight by life-style intervention or were provided by a GLP-1 receptor analogue liraglutide from the 9thstudy month onwards. All participants use smart technologies.
Conclusion
This time calls for wider usage of smart technologies and telemedicine. Our preliminary results are very promising in relation to their usage in the management of obesity.

Functional analysis of melanocortin-4 receptor variants linked to obesity

Alejandra Virginia, Rodriguez Rondon[1,2], Martin Huisman[1,2], Mila Welling[1,2,3], Erica van den Akker[2,3], Elisabeth van Rossum[1,2], Patrick Delhanty[1,2] & Jenny Visser[1,2]
[1]Erasmus MC, Department of Internal Medicine, Rotterdam, Netherlands; [2]Obesity Center CGG, Erasmus MC, Rotterdam, Netherlands; [3]Erasmus MC, Department of Pediatrics, Rotterdam, Netherlands

Introduction
Melanocortin-4 receptor (MC4R) is a G-protein-coupled receptor expressed in regions of the hypothalamus regulating appetite and energy expenditure. Extensive evidence from genetic and biological studies show that MC4R is a key player in the homeostatic regulation of body weight. MC4R loss of function (LoF) variants are the most common cause of monogenic obesity. We have identified 13 heterozygous MC4R variants in patients with obesity at our academic Obesity Center CGG, Erasmus MC. However, it is unknown whether these variants affect MC4R signaling and are causing obesity. Here, we functionally characterized these variants by analyzing the effects on cell surface expression, MSH-induced cAMP production and β-arrestin 2 (βarr2) recruitment.
Methods
HEK293 cells were transiently transfected with expression plasmids encoding WT or variant MC4R and stimulated with MSH. cAMP response was measured using GloSensor cAMP bioluminescence assay, NanoBiT complementation luminescence assay was used to measure βarr2 recruitment, and the cell surface expression was measured using HiBiT Detection System.
Results
Thirteen variants were identified by sequencing the *MC4R* gene of adult and pediatric patients with obesity using an obesity gene panel. Eight of these variants have not been previously reported in literature. The median age of onset obesity for the adult patients was 1.0 year and for the pediatric patients was 1.9 years. Furthermore, the median BMI of the adult patients was 48.8 kg/m^2(range 36 - 58.8) and the median BMI-SD of the pediatric group was +4.2 SD (range +3 SD - +7 SD). Eleven out of 13 patients presented with hyperphagia. MC4R variants had differential effects on cAMP production, βarr2 recruitment and cell surface expression. Eight of the 13 MC4R variants caused partial or complete LoF for both cAMP production and βarr2 recruitment; out of those eight variants, three showed no cell surface expression. Surprisingly, two of the 13 MC4R variants resulted in a gain of function for cAMP production, and two other variants showed a normal cAMP response as well as βarr2 recruitment.
Conclsion
We show that the MC4R variants identified in our patients with obesity affect MC4R signaling differently, through modulation of cell surface expression, cAMP and/or βarr2 signaling pathways. Therefore, this study demonstrates the value of examining different aspects of MC4R signaling to understand possible biased effects of mutations on these pathways. Overall, our results show the clinical importance of assessing the function of MC4R variants as these studied variants are likely to be causative of obesity.

Comparison of glycemic variability in type 2 diabetes mellitus patients on oral anti diabetic drugs (OAD) with and without insulin using ambulatory glucose profile (AGP)

Sidharth S[1], Ramesh Aggarwal[1], Anupam Prakash[1], L H Ghotekar[1] & Meenakshi Aggarwal[2]
[1]Lady Hardinge Medical College, Medicine, New Delhi, India; [2]Kalawati Saran Children's Hospital, Microbiology, New Delhi, India

Introduction
Assessment of diabetes with daily blood glucose fluctuations including peaks and nadirs forms the crux of the modern management. Use of glycemic variability

(GV) as a parameter to assess these fluctuations is emerging. Diabetes mellitus patients follow different clinical trajectories which can be traced by the ambulatory glucose profile (AGP) obtained from flash glucose monitoring system (FGMS).
Methodology
This comparative observational study enrolled 106 adult (>18 years) type 2 diabetes patients with HbA1c<8% from a tertiary care hospital in India. Patients were divided into two groups (group A & group B) with 53 patients each. Group A included patients on OAD's with insulin and Group B included patients on OAD's without insulin. The patients were put on FGMS for 14 days and their AGP was analysed. Indices of glycemic variability like Mean, MAGE (Mean amplitude of glycemic excursion), SD (Standard deviation), COV (Coefficient of variation), time in target (TIT), time above target (TAT), time below target (TBT), MODD (Mean of daily differences) were computed using Mann Whitney test.
Results
Median (25th-75th percentile) of glycemic variability parameters - Mean(mg/dl), MAGE(mg/dl), SD(mg/dl), time above target(%), MODD in group A {Insulin} was {139, 145, 44.68, 40, 38.47} respectively which was significantly higher as compared to group B{OAD} {111, 123, 33.31, 18, 26.31} respectively ($P<0.05$). Time in target (%) depicting time in glucose range of 70–180 mg/dl and time below target was achieved more with group B{OAD} (54% & 12%) as compared with group A {Insulin} (39% & 7%) respectively ($P<0.05$). No significant difference was found for COV between the groups. Amongst the OAD's used in patients taking insulin {group A}, glycemic variability was higher with sulfonylurea as compared with DPP-4 inhibitors for the parameter of mean(mg/dl) and MODD (217.5 & 52.4 vs 126.5 & 31.38 respectively). DPP-4 inhibitors achieved higher time in target (53%) as compared with sulfonylurea (11%) ($P<0.005$). No significant difference in glycemic variability was found in subgroup analysis of group B (OAD) in our study. Group A patients had significantly higher (29.99%) total number of hyperglycemic episodes than with group B (9.08%) (p value<0.0001).
Conclusion
Our study showed that the glycemic variability was found to be significantly higher in patients taking OAD's with insulin (group A) as compared with patients who were taking OAD's without insulin (group B). DPP-4 inhibitor was found to achieve more time in target range with less glycemic variability as compared with sulfonylurea.

Morphofunctional assessment of cancer patient's nutritional status receiving systemic treatment and oral nutritional supplements

Soraya León-Idougourram, Mireia García-Ramírez, Carlos Manuel Alzás-Teomiro, Gregorio Manzano-García, Concepción Muñoz-Jiménez, Alfonso Jesús Calañas-Continente, Rosa Rodríguez-Alonso, Maria José Molina-Puerta, María Ángeles Gálvez-Moreno & Aura Dulceida Herrera-Martínez
Hospital Universitario Reina Sofia, Endocrinología, Córdoba, Spain

Introduction
Disease-related malnutrition is one of the main factors associated with morbidity and mortality in cancer patients. Furthermore, maintaining and improving muscle mass and function are important to achieve an optimal nutritional status. In this sense, the role of leucine-enriched essential amino acids supplementation for the therapeutic approach to the promotion of muscle anabolism stands out.
Methods
46 cancer patients with malnutrition receiving systemic treatment were randomized to receive for three months leucine-enriched essential amino acids supplementation or standard supplements. Patients were evaluated before and after three months. Nutritional assessment was performed using bioelectrical impedance analysis (BIA), dynamometry, ultrasound of rectus femoris muscle and subcutaneous fat tissue, functional tests and laboratory parameters.
Results
54% women. Mean age: 65 years. Median BMI: 24 kg/m2. 19,6% with colorectal cancer. Regardless of primary tumor origin, 63% of patients received combined modality therapy consisting of surgery along with chemotherapy and/or radiotherapy. 80% of patients were classified as malnourished according to the GLIM criteria and 67% of patients presented decreased standardized phase angle (SPA) in the first morphofunctional assessment (Median 4.5° IQR 3.6–5.9). Positive correlation between 'Timed-Up-and Go' test (TUG), dynamometry and SPA was demonstrated ($P<0.05$). Nutritional supplementation increased prealbumin levels and decreased CRP values. Malnutrition was resolved three months later in 16% of patients. There were no significant differences between nutritional supplements in ultrasound parameters, body composition, functional test or prevalence of malnutrition after intervention.
Conclusion
In a third of patients disease-related malnutrition was resolved despite being in treatment with combined therapy. There were no differences between nutritional supplements, probably because of the short duration of nutritional treatment.

Evaluation of the Ankle-brachial index in a group of long-standing type 1 diabetic patients

Emna Bornaz[1], Haifa Abdesselem[1], Hajer Moalla[1], Nesrine Souissi[1], Kamilia Ounaissa[1], Fatma Boukhayatia[1], Imene Sebai[1], Feyka Ben Mami[2] & Chiraz Amrouche[1]
[1]National Institute of Nutrition, Outpatient Department and Functional Explorations, Tunis, Tunisia; [2]National Institute of Nutrition, Department of Diabetology and Therapeutic Dietetics, Tunis, Tunisia

Background
Lower extremity artery disease (LEAD) is a common complication of diabetes, with increasing prevalence with duration and/or the coexistence of other cardiovascular risk factors. The Ankle-brachial index (ABI) is the first diagnostic step after clinical examination, for screening and diagnosis of LEAD. The aim of our study was to evaluate the ABI in a group of long-standing type 1 diabetic patients.
Methods
We conducted a cross-sectional study at the National Institute of Nutrition of Tunis. We included type 1 diabetic patients who had diabetes for more than 20 years. We measured the brachial systolic pressure using the tourniquet and the Doppler probe and the posterior tibial systolic pressure. A high ABI (>1.30) suggests the presence of mediacalcosis. An ABI ≤0.90 indicates the presence of LEAD.
Results
We included 155 type 1 diabetic patients with mean age39.7±9.8 years. The population was predominantly female (67.1%). Mean duration of diabetes was 27.33±6.38 years [ext : 20–48 years]. Mean glycatedhemoglobin (A1c)was 9.45±1.62%. The mean ABI was 1.22 ± 0.25 with extremes ranging from 0.76 to 2.18. The majority had an ABI between 0.9 and 1.3. An ABI > 1.3 was found in 18.6% of patients. Only 5.2% of patients had an ABI < 0.9. The ABI was correlated with age ($r=0.360$; $P<0.001$) and duration of diabetes ($r=0.398$; $P<0.001$). It was inversely correlated with insulin dose ($r=-0.279$; $P=0.006$).
Conclsion
Most patients with LEAD are asymptomatic. Patients with diabetes are at higher risk of chronic limb-threatening ischaemia as the first clinical manifestation of LEAD, supporting regular screening with ABI measurement for early diagnosis.

Acute hemolytic anemia due to glucose-6-phosphate dehydrogenase deficiency during treatment of diabetic ketoacidosis in an African American patient diagnosed with Ketosis-prone diabetes

Panagiotis-Nikolaos Tsakalomatis, Vasiliki Daraki, Rodanthi Vamvoukaki, Maria Mytilinaiou, Eleni-Konstantina Syntzanaki, Kalliopi Kontolaimaki, Maria Chrysoulaki, Maria Sfakiotaki, Vasiliki Venetsanaki, Katerina Bouki, Grigoria Betsi & Paraskevi Xekouki
University General Hospital of Heraklion, Endocrinology and Diabetes Clinic, Heraklion, Crete, Greece

Background
Diabetic ketoacidosis (DKA) has been associated with severe hemolysis in patients with Glucose-6-phosphate dehydrogenase (G6PD) deficiency after restoration of euglycemia. Less than 30 cases have been reported so far. The exact mechanism is not fully understood.
Case presentation
A 35-year-old African American man presented to the emergency department with polyuria, polydipsia, abdominal pain and weight loss the last 15 days. Physical examination revealed an afebrile man with severe dehydration, tachypnoea and tachycardia. Diagnosis of DKA was confirmed by laboratory tests. Remarkably, he had no previous history of precipitating factors but he reported use of cannabis twenty days ago, which was confirmed by toxicological testing. He was treated with hydration and intravenous insulin infusion, with a remarkable clinical and biochemical improvement. One day after he was switched to subcutaneous insulin therapy, a significant reduction in hemoglobin (9.2 g/dl)

accompanied by an increase in indirect bilirubin (1.59 mg/dl) was observed. Direct Coombs was negative and haptoglobin was <7.38 (20–200) mg/dl. Examination of peripheral blood smear revealed blister cells, indicative of hemolysis. Medical history was negative for common hemolytic causes. Considering that African American men are commonly affected with G6PD deficiency, with a prevalence of approximately 10%, deficiency of this enzyme was suspected and confirmed by its low level (3 IU). Hemolysis was resolved after several days, and the patient left the hospital on intensive insulin regimen. During follow up, gradual reduction of total daily insulin requirements was observed, with permanent discontinuation 10 weeks later. C-peptide stimulation test, showed a peak c-peptide up to 1.1 mg/dl, suggesting residual pancreatic b-cell function. Antibodies to insulin, islet cell, glutamic acid decarboxylase and protein tyrosine phosphatase were negative. The diagnosis of Ketosis-prone diabetes (KPD) A-β+ subtype was established. During annual follow up, patient was euglycemic without any antidiabetic treatment.
Discussion
KPD is a heterogeneous syndrome characterized by varying degrees of insulin deficiency. It is classified into four subgroups according to Aβ classification system. 'A' is referring to the presence or absence of islet autoantibodies and 'β'is referring to the presence or absence of b-cell functional reserve, measured 6–8 weeks after DKA episode. Recent data suggest that alterations in genes controlling both insulin secretion and G6PD-mediated antioxidant defenses may contribute to the predisposition to KPD in West Africans with G6PD deficiency. The occurrence of hemolysis in these patients during treatment of DKA is increased and should be investigated.

Flash glucose monitoring in patients with DM3c

Ángel Rebollo-Román, Soraya León-Idougourram, Carlos Manuel Alzás Teomiro, Paloma Moreno-Moreno & Maria Angeles Galvez Moreno
Hospital Universitario Reina Sofía, UGC Endocrinología y Nutrición, Córdoba, Spain

Objective
Flash glucose monitoring (FGM) allows non-invasive glucose level assessment. Since November 2020 the use of this system is subsidized in patients with type 3c diabetes (DM3c) Our objective was to describe the characteristics of these patients and their glycemic control expressed as times in range.
Methods and patients
Observational longitudinal clinical study between January 2021 and December 2021 in patients with DM3c in which FGM implementation was subsidized
Results
26 patients included. Mean age: 59.27 ± 12.22 years, with DM diagnosed with a mean age of 51.85 ± 12.19 years. 30.8% women. 76.9% use of pancreatic enzymes in these patients. FGM metrics: A mean use of 91.17 ± 8.57%. 74.83 ± 16.12% time in range, 16.91 ± 11.82% time between 180–250 mg/dl, 5.35 ± 7.50% time above 250 mg/dl, 2.65 ± 2.99% time between 54–70 mg/dl, 0.13 ± 0.34% time below 54 mg/dl. Glycemic CV 31.59 ± 6.61%. 39.1% of patients achieved all clinical targets for FGM metrics.
Conclusion
- The main cause of DM3c in our series was surgical pancreatic resection (38.5% of patients)
- In our series of patients with DM3c and FGM, metabolic control was adequate using the same clinical targets as in DM1. 39.1% of patients achieved all clinical FGM targets.

Table 1.

Cause of DM3c	n	%
Chronic pancreatitis (CP) due to alcohol abuse	4	15.4
CP w/o alcohol abuse	4	15.4
Pancreatic surgery (Tumour)	3	11.5
Pancreatic surgery (Non tumoral)	10	38.5
Cystic fibrosis	1	3.8
Others	3	11.5

Impact of glucose monitoring on quality of life

David Veríssimo, Catarina Ivo, Vitória Duarte, Ana Cláudia Martins, Joao Silva, Luis Lopes, Dolores Passos, J Jácome Castro & Mafalda Marcelino
Portuguese Armed Forces Hospital, Endocrinology Department, Lisboa, Portugal

Introduction
The quality of life (QoL) of patients with Diabetes has been the subject of several studies worldwide. In Portugal, studies have shown that patients under intensive insulin therapy had worse results in QoL questionnaires. The introduction of interstitial glucose monitoring (IGM) appears to reduce the impact of insulin therapy on QoL.
Objective
To assess whether IGM changes the quality of life of patients with diabetes, compared to the assessment of glycemia and its impact on glycemic control of patients.
Methods
Retrospective cohort study of patients with diabetes under intensive insulin therapy and IGM system. The 'Appraisal of Diabetes Scale' (ADS) questionnaire was used, which consists of a set of 7 items summed to reflect the patients' self-appreciation of their diabetes management. A 0 score indicates good management, with minimal impact on quality of life and 35 worse management and a negative impact on quality of life. The ADS was completed in two stages: a questionnaire applied at the time they used blood glucose monitoring and a questionnaire applied when using IGM systems.
Results
29 patients, 80.6% male, mean age 61 years, 58.6% with type 2 diabetes and 41.4% with type 1 diabetes. At the implementation of the IGM system, the mean duration of diabetes was 19.3 +/- 11.2 years, with HbA1c of 8.4 +/- 1.5% and 4.5 +/- 2.6 daily capillary blood glucose tests, on average. The ADS result reported to this date averaged 19 +/- 5 points. After the introduction of IGM, for an average period of 13.9 +/- 10.6 months, the mean ADS value was 16 +/- 4, corresponding to a significant reduction of 17% ($P<0.0001$). The mean HbA1c was 7.8 +/- 1.2%, corresponding to a 7% reduction ($P=0.03$), with an increase in the number of glucose measurements (12 +/- 11 IGM measurements per day ($P=0.004$). ADS and HbA1c results were independent of time of IGM use ($P=0.2$ and$P=0.4$) and number of daily glucose measurements ($P=0.7$ and$P=0.9$).
Discussion
The results demonstrate that the use of IGM, regardless of the number of measurements or the date of placement, has a positive impact both on diabetes control and on patients' perception of their disease management, with a consequent improvement in QoL.

Metformine: anti-fibrotic molecule?

Dayssem Khelifi[1], Ibtissem Ben Nacef[1], Kahena Bouzid[2], Imen Rojbi[1], Youssef Lakhoua[1], Nadia Mchirgui[1] & Karima Khiari[1]
[1]Charles Nicolle University Hospital, Endocrinology's Department, Tunisia; [2]Charles Nicolle University Hospital, Clinical Biochemistry Department, Tunisia

Background and aims
Diabetes causes tissue fibrosis by still poorly understood mechanisms which involve glycation products. Galectin-3 (Gal-3) is an emerging key player in metabolic disorders and a powerful factor in the development and progression of the fibrotic process in target organs in diabetic patients. The plasma level of Gal-3 increases during diabetic cardiomyopathy and diabetic nephropathy. We have studied the correlation between serum Gal-3 level and anti-diabetic treatment.
Methods
We carried out a cross-sectional study with an analytical aim. This work was carried out on type 2 diabetic patients followed in our department whose age range between 35 years and 80 years.
Results
On the therapeutic level, 11 patients (4.2%) were under hygieno-dietetic rules alone, 131 patients (50.4%) on oral anti-diabetics alone, 30 patients (11.5%) on insulin therapy alone and 88 patients (33.8%) on oral anti-diabetics and insulin therapy. For the oral treatment class, 207 patients (79.8%) were on metformin, 64 patients on sulfonylureas (24.6%), 13 patients (5%) on acarbose, 2 patients (0.8%) on glinide. We found a significant negative correlation of Gal-3 with metformin treatment ($r=-0.042$; $P=0.028$).

Conclsions
We observed a significant inverse correlation between Gal-3 and metformin treatment and this effect was independent of BMI, HbA1c and CRP. Metformin reduces oxidative stress and the formation of AGEs (advanced glycation products). This may help lower serum Gal-3 levels. Metformin has also been shown to reduce Gal-3 in human adipocytes and monocytes indicating a direct effect of metformin against fibrosis. Metformin has been argued to exert a nephroprotective effect by attenuating renal fibrosis, as well as as an effect on reducing cardiac remodeling.

Comparative analysis of clinical, obstetric and perinatal characteristics of pregnant women according to serum levels of vitamin D

Víctor José Simón Frapolli, Andrea Fernández Valero, Miguel Damas Fuentes, María Molina Vega, María José Picón César & Francisco José Tinahones Madueño
Hospital Universitario Virgen de la Victoria, Endocrinology and Nutrition, Málaga, Spain

Introduction
Vitamin D is considered a fat-soluble vitamin and a fundamental prohormone in mineral and bone metabolism, with an immunoregulatory, cardiovascular and neuroprotective effect, among others. Vitamin D can be found as vitamin D2 or ergocalciferol and vitamin D3 or cholecalciferol. The main source of vitamin D comes from ultraviolet radiation in sunlight, but it is also obtained through food. Vitamin D deficiency is very prevalent in Europe, with a significant peak in Spain among the pregnant and infant population, being associated with adverse maternal-fetal effects such as gestational diabetes mellitus (GDM), deficit of bone mineralization in the newborn and increased risk of preeclampsia.
Material and method
Retrospective observational study that analyzes the data of 148 pregnant women, with a mean age of 33.32 ± 5.29 years, who came to our service to undergo 100g-SOG as a diagnostic test for GDM. Pregnant women were classified into 3 categories based on serum vitamin D levels (≤20 ng/ml, 20–29.99 ng/ml, ≥30 ng/ml), and different clinical, obstetric and perinatal variables were compared. In addition, the correlation of these variables with vitamin D levels was studied.
Results
No statistically significant differences were observed between serum vitamin D levels and the prevalence of GDM, BMI prior to pregnancy, blood pressure, HOMA-IR, total cholesterol, LDL, triglycerides, or newborn weight, among others. However, an elevation of HDL is observed in the pregnant group with higher levels of vitamin D, and an inverse correlation is observed between vitamin D and BMI prior to pregnancy, but not with the rest of the variables.
Conclsion
In our population, no differences were found between clinical, perinatal and obstetric parameters according to vitamin D levels. Vitamin D levels were only inversely correlated with BMI prior to pregnancy.

A role for somatostatin in regulating weight regain after bariatric surgery in mice

Doron Kleiman, Yhara Arad, Anna Permyakova, Joseph Tam, Rachel Ben-Haroush Schyr & Danny Ben-Zvi
Hebrew University of Jerusalem, Jerusalem, Israel

Somatostatin is a hormone and neuropeptide expressed in the pancreas, gastrointestinal tract, hypothalamus, and other tissues. It regulates directly the secretion of insulin, glucagon, many of the gastrointestinal hormones, and growth hormone. It is therefore surprising the somatostatin knockout (sst-ko) mice have a very mild phenotype. We subjected sst-ko mice and heterozygous siblings which served as controls to a high-calorie diet, and confirmed that sst-ko mice gain weight normally and have slightly more adipose tissue. Continuous glucose measurement of these mice has shown they have lower glycemia than controls. both groups of mice lost weight and regained weight at the same rate after a short transition to a normal chow diet. However, sst-ko mice did not regain weight following sleeve gastrectomy (SG), a common bariatric surgery. Sst-ko mice maintained low weight 90 days after surgery, while fed on a high-calorie diet and were leaner than heterozygous siblings that had the same procedure. SG operated sst-ko mice had low fasting insulin levels, and very rapid glucose clearance. Mechanistically, SG sst-ko mice had an exaggerated post-prandial Glp1 secretion. Post-prandial Glp1 levels were higher than in heterozygous controls that had the same surgery. Sham-operated sst-ko mice did not display an elevation in Glp1 secretion. In conclusion, by performing sleeve gastrectomy on sst-ko mice we were able to expose a role for somatostatin in regulation glycemia and weight gain, in part via regulating postprandial Glp1 secretion.

Differential localisation of the A-ring reductases in human hepatocytes: implications for substrate preference and utilisation

Tom Potter[1], Ismael da Conceição[2], Nikolaos Nikolaou[2], Nellie Loh[2], Jeremy Tomlinson[2] & Laura Gathercole[1]
[1]Oxford Brookes University, Department of Biological and Medical Sciences, Oxford, United Kingdom; [2]University of Oxford, Radcliffe Department of Medicine, Oxford Centre for Diabetes, Endocrinology & Metabolism, Oxford, United Kingdom

The 5-reductases are steroid metabolising enzymes that saturate the C4=C5 bond of the steroid A-ring, and their substrates include androgens, glucocorticoids, and bile acids. 5β-reductases (SRD5A1 & SRD5A2) convert testosterone to the more potent androgen 5β-dihydrotestosterone, and carry out the first step in glucocorticoid clearance, generating 5β-dihydrocortisol from cortisol. 5β-reductase (AKR1D1) is also able to carry out the first step of glucocorticoid clearance, converting both cortisol and cortisone to 5β-dihydrocortisol and 5β-dihydrocortisone but, in contrast to 5β-reductases, it converts testosterone to a low activity intermediate, 5β-dihydrotestosterone. In addition, it catalyses an essential step in bile acid synthesis. The subcellular localisation of steroid metabolising enzymes is thought to have a role in determining their activity and substrate preference. In this regard, hepatic SRD5A1 is reported to be

localised in either the nucleus, cytoplasm or both. However, evidence for the subcellular localisation of SRD5A2 and AKR1D1 in hepatocytes is lacking. To determine whether SRD5A2 and AKR1D1 are localised to the nucleus or cytoplasm, nuclear and cytoplasmic fractions were isolated from HepG2 hepatoma cells. The purity of the fractions was confirmed by Western blot, using Lamin A/C as a nuclear and β-tubulin as a cytosolic marker. Similar to SRD5A1, SRD5A2 was detected in both cytoplasmic and nuclear fractions. In contrast, AKR1D1 was detected only in the cytoplasmic fractions. Further work is required to determine whether the localisation of SRD5A1 and 2 impact on their substrate preference, and to determine the localisation of AKR1D1 within the cytoplasm.

Body composition in patients undergoing liver transplantation

Maria Argente Pla[1], Katherine Garcia-Malpartida[1], Regina Lopez-Gironás[1], Silvia Martín-Sanchis[1], Andrea Mico-Garcia[1], Eva Gasco[1], Angela Dura-De Miguel[1], Lorena Hernandez[1], Elena Vera[1] & Juan Francisco Merino Torres[1]
[1]La Fe Universitary Hospital, Endocrinology and Nutrition, Spain

Rationale
Liver cirrhosis frequently leads to changes in body composition consisting of a loss of lean mass, increased body water and variable alterations of fat mass. Changes in body composition may occur after liver transplantation (LT). Our aim was to study the changes that occur in body composition after LT (in the postoperative period after LT as well as 1 month later).
Methods
A body composition study was carried out using the bioimpedance InBody S10® in patients undergoing liver transplantation, postoperatively and 1 month after discharge. Several markers were analyzed: appendicular skeletal muscle mass (ASM), percentage of body fat, phase angle (PA) and extracellular water ratio (ECW ratio). Low muscle mass was considered when the ASM/height^{2}was <7 kg/m^{2}in men or <5.5 kg/m^{2}in women; normal PA according to the standardized tables by age and sex and using the cut-off value of 4^o; normal ECW ratio between 0.360–0.390; and normal fat mass in men between 10–20% and in women between 18–28%. Means comparison was carried out using the T-student test for paired samples and the comparison of proportions using the McNemar test.
Results
60 patients(78.3% men) were included. The age was 60.8(7.5) years. The median stay was 10.5(5–88) days. The time elapsed between both evaluations was 32.8(11.1) days. The assessment of body composition before and 1 month after discharge from transplantation is shown in the following table. Sarcopenia was present in 2.1% and 12.7% of men at the first evaluation and 1 month later, respectively($P<0.001$). No women presented sarcopenia in the immediate post-transplant period vs 23% at one month. Table-2 shows SMI and PA.

Variable:	Baseline	1 month	p-value
Body Mass Index(kg/m2)	25.3(3.6)	23.8(3.3)	**<0.001**
Fat mass(%)	23.2(7.6)	23(7.9)	0.69
Visceral fat area(cm)	79.2(30)	74.2(29.4)	0.07
Extracellular water ratio	0.40(0.1)	0.39(0.1)	**<0.001**
Body cell mass(kg)	34.3(8)	32.8(5.8)	**0.038**

	ASM/height^2 (baseline vs 1 month, *P*-value)	PA (baseline vs 1 month, *P*-value)
Men:	8.2(1.4) vs 7.8(1.0), **$P<0.001$**	4.2(0.9) vs 4.4(1.4), **$P<0.001$**
Women:	7.2(1.2) vs 6.3(0.8), $P=0.082$	3.5(0.8) vs 4.3(0.6), **$P=0,02$**

Conclusion
Alterations in body composition in patients with LT are very frequent. One month after LT, there was a decrease in BMI, ASM, cell mass and body water, and an increase in PA. The worsening of muscle mass indicates that this period is critical in these patients. It would be interesting to assess body composition in the longer term. Since impedance metry is altered by excess extracellular water, these findings could be compared with other techniques for assessing body composition.

Impact of diabetes mellitus on patients' quality of life

David Veríssimo, Catarina Ivo, Vitória Duarte, Ana Cláudia Martins, Joao Silva, Luis Lopes, Dolores Passos, J Jácome Castro & Mafalda Marcelino
Portuguese Armed Forces Hospital, Endocrinology Department, Lisboa, Portugal

Introduction
Diabetes is a disease with great psychosocial impact and reduced quality of life (QoL), and psychosocial factors seem to be excellent predictors of clinical outcomes.
Objective
Assess the relationship between the patient's perception of diabetes management and its impact on QoL.
Methods
Interview of patients with type 1 (T1D) and type 2 diabetes (T2D), using the 'Appraisal of Diabetes Scale' (ADS), a questionnaire composed of 7 items that are summed to reflect the patients' self-appreciation of their diabetes. A 0 score indicates good management, with minimal impact on QoL and 35 a worse management and a negative impact on QoL. Analysis of the association between the ADS result and the following factors: type of treatment, duration and control of diabetes, chronic complications (assessment of the number and severity using the 'Diabetes Complications Severity Index' (DCSI)), daily number of blood glucose measurements and number of consultations in the last year.
Results
165 patients, 86.2% male, mean age 65 +/- 11 years, 92.1% with T2D and 7.9% with T1D, with a mean duration of 13.5 +/- 10.5 years. 64.8% of patients were on oral antidiabetic drugs (OAD), 5.5% on daily injectable GLP-1 agonists (aGLP-1), 14.5% on basal insulin and 15.2% on basal-bolus insulin regimen. The mean HbA1c was 7.1 +/- 1.4% and the DSCI result was 2 +/- 2, corresponding to 1 +/- 1.2 complications per patient. Daily glycaemia measurements were on average 1+/-2 and the average medical visits per year was 3.5 +/- 1.7. The ADS result was 16 +/- 4 in the OAD and aGLP-1 groups, 18 +/- 4 in the basal insulin group, and 19 +/- 5 in the basal-bolus insulin group, with a significant difference between groups ($P=0.018$). Higher HbA1c values correlated with worse ADS results ($P=0.009$), but the same was not observed with the number and severity of diabetic complications (DSCI) ($P=0.58$), nor with the duration of diabetes ($P=0.5$). A greater number of daily blood glucose measurements and annual medical visits correlated with worse results in the ADS ($P=0.02$ and$P=0.03$).
Discussion
The results demonstrate that patients' perception of diabetes management was adequate for their actual control and that the introduction of insulin regimens or stricter follow-up (greater number of blood glucose tests or consultations per year) are correlated with worse QoL. However, the impact of diabetic complications is undervalued by patients, which reinforces the need to raise awareness about them.

Auto-immune diabetes associated with systemic scleroderma: a case report

Hind Ouakrim, Bilihi Natacha, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari

Mohammed VI University Hospital, Department of Endocrinology, Diabetes, Metabolic diseases and Nutrition, Marrakech, Morocco

Introduction

The association of multi-organ autoimmune diseases is described. We report a case of association between Latent autoimmune diabetes in adults (LADA) and systemic scleroderma (SSc), which remains a rarely reported entity in the literature.

Observation

38-year-old female patient, followed for systemic scleroderma with digestive and pulmonary involvements. The patient presented a dysphagia to solids with dyspnea installed in the last 2 months, with general state alteration. No polyuro-polydipsic syndrome, no diabetic heredity. A generalized cutaneous sclerosis was objectified at the clinical examination. A standard workup showed fasting blood glucose at 1.69 g/l with HbA1c: 8.6%, the patient is treated with insulin-therapy. Immunology typing test of diabetes: anti GAD, anti Znt8: positive Skin biopsy: Morphological aspect compatible with scleroderma.

Discussion

Cases of coexistence of autoimmune diabetes with systemic sclerosis are rare. The pathogenesis of this association is not yet well understood. Interferon seems to play a major role as an immunomodulator and inhibitor of collagen production, and hypotheses suggest that it is also involved in the pathophysiology of several autoimmune diseases, including diabetes. And it is well known that autoimmune diseases with the presence of organ-specific antibodies such as autoimmune diabetes or autoimmune thyroiditis can coexist with other non-organ-specific autoimmune diseases such as SSc. In addition, autoimmune diabetes has been shown to be more likely to occur in first-degree relatives of patients with SSc.

Conclsion

The association of autoimmune diabetes and systemic scleroderma could be at the origin of a difficulty to assure insulin injections, which may be responsible for an important blood glucose unbalance.

Threshold value of galectine-3 in a Tunisian diabetic population

Dayssem Khelifi[1], Ibtissem Ben Nacef[1], Kahena Bouzid[2], Imen Rojbi[1], Youssef Lakhoua[1], Nadia Mchirgui[1] & Karima Khiari[1]
[1]Charles Nicolle University Hospital, Endocrinology's Department, Tunisia; [2]Charles Nicolle University Hospital, Clinical Biochemistry Department, Tunisia

Background and aims

Plasma Galectin-3 (Gal-3), mediator of fibrogenesis and inflammation, has been implicated in many diseases. Particularly in diabetics, this lectin directly mediates transdifferentiation in collagen-producing cells thus leading to fibrosis of target organs and accelerating the development of complications. The objective of our study was to determine a cut-off value for Gal-3 in our population.

Methods

We conducted a cross-sectional, analytical study including 260 type 2 diabetic patients. For statistical purposes, we solicited a second control group of non-diabetic patients. For the determination of the discriminating threshold of the quantitative variable, we established ROC curves (Receiver Operating Characteristics).

Results

In our series, the mean serum Gal-3 level in our diabetic patients was in the order of 14.24 ng/ml $\pm$ 7.32 (range: 3.30 and 69.30 ng/ml). The median concentration was 12.4 ng/ml. The mean Gal-3 value in the control group was 11.80 ng/ml $\pm$ 3.75 (range: 4.4 and 25.5 ng/ml) and a median of 10.9 ng/ml. A statistically significant increase in serum Gal-3 ($P<0.001$) in the diabetic group was observed. We carried out an ROC curve which allowed us to define a value of Gal-3 at 11.25 ng/ml as the best threshold of sensitivity and specificity. The area under the ROC curve was 0.61 (Confidence Interval: CI95 [0.55–0.67], $P=0.001$).

Conclsions

The level of Gal-3 differs from study to study. This could be explained by the fact that the plasma levels of Gal-3 are influenced by socio-demographic, anthropometric, clinical and biological factors. Hence the need to determinate a specific serum threshold for each population.

More than 20 years after diagnosis of type 1 diabetes: what about the quality of life?

Emna Bornaz, Haifa Abdesselem, Chaima Sdiri, Kamilia Ounaissa, Fatma Boukhayatia, Imene Sebai, Asma Ben Brahim, Rim Yahiaoui & Chiraz Amrouche
National Institute of Nutrition, Outpatient Department and Functional Explorations, Tunis, Tunisia

Background

Long-standing type 1 diabetes, had many complications which have an impact on both life expectancy and quality of life of these patients. The aims of our study were to evaluate the quality of life of a group of Tunisian patients with type 1 diabetes evolving for more than 20 years as well as to determine the factors associated with its alteration.

Methods

We conducted a descriptive observational cross-sectional study including type 1 diabetic patients who had diabetes for more than 20 years, followed at the National Institute of Nutrition. Quality of life was assessed using the version 19 of the Audit of Diabetes Dependent Quality of Life (ADDQOL-19), translated into Tunisian dialect; which includes, in addition to two general questions, 19 questions specifically assessing 19 life domains. From these 19 questions, a weighted composite score was calculated. We considered that quality of life was impaired if this score was $\leq$-3.

Results

A total of 155 patients with a mean age of 39.7 $\pm$ 9.8 years were included in the study. The diabetes had progressed for 27.33 $\pm$ 6.38 years. The sex ratio M/F was 0.49. More than half of the population (53.4%) had an impaired quality of life with a mean composite score of -3.22 $\pm$ 2.19. Of the nineteen life domains assessed, thirteen had a mean score $\leq$-3. Fear of the future, physical ability and freedom to eat, were the most impaired life dimensions. Their mean scores were -4.39$\pm$3.4, -4.09$\pm$2.9 and -3.91$\pm$3.2, respectively. Univariate analysis showed that impaired quality of life was associated with unemployment ($P=0.02$), low level of education ($P=0.049$), low socioeconomic status ($P=0.009$), frequency of hypoglycemia ($P<0.001$), complicated retinopathy ($P=0.037$), peripheral neuropathy ($P=0.012$), disorders of the lower urinary tract ($P=0.047$) and category of risk of foot ulceration ($P=0,028$).

Conclsion

Our study highlights that after more than 20 years of the diagnosis of type 1 diabetes, the quality of life is often impaired. Prevention of chronic complications, psychological management, and adoption of therapeutic techniques that preserve dietary autonomy, could improve the QOL of long-standing type 1 diabetic patients.

Diabetic retinopathy and erectile dysfunction: is there a relationship ?

Emna Bornaz, Haifa Abdesselem, Skander Msolly, Kamilia Ounaissa, Boukhayatia Fatma, Imene Sebai, Asma Ben Brahim, Rim Yahiaoui & Chiraz Amrouche

National Institute of Nutrition, Outpatient Department and Functional Explorations, Tunis, Tunisia

Background
Erectile dysfunction impairs the quality of life of men with type 1 diabetes. Many factors are involved in this complication. According to the literature, diabetic microangiopathy is associated with erectile dysfunction. The aim of our study was to evaluate the impact of diabetic retinopathy on erectile dysfunction in a group of long-standing type 1 diabetics.
Methods
We conducted a cross-sectional study that included male patients with type 1 diabetes for 20 years or more and followed at the National Institute of Nutrition of Tunis. Diagnosis and severity of erectile dysfunction were assessed by the short version of the International Index of Erectile Function (IIEF-5), translated and validated in Arabic. Diabetic retinopathy (DR) and its degree of severity were diagnosed by fundus examination and retinal angiography if abnormalties.
Results
A total of 51 men with a mean age of 41 ± 9.7 years wereincluded in the study. Diabetes was diagnosed at the age of 14.8 ± 7 years. Mean duration of diabetes was 26.4 ± 6 years. Only one-fifth (21.1%) of the population did not have DR on fundus examination. Two patients had permanent blindness. DR was minimal, moderate and severe in 18.4%, 21.1% and 15.8% of participants, respectively. It was proliferative in 10.5% of patients and complicatedin 7.9%. Mean IIEF-5 score was 15.3 ± 5.3. Erectile dysfunction was diagnosed in 85% of participants. It was mild in 39.1%, moderate in 43.5% and severe in 17.4% of cases. Univariate analysis showed a significant association between DR and erectile dysfunction ($P = 0.014$). Severity of DR was associated with severity of erectile dysfunction ($P = 0.034$).
Conclsion
Erectile dysfunction remains under-diagnosed and untreated in many diabetic patients. However, as our study showed, systematic screening in all patients with DR, especially in the advanced stages, should be recommended.

Diabesity showcases the need for intensive care for COVID-19

Ak Das[1], Shaibal Guha[2], Subhash Kumar[2] & Anand Shankar[2]
[1]Diabetes, Muzaffarpur, India; [2]Diabetes, Patna, India

Background
Old age is proven to be one of the greatest danger factors for intensively dealing with COVID-19 patients. Stoutness and diabetes are enhancers of dangers among COVID-19 patients. In any case, there exists restricted proof for the modifiable danger components, for example, bodyweight which is an indicator of the Intensive Care Unit and its need among type 2 diabetes patients. In this review, the subject of body weight as an indicator of ICU confirmations will be investigated.
Methods
A total of 127 Type 2 DM patients were selected. These patients had recovered from COVID-19, on follow up for diabetes care, from eight diabetes clinics that had the association of the metabolic risk factors with the need for intensive care. Descriptive statistics and Fisher's exact test were performed.
Results
100 hypertensives and 104 patients had recovered without intensive care. The mean age was 6 (±14, minimum 11, maximum 94, range 83, 95% CI 55 to 58), BMI (kg/m^2) was 27 (±4.7, minimum 17, maximum 44, range 83, 95% CI 27 to 28), and HbA1c (%) was 8.1 (±1.6, minimum 4.8, maximum 15, range 10, 95% CI 7.9 to 8.4). 10 patients at follow-up, for diabetes consultation, post COVID-19 had good glycaemic control with less than 7% of HbA1c. 23 patients needed ICU care. The higher proportion with BMI $\leq$ 25, 27% required ICU as compared to 20% out of the 62 patients who had BMI $<$ 25 kg/m2.
Conclusion
ICU admission risk had heightened for both the obese patients and the elderly patients among the Type-2 DM patients who were diagnosed with COVID-19. The findings of this study reveal that obesity needs to be managed for reducing the severity of COVID-19, bodyweight needs to be reduced to lessen the need for ICU care.

Study of musculoskeletal manifestations in type 2 diabetes mellitus

Biswajit Payra[1], Sachin K. Jain[1], Anupam Prakash[1], Alok Sud[2], Ritika Sud[1] & Ramesh Aggarwal[1]
[1]Lady Hardinge Medical College, Medicine, New Delhi, India; [2]Lady Hardinge Medical College, Orthopaedics, New Delhi, India

Introduction
Musculoskeletal manifestation is one of the leading cause of morbidity and disability among type 2 diabetics. Also management of these conditions with steroids and non-steroidal anti-inflammatory drugs, adversely impact the glycaemic control of diabetics. Our study aims to look for prevalence of different musculoskeletal manifestation among type 2 diabetes.
Methodology
Our study is a cross-sectional observational study and it is comprised of 200 type 2 diabetics (>1 year duration) and 200 non-diabetic adult (>18 years) populations. All the cases were subjected to GALS screening (Gait, Arm, Leg and Spine). Patients with positive GALS screening were evaluated by REMS (Regional Examination of Musculoskeletal systems). Radiological examinations were done where needed.
Results
Prevalence of musculoskeletal manifestations was 55% ($n = 1110$) among diabetics compared to 22.5% ($n = 44$) among non-diabetics ($P < 0.001$). 8% of diabetic patients with musculoskeletal manifestations were asymptomatic and detected by GALS screening. According to prevalence most common musculoskeletal manifestation among diabetics was cheiroarthropathy (21.5%; $n = 43$) followed by osteoarthritis (19%; $n = 38$), Adhesive capsulitis (11.5%; $n = 23$), dupuytren's contracture (6.5%; n-13), flexor tenosynovitis (2%; $n = 4$), Charcot joint (2%; $n = 4$) and carpal tunnel syndrome (1.5%; $n = 3$). Presence of musculoskeletal manifestations is found to be significantly associated with long duration of diabetes, glycaemic control and presence of one or more microvascular complications.
Conclusion
Our study showed that the musculoskeletal manifestations are more prevalent among type 2 diabetics compared to non-diabetes population. A significant proportion of diabetics have these manifestations asymptomatically. Early diagnosis of these manifestations and good glycaemic control are important for the management.

Metabolic dysfunction–associated fatty liver disease and cardiovascular risk characterization

Carolina M. Perdomo[1], Jorge Nuñez[2], Ana Ezponda Casajús[3], Francisco J. Mendoza[3], Gorka Bastarrika Alemañ[3], Gema Fruhbeck[1,4,5] & Javier Escalada[1,4,5]
[1]Clínica Universidad de Navarra, Endocrinology and Nutrition, Pamplona, Spain; [2]Clínica Universidad de Navarra, Research Support Service, Central Clinical Trials Unit; [3]Clínica Universidad de Navarra, Radiology; [4]IdiSNA, Pamplona, Spain; [5]CIBERObn

Objectives
Metabolic dysfunction–associated fatty liver disease (MAFLD) is a new nomenclature for fatty liver disease (FLD). The clinical impact of the change in nomenclature on the ability to identify individuals at risk for cardiovascular disease (CVD) has not yet been elucidated. The aim of this study is to describe the cardiovascular risk and subclinical CVD of the different MAFLD subtypes.
Methods
Retrospective analysis of patients who attended a medical check-up at Clínica Universidad de Navarra between June 2003-December 2006 who had whole-body CT scan and analytics. Exclusion criteria included cerebral vascular diseases, heart disease, excessive alcohol consumption, advanced liver diseases and malignant disease. The cardiovascular risk was assessed through visceral adipose tissue (VAT)/subcutaneous adipose tissue (SCAT) Ratio. The presence of subclinical CVD was assessed by quantifying epicardial adipose tissue adjusted for body surface area (EATi) and Coronary Calcium according to Visual Scale (CAC-V).
Results
A total of 374 patients were included in the analysis: 154 without FLD and 220 with FLD. Mean age was 57.9 ± 9.3 years and 71.4% (267/374) of the cohort were men. Of the FLD cohort: 12.7% (28/220) were patients without metabolic

dysfunction (non-MD FLD), 69.5% (153/220) were patients with MAFLD due to the presence of overweight/obesity (MAFLD-overweight), 3.2% (7/220) were patients with MAFLD due to the presence of two metabolic abnormalities (MAFLD-MD) and 14.5% (32/220) were patients with MAFLD due to the presence of T2D (MAFLD-T2D). Compared with patients without FLD, patients with FLD had increased HOMA-IR, a more detrimental lipid profile, worse kidney and liver function ($P<0.001$) and a higher prevalence of metabolic syndrome disorders ($P<0.001$). MAFLD-T2D had significantly higher subclinical cardiovascular disease markers and cardiovascular risk, followed by MAFLD-overweight with metabolic dysfunction (MD) (VAT/SCAT Ratio: 1.070 ± 0.456 and 0.889 ± 0.291 [$P<0.001$]; EATi: 113.3 ± 42.5 $cm^2$and 108.2 ± 46.9 cm^2[$P<0.001$]; CAC-V: 3.3 ± 3.4 and 1.87 ± 2.61 [$P<0.001$], respectively) . MAFLD-overweight without MD, MAFLD-MD, non-MD FLD and non-FLD had similar subclinical cardiovascular disease markers and cardiovascular risk (VAT/SCAT Ratio: 0.807 ± 0.327, 0.794 ± 0.420, 0.695 ± 0.359 and 0.615 ± 0.382 [$P>0.05$]; EATi: 82.3 ± 33.5 cm^2, 78.6 ± 39.9 cm^2, 57.1 ± 27.0 $cm^2$and 67.7 ± 38.1 cm^2[$P>0.05$]; CAC-V: 1.04 $\pm$1.8,9, 1.14 ± 1.77, 1.21 ± 2.57 and 1.28 ± 2.25 [$P>0.05$], respectively).

Conclusions

MAFLD–T2D and MAFLD–overweight with MD had the highest subclinical CVD and risk for CVD. Changing to the MAFLD criteria may help to stratify CVD risk and, therefore, aid clinicians in the task of reducing cardiovascular risk. Omitting a small fraction of individuals with metabolically uncomplicated FLD apparently does not confer an issue regarding heart outcomes.

When and How to Screen for Glucose Dysregulation (GD) in patients with β-Thalassemia Major (β-TM): A retrospective study by The International Network of Clinicians for Endocrinopathies in Thalassemia and Adolescent Medicine (ICET-A)

Vincenzo De Sanctis[1], Ashraf Soliman[2], Shahina Daar[3], Ploutarchos Tzoulis[4], Mehran Karimi[5], Salvatore Di Maio[6] & Christos Kattamis[7]

[1]Quisisana Hospital, Ferrara, Italy; [2]Hamad Medical Center, Pediatrics, Doha, Qatar; [3]College of Medicine, Sultan Qaboos University, Muscat, Oman; [4]Department of Diabetes and Endocrinology, Whittington Hospital, University College London, London, UK;, United Kingdom; [5]Hematology Research Center, Shiraz University of Medical Sciences, Shiraz, Iran, Shiraz, Iran; [6]Children's Hospital 'Santobono-Pausilipon', Pediatrics, Naples, Italy; [7]National Kapodistrian University of Athens 11527, Greece, Pediatrics, Athens, Greece

To investigate the best criteria and time to diagnose dysglycemia in β-TM patients, the ICETA performed a retrospective study on glycemic abnormalities (GD) in 397 with β-TM patients (aged 5–40 years; 56.3% males) followed between 1988 to 2021 in a single centre (by VDS) (40 years).

Methods

Fasting blood glucose (FPG) and standard oral glucose tolerance test (OGTT) results were collected over 40 years of follow up and results were categorized following ADA and WHO criteria.

Results

Based on the FPG data, using the ADA criteria, the prevalence of isolated IFG was 23.6 %, while increasing the threshold value of FPG to 110 mg/dl according to WHO criteria, decreased the prevalence to 15.3%. β-TM patients showed a higher prevalence of GD mainly in the second to third decade of life. Based on the OGTT, 44 of 234 β-TM patients presented with IFG (18.8%), 3 (1.2%) with IGT and 1 with a new diagnosis of thalassemia related DM (Th-RD). In patients with IFG the probability of diagnosing IGT was higher (46.1%) in subjects with FPG between 100 and 109 mg/dl compared to subjects with FPG between 110 and 125 mg/dl ($P=0.0071$). Both ADA and WHO criteria for IFG missed the diagnosis of Th-RD in 4 of 91 patients (4.3%) and 11 of 59 patients (18.6%), respectively. The number of patients with a new diagnosis of diabetes, after OGTT, increased progressively starting from the age of 11 years (Table).

Conclusion

Many β-TM patients who have a normal FPG may present with GD after OGTT. Dysglycemia may occur in very young patients. OGTT screening seems to be cost-effective. ADA criteria used for the diagnosis of IFG identified an additional group of patients with dysglycemia. Diagnostic value of FPG and OGTT in detecting Th-RD in 384 patients with β-TM aged 5–40 years.

Table 1. Comparative characteristics of 2019 and 2020 groups

(FPG)	5–10 years N (%)	11–20 years N (%)	21–30 years N (%)	31–40 years N (%)
FPG < 100 (mg/dl) ($n=40$)	0/63 (0 %)	0/78 (0 %)	0/53 (0 %)	3/40 (7.5%)
IFG_{low}: 100–109 mg/dl ($n=33$)	0/11 (0 %)	0/47 (0 %)	2/19 (10.5%)	2/14 (14.2%)
IFG_{high}: 110–125 mg/dl ($n=55$)	0/4 (0 %)	1/25 (4%)	6/23 (26.0%)	4/7 (57.1%)
New Th-RD PG after OGTT: ≥ 200 mg/dl	0/78 (0 %)	1/150 (0.6 %)	8/95 (8.4 %)	9/61 (14.7 %)

Glycogen hepatopathy- a rare and frequently misdiagnosed hepatic complication of diabetes mellitus

Swayamsidha Mangaraj

IMS and SUM Medical College and Hospital, Endocrinology, Bhubaneswar, India

Introduction

Glycogenic hepatopathy(GH) refers to excessive intrahepatic glycogen accumulation in patients with poorly controlled diabetes mellitus especially type 1 diabetes mellitus. It is a rare and frequently misdiagnosed complication of diabetes mellitus. The patients present with non-specific pain abdomen may be incidentally detected during evaluation of deranged liver function tests(LFT).

Case report

A 15 years old female presented with pain abdomen, nausea and lethargy for last ten days. She was a known case of type 1 diabetes mellitus for last two years and was currently on multiple daily subcutaneous insulin injection regimen. However, her glycemic control was very poor due to poor compliance and she had three episodes of diabetic ketoacidosis(DKA) in the past. Clinical evaluation revealed presence of lethargy and dehydration. Hepatomegaly(palpable 5 cm below costal margin) was also seen. Blood investigations revealed presence of DKA. Blood gas analysis showed arterial pH 7.1 and bicarbonate level of 12 meq/l. Her random blood glucose at the time of hospitalization was 435 mg/dl and HbA1c was 12.9 %. Urine analysis confirmed presence of ketonuria (urine ketone 3+). Renal function tests including serum electrolytes were normal. LFT revealed aspartate aminotransferase (AST) 208 IU/ml, alanine aminotransferase (ALT) 186 IU/ml and alkaline phosphatase (ALP) 198 U/l. The patient was managed with intravenous fluids, insulin infusion and other supportive measures as per DKA treatment protocol. After three days of treatment, the patient improved and she was transitioned to subcutaneous basal bolus insulin regimen. However, despite improvement in all other metabolic parameters, LFT derangement persisted. Abdominal ultrasonography showed hepatomegaly with gross hepatosteatosis without any other organ abnormality. Contrast enhanced computerized tomography also showed significant hepatomegaly with diffuse fatty infiltration. A thorough screening for liver disease markers including viral markers, autoimmune panel, coeliac disease, hemochromatosis and Wilson's disease was negative. Subsequently, a liver biopsy as per advice of treating gastroenterologist was done and it confirmed presence of classical glycogen hepatopathy. The parents were counseled regarding nature of disease and advised to maintain strict glycemic control. Subsequently after three months post discharge, revaluation confirmed regression of hepatomegaly and significant normalization of liver function tests.

Conclusion

GH is a very rare metabolic complication of poorly controlled type 1 diabetes mellitus. It may be frequently missed or misdiagnosed if clinical vigil is not high. The treatment of choice for management of GH includes strict glycemic control, periodic follow up and prevention of DKA episodes recurrence.

Telephone support program for patients with type 2 diabetes under treatment with insulin glargine 300 u/ml (t-coach) in the area of cadiz (spain)

Jesus Manuel Cornejo Dominguez[1], Esteban Sanchez Toscano[1], Maria Isabel Mateo Gavira[1], Lourdes Garcia Garcia-Doncel[2] & Florentino San Laureano Carral[3]
[1]Hospital Universitario Puerta del Mar, Cádiz, Spain; [2]Hospital Universitario De Jerez, Jerez de la Frontera, Spain; [3]University Hospital of Puerto Real, Puerto Real, Spain

Introduction
The T-Coach® telephone support program for patients with type 2 diabetes (DM2) treated with insulin glargine 300 u/ml, facilitates dose adjustments of basal insulin therapy through regular telephone consultations and offers diabetes education in order to improve empowerment of the patient. Objective: To assess the usefulness of the T-Coach® program in metabolic control and degree of satisfaction in patients with T2DM.
Patients and methods
Observational, descriptive, retrospective, multicenter study, including patients with type 2 Diabetes (T2DM) included in the T-coach® program from October 2016 to December 2020, attended in Endocrinology in the province of Cádiz. Demographic data, baseline clinical and laboratory parameters, 3 and 6 months after inclusion in the program are analyzed. The degree of patient satisfaction and evolution of the level of knowledge with the use of the platform are evaluated.
Results
286 patients are included, 50.2% ($n=143$) women, age 66.05 ± 11.62 years and T2DM evolution time 15.4 ± 8.2 years. 45.4% ($n=71$) had microangiopathy and 24.5% ($n=70$) macroangiopathy. 19% started long-acting insulin. Average of 7.2 calls per patient. At baseline long-acting insulin dose was $25.5 \pm 16{,}34$ U/day after 6 months $36.2 \pm 19{,}26$ U/day. At baseline *Fasting plasma glucose* $188.5 \pm 76{,}45$ mg/dl after 6 months 119 mg/ ($P<0.001$). The initial mean HbA1c was $9 \pm 1{,}42$ % and at 6 months $7.30 \pm 1{,}38$ % ($P<0.001$). The level of knowledge raises from 5.2/8 to 7.7/8 points at 3 months. The degree of patient satisfaction was high, with scores above 9/10 in most of the items evaluated.
Conclsions
In our setting, the T-Coach® program is shown to be a useful tool for adjusting the dose of long-acting insulin, with the consequent improvement in glycemic control in these patients. The degree of patient satisfaction with the support for insulin dose adjustment is high and the level of knowledge improves with telephone reinforcement of diabetes education.

Total daily dose of insulin at the beginning of treatment with Continuous Subcutaneous Insulin Infusion system: which is the best formula?

Vânia Benido Silva, Susana Garrido, Joana Vilaverde, Sofia Teixeira & Maria Helena Cardoso
Centro Hospitalar Universitário do Porto, Endocrinology, Diabetes and Metabolism, Porto, Portugal

Introduction
Several formulas are described to calculate the Insulin Dose to start insulin pump therapy. However, there are no data demonstrating their effectiveness in achieving good glycemic control.
Aim
To assess the Total Daily Dose of Insulin (TDDI) at 3 months after beginning an insulin pump, and determine which formula most closely matches the TDDI required in cases where good glycemic control is achieved after that period.
Methods
Retrospective study including individuals with type 1 diabetes who started treatment with an insulin pump between 1st of January of 2019 and 30th of September of 2021 at our center. Patients were frequently evaluated until glycemic control was achieved. Glycemic control was assessed at 'time zero'(T0) and 'time 3 M'(T3 M) through the HbA1c value, % time in target range(%TIR), % time above(%TAR) and below the target range(%TBR). The TDDI at T3 M months was compared with the insulin dose calculated by the different formulas at T0: F1-mean TDDI of the 7 days preceding the beginning of treatment;F2-TDDI calculated by weight(0.5xweight);F3-obtained by 90% of the mean of F1 and F2 ([F1 + F2]/2x0.9).
Results
Of the 62 individuals who started treatment, 52 were included(30[57.7%] women; median age 39 years [minimum-maximum:19–70 years]), with a mean of 22 ± 13.28 years of disease progression. At T3 M, the median %TIR was 63.5%(IQR 24%), the median %TAR 32%(IQR 31), the median %TBR 3%(IQR 6) and the median HbA1c 7.1%(IQR 1.3). The median TDDI at T3 M was 42 UI (IQR 21.5UI) and was similar to TDDI at T0 by F1(40.5UI[IQR 19.2], $P=0.723$) but with a significantly lower percentage of basal insulin(38%vs.49.3%, $P<0.001$). The median TDDI at T3 M was significantly superior than TDDI obtained by F2(42UI[IQR 21.5UI]vs.32.5UI[IQR 12.3], $P<0.001$) and by F3(34.1UI[IQR 13.3], $P<0.001$). In the 19 patients with %TIR > 70% at T3 M, the median TDDI at T3 M was not different from the TDDI at T0 calculated by F1($P=0.268$) and F2($P=0.427$), but major differences were found comparing with F3(37.0UI[IQR 23.8]vs.29.4[IQR 12.2], $P=0.05$).
Conclusion
The TDDI in use 3 months after the beginning of an insulin pump in this work was quite similar to the mean TDDI of the 7 days preceding the starting of this treatment. This result was similar in patients with TIR above or below 70% at T3 M. The main difference at T3 M was the percentage of basal insulin which decrease significantly from almost 50% to 40%. These results suggest that the mean TDDI of the 7 days preceding the starting of this treatment can be the best option to begin the insulin pump.

Impact of whatsapp based Communication on insulin adherence and glycemic control in patients with Diabetes in Indian population

Bharat Saboo[1], Abhishek Shrivastav[2], Banshi Saboo[3] & Aniket Inamdar[4]
[1]Prayas Diabetes Center, INDORE, India; [2]R R Hormone Clinic, Jabalpur, India; [3]Dia Care - Diabetes Hormone Clinic, Ahmedabad, India; [4]Samarpan Clinic, Omerga, India

Introduction
Diabetes treatment requires the involvement of people with diabetes in the form of medication adherence. Insulin treatment is an important aspect of diabetes therapy. Regular and timely insulin therapy is necessary for good glycaemic control and complications prevention. Newer follow-up techniques, such as WhatsApp based communication are now finding their way into diabetes care and treatment. It can assist diabetes patients to maintain a regular treatment schedule and drug adherence.
Materials and Methods
A total of 342 Diabetic patients aged 15–65 years were selected by random sampling. Inclusion Criteria : 1. Known case of Diabetes mellitus 2. Consent to take part in study. 3. Ability to use WhatsApp messaging Exclusion criteria: 1. Inability to use WhatsApp 2. Not consenting to be a part of the study. They were randomly allocated to two groups of 171 people each. In the first group, the participants were added to a WhatsApp group and were asked to regularly answer a question about whether they have taken insulin or not on that particular day to the clinic over WhatsApp. The other group was treated as usual. The participants were monitored for HBA1C and insulin adherence at 3 and 6 months. The results were analysed using SPSS.
Result
After excluding 4 droupouts the analysis of data shown : HBA1C reduction in the WhatsApp group was 1.8 % as compared to 0.8 % in the routine care group. At the end of 3 months and was 2.3 % in the WhatsApp group and 1.3 % at the end of 6 months. The number of patients achieving the target goal of 7% HBA1C was better in the WhatsApp group (54%) as compared to the routine group (38%) at the end of 3 months and in the WhatsApp group (72%) as compared to the routine group (53%) at the end of 6 months. 82 % of patients in the WhatsApp group were insulin compliant compared to 63 % in the routine group.
Discussion
The strategies and means of communicating with patients have improved with the emergence of modern modes of communication. This has paved the door for the development of innovative messaging systems such as WhatsApp that enable more patient-centric communication. When utilized properly, these tools can help

reduce in-person follow-ups while increasing the connection between caregiver and patient. Additionally, this can result in improved patient outcomes, as well as fewer complications and financial repercussions.

Maturity-onset diabetes of the young in a large portuguese cohort

Sílvia Santos Monteiro[1], Liliana Fonseca[1], Tiago S. Santos[1], Guilherme Assunção[1], Ana M. Lopes[1], Diana B. Duarte[1], Ana Rita Soares[2], Francisco Laranjeira[3], Maria João Oliveira[4], Teresa Borges[4] & Maria Helena Cardoso[1]

[1]Centro Hospitalar Universitário do Porto, Department of Endocrinology, Diabetes and Metabolism, Porto, Portugal; [2]Centro Hospitalar Universitário do Porto, Department of Medical Genetics, Porto, Portugal; [3]Centro Hospitalar Universitário do Porto, Department of Genetic Biochemistry, Porto, Portugal; [4]Centro Hospitalar Universitário do Porto, Department of Pediatric Endocrinology, Porto, Portugal

Introduction

Monogenic forms of diabetes that develop with autosomal dominant inheritance are classically aggregated in the maturity-onset diabetes of the young (MODY) categories. Despite increasing awareness, its true prevalence remains largely underestimated.

Aim

o evaluate the clinical and molecular characteristics of patients with MODY.

Methodology

This single-center retrospective cohort study enrolled patients with positive genetic testing for MODY between 2015 and 2021, followed at our Pediatric and Adult Endocrinology Outpatient Clinic. Clinical and molecular characteristics were described.

Results

Eighty-two patients were included, mostly female (51.2%), with a median age at diabetes diagnosis of 23 years (interquartile range [IQR] 23). The most frequent mutation was in the *HNF1A* gene (43.9%, $n=36$), followed by *GCK* (32.9%, $n=27$), *HNF4A* (12.2%, $n=10$), *HNF1B* (4.9%, $n=4$), *PDX1* (2.4%, $n=2$), *INS* (2.4%, $n=2$) and *APPL1* (1.2%, $n=1$). The mean number of family generations affected was 2.3 ± 0.7. The following table summarizes the main characteristics of the four most frequent types of MODY within our sample:

Conclusion

Mutations of *HNF1A* gene were the most common within our cohort, followed by *GCK*. This study highlights the need to increase accuracy in the diagnosis and characterization of monogenic forms of diabetes. This strategy may contribute to a better understanding of this type of diabetes and a more personalized clinical management and follow-up of these individuals and their families.

Table 1

MODY	Age at diagnosis years)**	Symptoms of insulin deficiency	Kidney malformations	Non-insulin hypoglycaemic agents	Insulin	HbA1c at diagnosis (%)*	C-peptide (ng/ml)**	Atual HbA1c (%)*	Follow-up (months) **	Diabetes-related complications
HNF1A	30 (23)	5.6%	None	75%	30.6%	8.7±2.5	1.7 (1.46)	7.1±0.9	27 (115)	27.8% microvascular 8.3% macrovascular
GCK	10 (8)	None	None	22.2%	None	6.2±0.4	1.4 (0.7)	6.2±0.4	15 (41)	None
HNF4A	22 (29)	10%	None	50%	20%	6.1±1.6	1.1 (0.7)	6.1±0.8	17 (62)	20% microvascular 10% macrovascular
HNF1B	11.5 (13)	50%	100%	None	75%	6.8±1.5	2.6	6.9±1.4	36.5 (173)	50% microvascular

Ketosis prone type 2 diabetes in covid times - a missing link?

Bhavna Sharma & Mushtaqur Rahman
Northwick Park Hospital, United Kingdom

Traditional literature agrees that Diabetic Ketoacidosis is typically associated with Type 1 Diabetes Mellitus, but can be associated with stress including infections in Type 2 diabetics. The authors did a restrospective evaluation of diabetic ketoacidosis presenting to a large district hospital in London. 343 patients were admitted with diagnosis of Diabetic Ketoacidosis during the COVID peaks from January 2020 to January 2021. 57% of these were Type 1 diabetics and 43% were found to be Type 2 diabetics. 23% of the patients admitted with Type 2 diabetes and DKA did not have a previous presentation with ketosis. 68% of both Type 1 and Type 2 diabetics tested negative for COVID 19 on first/second swab (accounting for hospital exposure). 56% of Type 2 diabetics with DKA tested positive for COVID-19 on first/second swab. 32% of Type 2 diabetics were new diagnosis of diabetes. Initial studies agreed a significant increase in ketosis prone DKA in Type 2 diabetics during COVID times however were unable to establish a clear correlation with COVID infection. Our Initial studies did suggest a possible extrapolation with widespread vaccination of a possible emerging cohort of ketosis prone type 2 diabetes. We therefore evaluated the incidence of ketosis prone type 2 DKA in vaccinated individuals with a total of 178 admissions with diabetic ketoacidosis evaluated between August 2021 and December 2021. 58.7% of patients admitted with diabetic ketoacidosis were Type 2 diabetics. 23% of patients presenting with diabetic ketoacidosis were new diagnosis of diabetes (19% Type 1 Diabetes). An overall increase in monthly admissions over five months was noted when compared to previous one year evaluated was noted. The authors suggest that exposure/immunity to COVID 19 may be a contributing factor to increase in ketosis prone diabetic ketoacidosis. Several etiologies may be suggested including viral destruction of beta cells in patients with widespread subclinical infection or possible role of antibodies in vaccinated individuals. More research is needed for the same particularly with emergence of variants and widespread vaccination as this has potential to change the understood epidemiology of Type 2 Diabetes.

Covid-19, Dexamethasone and Diabetes(CODED) study: a single centre experience

Noha Meneissy, Scott Waring, Umme Farhana, Sarah Kasigwa, Yishan Wang, Tasfia Rashid, Sohee Kim, Shanta Paul, Htet Myat Hlaing,

Sukuta Darego, Sadia Siddika, Olga Nachas, Lamis Fahal, Bashir Mahamud & Gideon Mlawa
Queen's Hospital, Romford, United Kingdom

Coronavirus (COVID-19) caused by severe acute respiratory syndrome (SARS)-CoV-2, which leads to multi-organ disease. Covid-19 high mortality and morbidity arising from autoimmune destruction of the lungs due to pro-inflammatory cytokines storm, has enabled worldwide collaborative studies aimed at elucidating potential management strategies in order to overcome pandemic. The RECOVERY trial, a multi-centred trial involving 175 United Kingdom based hospitals. The results from this trial revealed that using dexamethasone lowered 28-day mortality rate for patients receiving either invasive mechanical ventilation or oxygen but had no effect on patients not receiving respiratory support. Using dexamethasone can cause manifestation of hyperglycaemia or induce Diabetes mellitus in previously non-diabetic patients. In the present study, we looked at 100 patients (both diabetics and non-diabetics) with COVID 19 on dexamethasone and we monitored their glucose levels.
Aims
1. To assess doctors' and nurses' knowledge of dexamethasone related hyperglycaemia and diabetes.
2. To assess doctors' awareness of guidelines for management of patients with COVID-19 who started on dexamethasone and whether they were using it.
3. To assess if patients who had hyperglycaemia and/or hyperglycaemia related complications were seen by diabetes team when appropriate
4. To improve doctors and nurses' awareness of proper management of patients with COVID-19 who need to be started on dexamethasone
Methods
Retrospective analysis of paper notes, case notes & electronic records of patient reported outcome (EPRO). Single centre study 100 randomly selected patients with RT-PCR COVID-19 treated with dexamethasone admitted to Queens hospital.
Results
100 COVID-19 positive given dexamethasone treatment. 18 patients were known T2DM, 82 were non-diabetic. Of the 100 patients, only 87 had regular glucose monitoring, 67 had monitoring as per BHRUT guidelines. Out of the monitored patients (87) 30 patients had hyperglycaemia which was more frequent in T2DM patients (9; 50%). Of those who developed hyperglycaemia 11 (37%) patients had their hyperglycaemic episodes treated as per national guidelines and 10 diabetic patients (56%) with T2DM required up titration of their medications. One of non-diabetic patients started on insulin.
Discussion/conclusion
Dexamethasone can be associated with hyperglycaemia in non-diabetic and known diabetic mellitus increasing their mortality and morbidity risk. Thus, it is important that these patients be monitored and managed according to national and local guidelines. Therefore, we intend to create new proformas to keep doctors and nurses up to date with the guideline of management of COVID 19 patients on dexamethasone.

Inflammatory markers in patients with type 1 diabetes and diabetic kidney disease

Aleksejs Fedulovs[1], Kaspars Jekabsons[1], Lıga Kunrade[1], Irena Puzirevska[1], Inese Folkmane[1,2] & Jelizaveta Sokolovska[1]
[1]University of Latvia, Faculty of Medicine, Riga, Latvia; [2]Pauls Stradins Clinical University Hospital, Riga, Latvia

Background
Inflammation is involved in the pathogenesis of complications of type 1 diabetes (T1DM). We aimed to assess the differences in the markers of endotoxaemia and faecal calprotectin in patients with T1D different status of diabetic kidney disease (DKD).
Methods
31 generally healthy adults (control) and 74 patients with T1DM and were included. Of the latter, 13 had DKD (defined as microalbuminuria, macro-albuminuria, estimated glomerular filtration rate (eGFR) below 60 ml/min/1.73^2, end stage kidney disease). In serum, lipopolysaccharide (LPS) activity was measured by Limulus Amebocyte Lysate assay, lipopolysaccharide binding protein (LPB), endogenous anti-endotoxin core antibodies (EndoCAb IgG and IgM), high sensitivity C reactive protein (hsCRP) and faecal calprotectin were measured by ELISA.
Results
The mean age in the T1D group was 42.3 ± 15.2 years and in the healthy participant group 37.3 ± 10.6 years. In the T1D group, the mean diabetes duration was 23.1 ± 12.2 years, the mean HbA1c was 8.2 ± 1.9%. Patients with and without DKD did not differ in age, anthropometric measures, prevalence of cardiovascular hard endpoints. Patients with DKD had longer T1D duration ($P = 0.04$); higher prevalence of arterial hypertension ($P = 0.08$); severe retinopathy ($P = 0.010$); end-stage renal disease ($P = 0.029$), and previous gastrointestinal surgery ($P = 0.02$). The levels of EndoCAb IgG and IgM did not differ between T1D and control. Compared to control group, patients with T1D had statistically significantly lower LPS (LPS: T1D 0.23 ng/ml (0.22;0.31) control 0.38 ng/ml (0.32;0.56), $P = 0.009$) and hsCRP (T1D 894.57 ng/ml (1255.91; 1990.92), control 313.29 ng/ml (368.82; 1173.07), $P = 0.01$). LPB was higher in T1D, compared to control, but the difference did not reach statistical significance (T1D: 11444.50 ng/ml (11076.45;13058.45), control 9776.60 ng/ml (8991.34; 12911.32)). None of the markers differed between DKD groups. The level of calprotectin did not differ neither between controls and T1D, nor between T1D patients with and without DKD. Within patients with T1D and DKD, LPS correlated positively strongly with serum creatinine and albuminuria; LPB correlated with HbA1c. In the whole cohort, LPS correlated weakly positively with faecal calprotectin.
Conclsions
In patients with T1D and DKD, markers of serum inflammation are associated with kidney function and HbA1c.

Association between clinical and genetic factors and glycemic and weight loss response to liraglutide in patients with type 2 diabetes

Artemis Kyriakidou[1], Angeliki V. Kyriazou[1], Theocharis Koufakis[1], Yiannis Vasilopoulos[2], Maria Grammatiki[1], Eirini Mellidou[1], PANTELITSA RAKITZI[1], Georgios Karaliolios[1], Dimitrios Goulis[3], Pantelis Zebekakis[1] & Kalliopi Kotsa[1]
[1]AHEPA University Hospital, Division of Endocrinology and Metabolism - Diabetes Center, 1st Department of Internal Medicine, Medical School, Aristotle University of Thessaloniki, Thessaloniki, Greece; [2]University of Patras, Department of Biology, Section of Genetics, Cell Biology and Development, Patras, Greece; [3]Medical School, Aristotle University of Thessaloniki, Unit of Reproductive Endocrinology, 1st Department of Obstetrics and Gynecology, Thessaloniki, Greece

Background
Previous research suggests an association between specific genetic variations and interindividual variability in response to treatment with glucagon-like receptor agonists (GLP-1 RAs) in patients with type 2 diabetes mellitus (T2DM). We aimed to evaluate the role of *CTRB1/2* rs7202877 (T > G) polymorphism in glycemic control and weight loss response to liraglutide among Greek patients with T2DM and to identify clinical factors related to prediction of response to liraglutide administration.
Methods
The medical records of 116 adults with T2DM [51% female, mean Body Mass Index (BMI) 35.4 ± 6.4 kg/m^2], who had been on treatment with liraglutide for at least 6 months and were genotyped for *CTRB1/2* rs7202877 (T > G) polymorphism, using real-time PCR, were evaluated. Clinical and laboratory parameters were measured at baseline, 3 and 6 months after initiation of liraglutide treatment. The good glycemic response was defined as one of the following: i) achievement of glycated hemoglobin (HbA_{1c}) < 7%, either at 3 or 6 months after treatment initiation ii) reduction of the baseline HbA_{1c} by ≥ 1% after

3 or 6 months of liraglutide use, and iii) maintenance of HbA_{1c} <7% that a patient had before switching to liraglutide, after 3 or 6 months of treatment. Weight loss responders were defined as subjects who lost ≥3% of their baseline weight after 3 or 6 months of liraglutide administration.
Results
97 (84%) patients were homozygous for the wild type rs7202877 T allele (TT) and 19 (16%) patients carried one polymorphic G allele (TG). 81 (70%) and 77 (66%) individuals were classified as glycemic control and weight loss responders, respectively. Heterozygotes had similar responses to liraglutide treatment in terms of glycemic control [odds ratio (OR): 1.25, 95% confidence interval (CI): 0.4, 3.8, $P=0.69$] and weight loss (OR: 1.12, 95% CI: 0.4, 3.2, $P=0.84$). In the multivariable analysis, higher baseline HbA_{1c} (adjusted OR: 1.45, 95% CI: 1.05, 2.1, $P=0.04$) and lower baseline weight (adjusted OR: 0.97, 95% CI: 0.94, 0.99, $P=0.01$) were associated with better glycemic response to liraglutide, while higher baseline weight was associated with worse weight response (adjusted OR: 0.97, 95% CI: 0.95, 0.99, $P=0.02$). Both glycemic responders and non-responders demonstrated a significant reduction in weight and BMI from baseline to 6 months ($P<0.0001$). Both weight responders and non-responders significantly reduced HbA_{1c} after administration of liraglutide ($P<0.0001$ and $P=0.008$, respectively).
Conclusion
Specific patient features can predict glycemic and weight loss response to liraglutide in patients with T2DM.

Hypoglycemia and impared hypoglycemia awareness: frequency and relevance in type 1 diabetes under continuous subcutaneous insulin infusion

MafaldaMartins Ferreira, Ana Carreira, Inês Vieira, Luísa Barros, Miguel Melo, Dírcea Rodrigues, Patrícia Oliveira, Carla Baptista, Carolina Moreno & Isabel Paiva
Centro Hospitalar e Universitário de Coimbra, Endocrinologia, Diabetes e Metabolismo, Coimbra, Portugal

Introduction
Continuous subcutaneous insulin infusion (CSII) therapy in type 1 diabetes (T1D) reduces the risk of hypoglycemia. Hypoglycemia remains a treatment-limiting factor. Impared hypoglycemia awareness (IHA) occurs in 25% of T1D cases and seems to be underestimated by continuous glucose monitoring (CGM). Glycemic variability (GV) is a increasingly valued parameter as a predictor of hypoglycemia and risk of chronic complications.
Objective
Analysis of the relationship between impared hypoglycemia awareness (IHA) and new metrics of glycemic control [estimated A1C (A1Ce), time in hyper- and hypoglycemia, GV] in T1D patients on CSII and CGM.
Methods
Cross-sectional, observational study of patients with T1D under CSII and intermittent-scanning GCM FreeStyle Libre® (active >70% of the time). Glycemic control assessed by the 30-day GCM (AGP report). IHA was defined by a score ≥4 on the Clarke Questionnaire (CQ).
Results
43 cases were analyzed: 61.5% were female; mean age of 33.3±12.7 years. Mean onset of CSII at 26.9±12.2 years. The mean duration of T1D was 20.5±9.3 years. The mean A1Ce was 7.1±0.7% and glycemic variability was 39.3±8.0%. The time spent in hyperglycemia was 35.2±18.7% (8.5 hours/day): 24.0±11.5% between 180–250 mg/dl and 11.2±9.4% above 250 mg/dl. Time spent in hypoglycemia was 7.0±5.9% (1.7 hours/day): 4.6±3.3% between 54–70 mg/dl (level 1) and 2.4±3.2% <54 mg/dl (level 2). From the Clarke Questionnaire, we obtained a prevalence of 14.3% of IHA and 9.3% of ≥1 level 3 hypoglycemia per year. There was a moderate to strong correlation between glycemic variability and time in hypoglycemia ($r=0.72$; $P<0.001$), as opposed to time in hyperglycemia which showed no significant correlation ($P=0.41$). GV did not show correlation with T1D duration but approached statistical significance ($P=0,06$). In patients with A1Ce < 7% medians of time in hypoglycemia were significantly higher – 7.0(4)% vs 3.0(3)%. Impared hypoglycemia awareness occurred in patients with lower A1Ce values (6.9±0.7% vs 7.2±0.7%) but without significant difference. There was no significant difference in time in hypoglycemia at 30 days in these cases.
Conclusion
Hypoglycemia occurred in a higher frequency than the goals especially for more demanding glycemic controls, correlating with the increase in glycemic variability (GV). GV was higher than desirable in most cases, underlining the difficulty of its optimization. Impared hypoglycemia awareness in this population had a lower prevalence than the overall estimated prevalence in T1D and did not show a significant correlation with the GCM data, highlighting the complexity of its pathophysiology and its possible undervaluation by glycemic control metrics.

Comparing global rating scores from simulation-based diabetes and endocrine scenarios between healthcare professionals of high- and low- and middle-income countries

Zakee Abdi[1,2], Dengyi Zhou[3], Kashish Malhotra[4], Anisah Ali[3], Jameela Sheikh[3], Pavithra Sakthivel[3], Emily Warmington[3], Carina Synn Cuen Pan[3], Wentin Chen[3], Harjeet Kaur[3], Rachel Nirmal[3], Vina Soran[3], Isabel Allison[3], Nia Evans[5], Dwi Delson[6], Meri Davitadze[7], Punith Kempegowda[3,8] & Simba Simulation[3,8]
[1]Medical University of Plovdiv, Plovdiv, Bulgaria; [2]School of Medicine, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK; [3]College of Medical and Dental Sciences, University of Birmingham, Birmingham, UK; [4]Dayanand Medical College and Hospital, Punjab, India; [5]Royal Glamorgan Hospital, Cwm Taf Morgannwg University Health Board, Rhondda Cynon Taff, UK; [6]School of Medicine, University of Dundee, Dundee, UK; [7]Georgian-American Family Medicine Clinic 'Medical House', Tbilisi, Georgia; [8]Institute of Metabolism and Systems Research, College of Medical and Dental Sciences, University of Birmingham, Birmingham, UK

Background
Simulation via Instant Messaging - Birmingham Advance (SIMBA) is an online simulation learning modality designed to recreate clinical scenarios, allowing participants to increase their confidence in a safe environment without compromising patient safety. The global rating scale (GRS) is a commonly used assessment tool in medical schools to assess participant competence and skills. Following SIMBA sessions, an independent assessor anonymously scores participants' performance of their simulated case using an adapted version of the GRS.
Objective
To study the pattern of GRS score across various domains of endocrine scenarios and the variation by country of residence.
Methods
We included all diabetes and endocrine SIMBA sessions conducted from July 2020 to October 2021. The participants' responses were divided into various domains and each domain was scored from 1 (poor) to 5 (excellent). Data were pooled during analysis and findings are reported as frequencies. Chi-square test was used to compare the differences between participants' performance across various domains. Participants were further grouped by the country's income according to the country of residence based on the 2022 World Bank Report: high-income countries (HICs) and low- and middle-income countries (LMICs).
Results
293 healthcare professionals participated in six SIMBA sessions (thyroid, pituitary, diabetes, metabolic bone, gonadal, and diabetic microvascular complications). The median (IQR) GRS scores for domains are as follows: history-taking: 4.0 (3.0–5.0), physical examination: 4.0 (3.0–4.6), investigations requested: 3.3 (3.0–4.0), results' interpretation: 2.6 (1.6–3.3), clinical judgement: 3.3 (2.6–4.0) and management and follow-up: 2.6 (2.0–3.3). HICs and LMICs (31.2%, $n=91$) scored similarly in history-taking (HIC: 3.81 vs LMIC: 3.79;$P=0.05$), physical examination (HIC: 3.67 vs LMIC: 3.68;$P=0.19$), investigations requested (HIC: 3.35 VS LMIC: 3.33;$P=0.27$), and results' interpretation (HIC: 2.63 vs LMIC: 2.61;$P=0.74$). HICs scored better in clinical judgement (HIC: 3.23 vs LMIC: 3.18;$P=0.008$) and providing management and follow-up plans (HIC: 2.66 vs LMIC: 2.64;$P=0.001$).
Conclusion
All participants, particularly those from LMICs, scored lower in the categories of investigations, clinical judgement, and management skills. This demonstrates the need for targeted educational programmes which can be both cost-effective and beneficial to all participants independent of country of residence.

P582

Diabetic foot association with premature cardiovascular mortality in a single centre prospective of study of people with diabetes

Dragan Tesic[1], Dragica Andric[2], Miroslav-Tomislava Tomic[3], Stefan Andric[4] & Mirjana Tomic[5]
[1]Clinics of Internal Diseases, Clinic of Endocrinology, Diabetes and Metabolic Disorders, Novi Sad,; [2]Institute for Cardiovascular Diseases, Clinic of Cardiology, Sremska Kamenica, Serbia; [3]Intiturte for Surgery, Clinic for Plastic Surgery, Novi Sad,; [4]Institut for Cardiovascular Diseases, Clinic of Cardiology, Sremska Kamenica,; [5]Clinics of Internal Diseases, Clinic of Hematology, Novi Sad

Background and aims
In many developing countries, diabetic foot is considered as a problem only when the patient develops a wound on the foot. Until that moment, the detection of changes in the neurovascular condition of the feet is rarely applied. The aim of this prospective, single centre study was to define factors associated with early cardiovascular mortality in diabetes.
Materials and methods
1345 patients under age 75 were included who were undergoing assessment of their diabetes between January 2008 and May 2010 as part of standard practice in a specilaist clinic at a regional teaching hospital in Serbia. Peripheral artery disease (PAD) and peripheral neuropathy was assessed. Evidence of other comorbidities was also collected. Outcome was determined in 2021 and baseline characteristics were compared between those who had and had not suffered cardiovascular death under age 75 years within 10 years of review in two casually selected cohorts.
Results
Those who died ($n2=70$) were more frequently male (60 vs. 45.3%, $P=0.08$), younger (66.4 $\pm$ 7.4 vs. 79.9 $\pm$ 3.4, $P<0.000$), had a shorter period of follow-up (3.6 $\pm$ 2.3 vs. 11.2 $\pm$ 1.7 years, $P<0.000$) when compared to those still alive ($n1=75$). Those who died were also significantly ($P<0.01$) more likely to have had PAD (48.6 vs. 9.3%), diabetic foot ulcer (25.7 vs. 9.3%), major amputation (17.1 vs. 1.3%) at baseline. Minor amputations were significantly more likely (8.6 vs. 1.3%, $P<0.04$). Following multivariable logistic regression analysis significant differences between groups remained for only creatinine (123 $\pm$ 45 vs. 88.9 $\pm$ 16.9 mmol/l, $P<0.003$) and vibration perception threshold <5 (7.8 [95% CI: 3.7-16.4)], $P=0.008$), estimated maximum lifetime BMI (3.4 [95% CI: 1.7-6.8)], $P<0.000$), alcohol usage (4.7 [95% CI: 1.5-14.7)], $P=0.005$), smoking habit (2.2 [95% CI: 1.1-4.3)], $P<0.03$) and earlier age of diabetes onset (43.4 $\pm$ 12.5 vs. 49.2 $\pm$ 9.9, $P=0.0029$). When the 72 patients with impaired vibration sense were compared with 73 with VPT >6 and there were significant differences in and PAD (3.9 [95% CI: 1.8-8.8)], $P<0.001$) and estimated maximum lifetime BMI (9.4 [95% CI: 3.4-25.7), $P<0.000$). Those who had had a previous MI at baseline ($n=46$) was associated with increased death rate (3.2[95% CI: 1.5-6.6)], $P=0.002$) and PAD (2.9[(1.3-6.1)], $P=0.007$).
Conclusion
Decreased VPT, the presence of PAD on clinical testing and higher maximum estimated lifetime BMI are strongly associated with premature cardiovascular death. Early detection of independent markers of greater risk of reduced life expectancy might improve management of their diabetes.

Introduction
Methods to predict clinically meaningful weight loss can help tailor treatment for people with overweight or obesity. LIGHT-UP (NCT03058029), is a multicenter, double-blind, randomized, placebo-controlled study over 25 weeks including 254 people with prediabetes or type 2 diabetes (127 each in the Gelesis200 and placebo arms) with a body mass index between 27 and 40 kg/m^2, which demonstrated that Gelesis200 offers a compelling new potential approach in the management of overweight and obesity. A stepwise logistic regression analysis was conducted on data from the LIGHT-UP study to identify variables at baseline that reliably predict body weight (BW) Responders and Super-Responders ($\leq$ 5% BW loss and $\leq$ 10% BW loss, respectively, from baseline at Week 25).
Methods
Two stepwise logistic regression analyses were conducted for each study arm (Gelesis 200 placebo). The dependent variables were the percentage of participants who were Responders and Super-Responders. The independent baseline variables included in the models were the ones hypothesized to potentially predict BW loss at Week 25 [e.g., gender, age, BW, body mass index, height, waist circumference, waist-to-height ratio (WHR), fasting plasma glucose, and fasting serum insulin].
Results
After WHR was included in the model, there were no other variables that were significant in the prediction of Responders or Super-Responders. The final regression model shows that for a 0.1 change in the WHR (e.g., from 0.6 to 0.7), the probability for a Responder increases from 53% to 66%, and the probability for a Super-Responder increases from 24% to 39%. For a 0.2 change in the WHR (e.g., from 0.6 to 0.8), the probability for a Responder increases from 53% to 78%, and the probability for a Super-Responder increases from 24% to 56%. None of the independent variables was a significant predictor of Responders or Super-Responders in the placebo arm.
Conclusion
The results of this study suggest that a higher baseline WHR is predictive of an increased rate of Responders and Super-Responders. It is well known that WHR is strongly correlated with fat mass and insulin resistance. With respect to weight loss, it can be speculated that Gelesis 200 is more effective in people with higher insulin resistance. If the findings of the LIGHT-UP study are replicated in larger clinical studies, baseline WHR would become a simple tool for clinicians to identify individuals likely to achieve meaningful weight loss on Gelesis200.

Gastroesophageal lesions after bariatric surgery: a controlled study

Catarina Ivo, David Veríssimo, Vitória Duarte, Ana Cláudia Martins, João Silva, Luís Lopes, Dolores Passos, João Jácome Castro & Mafalda Marcelino
Armed Forces Hospital - Lisbon, Endocrinology Department, Lisboa, Portugal

Introduction
Obesity is a multifactorial and chronic disease. Bariatric surgery (BS) is the most effective treatment. A prevalence of 45% of esophagitis and 40%-70% of gastritis after BS has been reported. We analysed the presence of gastroesophageal lesions in patients who underwent BS (By-pass Roux-en-Y(BP) and gastric sleeve(GS)) in our centre.
Methods
Patients submitted to BS between 2018-2020 were included. We retrospectively analysed clinical data, upper gastrointestinal endoscopy (UGE) and histologic results preoperatively and 12 months(M) after surgery. All patients underwent UGE and helicobacter pylori(HP) was eradicated if present. Protons pump inhibitors (PPI) were prescribed to all patients, until 6 M post-op. and maintained if upper gastric

symptoms(UGS). Endoscopic esophageal and gastric lesions were categorised based on Los Angeles and Sydney classification.
Results
32 patients (56% males) were included with mean age of 52±8.5 years-old and BMI of 41±4.4 kg/m^2. Mean follow-up was 29.4±9.3 M. 71.9% patients performed BP and 28% GS. At pre-op.:53% had positive HP, 21.9% had UGS and 21% were on PPI treatment. Class A or B esophagitis was diagnosed in 15.7% and erythematous gastritis in 78% of patients. Histologic results confirmed gastritis in 68.8%. 12 M after BS patients had a mean BMI of 28±3.7 kg/m^2 and 81.3% had no UGS. UGE revealed a total of class A or B esophagitis of 25%, in which 75% of the cases was "*de-novo*" lesion (83% submitted to GS and 33% had UGS). A significant reduction in erythematous gastritis was achieved in the corpus (18.8%; $P=0.05$) but not in the antrum (25%;$P=0.22$). 15.6% presented with "*de-novo*"ulcer (all of them underwent BP). Biopsy confirmed gastritis in 43.7%($P=0.85$). 1 case of Barrett's esophagus was diagnosed but no cases of dysplasia. No significant association was found between histologic result($P=0.537$) or PPI use ($P=0.654$), and BS procedure.
Conclusion
This study illustrates the importance of endoscopic follow-up of patients after BS, even if no UGS are present. After 12 M esophagitis was more prevalent, suggesting it was appropriate to maintain PPI use, in particular in those submitted to GS. A tendency to reduction was identified in gastric lesions.

Improvements in physiological and psychological status of patients with obesity in response to a combined lifestyle intervention with cognitive behavioral therapy are not necessarily related to successful weight loss

Mostafa Mohseni[1], Susanne Kuckuck[1], Renate Meeusen[1], Robin Lengton[1], Eline van der Valk[1], Anand M. Iyer[1], Corjan de Groot[2], Sjoerd van den Berg[3] & Elisabeth F.C. van Rossum[1]
[1]Erasmus MC, University Medical Center Rotterdam, Internal Medicine, Division of Endocrinology, Rotterdam, Netherlands; [2]Erasmus MC, University Medical Center Rotterdam, Obesity Center CGG, Sophia Children's Hospital, Department of Pediatric Endocrinology, Rotterdam, Netherlands; [3]Erasmus MC, University Medical Center Rotterdam, Department of Clinical Chemistry, Rotterdam, Netherlands

Background
Obesity (BMI $\leq$ 30 kg/m^2) is a chronic and relapsing disease, associated with numerous co-morbidities. Lifestyle intervention is the cornerstone of treatment of obesity, and is considered effective when weight loss of $\leq$ 5% is achieved. Here, we describe changes in physiological, psychological and behavioral health outcomes in response to a multidisciplinary combined lifestyle intervention (CLI).
Methods
In this longitudinal study we evaluated 97 adult subjects with obesity (74 women; mean age: 42 years; mean BMI: 40.1 kg/m^2). The 1.5 year CLI comprised physical activity, cognitive behavioral therapy and dietary advise tailored to promote a healthy normocaloric diet. We measured changes in physiological health (anthropometrics, metabolic and immune parameters), and used questionnaires to assess psychological health (HADS, SCL-90, PSS, FNAES, RSE), quality of life (IWQoL-Lite), eating behavior (DEBQ, EDE-Q, FCQ-T) and physical activity (IPAQ). In a subset of participants, DEXA-scans ($n=37$) were also performed to assess body composition. Linear regressions were used to investigate the association between weight loss and changes in physiological and psychological health outcomes, corrected for sex and age.
Results
After 1.5 years, there was a mean 5.1% weight loss ($P<.001$) along with a 6.1% decrease in waist circumference ($P<.001$). Total fat mass (-9.8%) and abdominal fat (-13.9%) decreased (both $P<.001$), while fat free mass did not. Fasting insulin, HOMA-IR, HbA1c, triglycerides and LDL-C decreased significantly (all $P<.01$), and HDL-C increased ($P<.05$). Levels of the immune parameters IL1ra, VEGF, sIL2R, sMR decreased (all $P<0.05$). Moreover, HADS scores ($P<.01$) and SCL-90 total score ($P<.05$) decreased, indicating lower psychological symptomatology. IWQoL-Lite scores were increased at 1.5 years ($P<.001$), indicating higher quality of life. Changes in DEBQ, EDE-Q and FCQT scores showed decreases in problematic eating behaviors ($P<.05$) while physical activity increased significantly ($P<.05$). Metabolic improvements correlated with the amount of weight loss ($P<.05$), except for LDL ($P>.05$). However, changes in most immune parameters, parameters of psychological health, and eating behavior did not correlate with the amount of weight loss, except for changes in IL1ra ($P>.001$), IWQoL, PSS (both $P<.05$) and EDE-Q total score ($P<.01$).
Conclsion
We show that the value of a multidisciplinary treatment approach for patients with severe obesity is not only limited to successful weight loss and improvements of body composition itself, but also includes the wide range of improvements in metabolic parameters, immunological, psychological, psychosocial, dietary, and behavioural improvements that may occur independently of weight loss.

Weight loss variability with SGLT2 inhibitors, GLP-1 receptor agonists and repetitive Transcranial Magnetic Stimulation in Type 2 Diabetes and Obesity: results of a retrospective, comparative study

Anna Ferrulli[1,2], Stefano Massarini[1], Daniele Cannavaro[2], Paolo Perilli[2], Ileana Terruzzi[1,2], Pamela Senesi[1,2] & Livio Luzi[1,2]
[1]IRCCS MultiMedica, Department of Endocrinology, Nutrition and Metabolic Diseases, Sesto San Giovanni, Italy; [2]University of Milan, Department of Biomedical Sciences for Health, Milano, Italy

Weight loss in individuals with Obesity (O) and Type 2 Diabetes (T2D), may improve glycaemic control and weight-related comorbidities, and in some cases, induce diabetes remission. However, body weight control is generally an unmet aim in this population. Thus, there is an increasing need to consider pharmacological approaches to assist weight loss in diabetes-obesity. Glucose-lowering agents as the sodium-glucose co-Transporter 2 inhibitors (SGLT2i) and GLP-1 Receptor Agonist (GLP1-RAs) have been proved to be capable to simultaneously control body weight and glucose levels, and their use has been recommended in individuals with O and T2D. Recently, we demonstrated the efficacy of repetitive Transcranial Magnetic Stimulation (rTMS) in inducing weight loss up to 1 year in O individuals with and without T2D.
Aim of this study was to compare retrospectively the efficacy of SGLT2i, GLP1-RAs and rTMS in long-term (up to 1 year) body weight reduction in patients with O and T2D. Data obtained from 31 patients with O and T2D were retrospectively analysed: 11 subjects (bw 98.1±18.3 Kg, BMI 36.8±5.7 Kg/m2) were treated for O with High Frequency rTMS for 5 weeks, 8 subjects (93.4±13.1 Kg, 33.6±3.1 Kg/m2) were treated for T2D with SGLT2i for 1 year, and 12 individuals (98.1±18.3 Kg, 36.8±5.7 Kg/m2) were treated for T2D with GLP1-RA for 1 year. Data relating to bw, BMI, glucose, glycated hemoglobin, cholesterol and triglycerides variations in the 3 groups have been analyzed with ANOVA, after 6 months (FU1) and 1 year (FU2) from the start of treatment. Body weight variation (%) between the 3 groups was significant both at F1 [-3.2±1.8% (SGLT2i) vs -3.5%±1.5% (GLP1-RA) vs -6.3±4.0% (rTMS);$P=0.026$] and FU2 [-2.1±2.1% (SGLT2i) vs -2.1±4.2% (GLP1-RA) vs −6.7±4.7% (rTMS);$P=0.017$]. As expected, glycated hemoglobin variation was significantly higher in SGLT2i and GLP-1 RA groups both at FU1 [-11.7±25.1% (SGLT2i) vs -11.9%±13.2% (GLP1-RA) vs -8.9±10.4% (rTMS);$P=0.922$] and FU2 [-15.9±24.2% (SGLT2i) vs -7.8±11.9% (GLP1-RA) vs -5.6±9.0% (rTMS);$P=0.116$], although not statistically significant. In this study, rTMS revealed to be a more effective intervention than SGLT2i and GLP1-RAs in promoting long-term weight loss in a population with O and T2D, probably due to a prevalent effect of rTMS on controlling food craving and appetite at the level of meso-cortico-limbic system. These findings lay groundwork for a potential use of dTMS as an add-on intervention for the treatment of T2D and O.

GLP-1 and glucagon depict complementary actions on visceral adipose tissue that could mediate metabolic shifts towards catabolism

Tiago Morais[1], Alexandre Seabra[1], Barbara Patrício[1], Marta Guimarães[1,2], Mário Nora[1,2], Pedro Oliveira[3], Marco Alves[1] & Mariana Monteiro[1]

[1]UMIB - Unidade Multidisciplinar de Investigação Biomédica, ICBAS - Instituto de Ciências Biomédicas Abel Salazar, Universidade do Porto, Porto, Portugal; [2]Centro Hospitalar de Entre o Douro e Vouga, Department of General Surgery, Santa Maria da Feira, Portugal; [3]QOPNA/LAQV - University of Aveiro, Department of Chemistry, Aveiro, Portugal

Visceral adipose tissue (VAT) metabolic fingerprints differ according to the individual's BMI and glycemic status. GLP-1 and Glucagon are two hormones that participate in energy homeostasis and glycemic control. Dual GLP-1/Glucagon agonists are a drug class under development for obesity and diabetes treatment. Although the pancreas and the liver are considered major GLP-1 and glucagon targets, these hormones act in other tissues, which could contribute for its effects on glucose balance. Thus, our purpose was to assess how GLP-1 and Glucagon influence VAT metabolic fingerprints according to the individual's BMI and glycemic status. Subjects ($n=19$) undergoing elective abdominal surgery for non-infectious nor oncologic conditions were included in this study. Subjects were allocated into 4 experimental groups according to BMI and glycemic status, namely with obesity and euglycemia (Ob+NGT, $n=5$), obesity and pre-diabetes (Ob+Pre-T2D, $n=5$), obesity and T2D (Ob+T2D, $n=5$). Subjects without obesity or dysglycemia were used as controls (Non-Ob, $n=4$). VAT harvested during the surgical procedure was kept in culture media supplemented with insulin (100 nM) and exposed for 48 h to GLP-1 or glucagon at different concentrations (1, 10 or 100 nM). Culture media was then collected for proton nuclear magnetic resonance (^{1}H-NMR) analysis. In VAT of Non-Ob controls, GLP-1 decreased acetate production (-25.20 %, $P<0.05$), while in Ob+NGT glucagon increased valine consumption (76.6%, $P<0.05$). In VAT of subjects with Ob + Pre-T2D, GLP-1 decreased isoleucine consumption (-99.6%, $P<0.05$), but increased alanine (32.6%, $P<0.05$) and lactate (43.8%, $P<0.01$) production. Glucagon decreased the consumption of isoleucine (-55.2%, $P<0.05$) and valine (-169.2%, $P<0.01$), as well as the production of alanine (-28.0%, $P<0.05$) and lactate (-54.4%, $P<0.05$), while increasing pyruvate consumption (10.9%, $P<0.05$). VAT of Ob+T2D subjects depicted no changes in metabolite profile after exposure to GLP-1 or glucagon. GLP-1 and glucagon are able to modify VAT metabolic profile, particularly in obesity and pre-diabetes. GLP-1 shifts VAT metabolic profile by decreasing isoleucine consumption and increasing alanine/lactate production, which suggests decreased gluconeogenesis. Glucagon lowers isoleucine and valine consumption, coupled with the decrease in lactate and alanine production, whilst increases pyruvate consumption, which suggests an increase in oxidative phosphorylation. Overall, out data suggests that dual GLP-1/Glucagon agonists' action in VAT could also play a role in mediating its glucose lowering and catabolic effects.

Influence of diabetes and metabolic risk factors on the outcomes of COVID-19 Vaccination: Scoping Review of the Observational Studies

Shailesh Trivedi[1], Renu Trivedi[2] & Akta Trivedi[3]
[1]Anand Hospital, Baroda, India; [2]Anand Hospital, India; [3]Anand Neurology Hospital, India

Introduction

Obesity and diabetes are the known risk factors for severity and susceptibility to severe COVID-19 with a poor prognosis. However, there is limited evidence for the implications and association of metabolic factors on COVID-19 vaccination.

Methods

We systematically searched PubMed/Medline and Cochrane library till January 28, 2022, using: ("diabetes OR BMI OR weight OR glucose OR obesity OR metabolic" and "COVID OR Coronavirus OR SARS-Cov-2" and "vaccine OR immunization OR vaccination"). Two independent researchers assessed the literature and conducted the review according to the Preferred Reporting Items for Systematic Reviews and Meta-Analysis guidelines for Scoping Reviews (PRISMA-ScR).

Results

We evaluated four studies (3 from Italy) with cumulative 1380 patients. The mean number of patients was 345 (±521, minimum 21, maximum 1123). One study ($n=84$) was only among healthcare workers. COVAC-DM cohort study suggests that humoral immune response to COVID-19 vaccination in diabetes is age dependent but is independent of type of diabetes and glycaemic control. CAVEAT study suggests that hyperglycaemia at the time of vaccination worsens the immunological response and, achieving adequate glycaemic control during the postvaccination period improves the immunological response. Evaluation of the protocols suggests that patients with higher BMI ≤ 30 kg/m^2 are significantly under-represented in most of the trials. Modulation of the diet to hypocaloric, very-low-carbohydrate diet one week before the mRNA vaccine and blood glucose reduction has a significant positive corelation on the adaptive humoral (anti-SARS CoV-2 S antibodies) and cell-mediated responses (IFN γ). Higher waist circumference, smoking, systemic hypertension and dyslipidaemia are independent confounding variables that lead to lower antibody titres. Diabetes and metabolic risk factors can modulate the immunogenicity of COVID-19 vaccine. Omission or under-representation of participants with higher BMI may cause poorer vaccine coverage for people with higher weight and contribute to greater health inequities.

Discussion

Obesity and hyperglycemia are associated with a reduced adaptive response to a COVID-19 mRNA vaccine. However, weight loss and metabolic−glycemic improvement may reverse the effect. Inclusion of higher BMI individuals in vaccine trials would yield a comprehensive evidence and help mitigate health inequities and potentially add value for substantial subgroup analysis based on the metabolic parameters and appropriately titrate vaccine dose regimes or earlier vaccine boosters, evaluate safety, and ensure equitable protection for higher weight people against COVID-19.

Utility of webinars with case-based learning approach in teaching endocrinology to undergraduate medical students during the COVID-19 pandemic

Kashish Goyal[1], Kashish Malhotra[1], Rohin Kansal[1], Mahima Marwah[1], Ravikant Goyal[2], Harry Goyal[3] & Anmol Galhotra[4]
[1]Dayanand Medical College and Hospital, Ludhiana, India; [2]Government Medical College, Amritsar, India; [3]All India Institute of Medical Sciences, New Delhi, India; [4]Pandit BD Sharma PGIMS, Rohtak, India

Background

Conventional methods of one-way teaching may not involve the integration of clinical skills and may become more inefficient and passive [1]. During the COVID-19 pandemic, limited patient interaction and shift to online lectures greatly reduced the clinical exposure and opportunity of developing interpersonal skills for junior medical students. In this study, we hosted online webinars with case-based teaching for medical students so that they can amalgamate clinical skills with patient-based care and systems-based practice.

Methods

Six free webinars were hosted at one-month intervals covering various endocrine topics for first and second-year medical students of Punjab, India. Each webinar started with three endocrine case vignettes containing the patient's chief complaints, history of present illness, and their clinical course. These anonymised clinical scenarios were derived from real-life patient transcripts. It was followed by a lecture explaining the pathophysiology of that system along with a clinical discussion. Then, students were divided into multiple breakout rooms where the instructors discussed the case vignettes and answered any further queries. Pre-webinar and post-webinar assessment were done using multiple-choice questions which were clinically oriented. Follow-up assessment was also done one month after each webinar to estimate the retention of knowledge by students. Students' attitudes regarding the usage of webinars and case-oriented teaching as compared to conventional training were ascertained using Likert scale (1=low, 5=high) and open-ended questions. Analysis was done using SPSS Statistics v26.0.

Results

72 students filled all the surveys and were included in the analysis. Significantly higher ($P<0.001$) improvement in student's post-session scores after attending each webinar and 1-month follow-up assessment were observed compared to pre-test scores. No significant differences were seen in post-webinar results and one-month follow-up results which is indicative of good retention of knowledge. The majority of the students (67, 93.1%) either strongly preferred or preferred case-based learning model compared to conventional one-way teaching. In thematic analysis, the key strengths of our model were simulating clinical scenarios and providing engaging and focused training with an emphasis on doubt-solving.

Conclusions

Webinars with a case-based learning approach provide an important utility in simulating endocrinological clinical scenarios and may be used

as an adjunct/alternative when compared to the traditional one-way teaching methods.

Type 1 diabetes on continuous subcutaneous insulin infusion: impact of glycaemic control on quality of life

Ana Carreira, Mafalda Ferreira, Inês Vieira, Mariana Lavrador, Luísa Barros, Carla Baptista, Carolina Moreno, Miguel Melo & Isabel Paiva
Centro Hospitalar e Universitário de Coimbra, Department of Endocrinology, Diabetes and Metabolism, Coimbra, Portugal

Background

In type 1 diabetes (T1D), quality of life (QoL) and the effectiveness of treatment influence each other. QoL has been associated with glycaemic control assessed by HbA1c in T1D on continuous subcutaneous insulin infusion (CSII), but data on the relationship between Continuous Glucose Monitoring (CGM) metrics and QoL are scarce.

Objectives

To assess QoL and the association between CGM metrics and QoL in T1D on CSII.

Methods

Transversal observational study of adults with T1D on CSII and CGM. Patients with active CGM time $<70\%$, age >65 years and severe unrelated illness were excluded. QoL was assessed by the 34-item ViDa1 questionnaire, between July-December/2021, after its translation and validation. ViDa1 is divided in 4 independent subscales: 2 positively related with QoL (self-care, wellbeing) and 2 negatively related (interference with life [IWL], concern about the illness). Each score is presented in percentage (0-100%).

Results

56 cases were analysed, with mean age of 34.5 ± 12.6 years, 6.5 ± 5.5 years of CSII and 20.6 ± 10.0 years of diabetes duration. 12.7% had diabetes complications. Mean Glucose Management Indicator (GMI) was $7.2\pm0.7\%$ (5.8-8.6), Time in range (TIR) $57.7\pm14.9\%$, above range (TAR) $35.2\pm17.1\%$ and bellow range (TBR) $7.1\pm5.5\%$, with mean Coefficient of Variation (CV) of $39.8\pm7.7\%$. The obtained QoL subscale's scores were $71.7\pm17.0\%$ for self-care, $60.6\pm19.7\%$ for wellbeing, $27.8\pm20.4\%$ for IWL and $70.2\pm20.1\%$. for concern. When questioned, 69.1% reported having overall good QoL. Self-care correlated negatively with GMI ($r=-0.42$, $P=0.001$) and TAR ($r=-0.40$, $P=0.003$) and positively with TIR ($r=0.38$, $P=0.004$), with higher self-care associated with higher TIR. Wellbeing had similar correlations ($r=-0.33$, $P=0.011$; $r=-0.34$, $P=0.012$ and $r=0.34$, $P=0.012$), with higher TIR associated with higher wellbeing. Mean IWL differed significantly across GMI range ($P=0.027$), scoring $45.5\pm20.1\%$ for GMI $>8\%$ vs $27.7\pm20.0\%$ and $21.9\pm18.3\%$ for GMI 7-8% and $<7\%$, respectively. Concern was associated with GMI and TAR, with levels of concern $\leq70\%$ showing significantly higher mean GMI ($7.3\pm0.7\%$ vs $6.9\pm0.6\%$, $P=0.034$) and TAR ($39.1\pm9.0\%$ vs $28.5\pm13.8\%$, $P=0.027$). QoL didn't differ significantly based on TBR or CV. In brief, patients with lower GMI and higher TIR had higher self-care and wellbeing, patients with lower GMI showed lower interference with life and patients with higher GMI and TAR showed higher concern about the illness.

Conclusions

T1D patients on CSII displayed overall satisfactory glycaemic control and QoL. Patients with better glycaemic control displayed better QoL. TBR wasn't associated with QoL. These results show that QoL may be more influenced by hyperglycaemia than by hypoglycemia.

Systematic review of ongoing clinical trials assessing the comparative therapeutic efficacy and safety of insulin glargine 300 u/ml with insulin degludec

Saibal Chakravorty[1], Aditya Chakravorty[2] & Monica Belagodu[1]
[1]Metro Multispeciality Hospital, Noida, UP, India; [2]School of Medical Sciences & Research - Sharda University, Greater Noida UP, India

Introduction

To systematically evaluate the study designs and the outcomes being analysed in the ongoing trials evaluating the efficacy and safety of Insulin Glargine 300 U/ml with insulin degludec

Methods

We reviewed contemporary protocols of trials that are currently ongoing through WHO-ICTRP (www.who.int/ictrp/search/en), www.clinicaltrials.gov trials registry database. Latest evaluation was on January 28, 2022 with key word 'insulin galrgaine U 300', degludec, for the trials initiated over the last two years (2019-2021). Two researchers independently extracted the protocols and analysed the outcomes.

Results

We evaluated clinical parameters to improve metabolic control and lower risk of hypoglycaemia. We analysed the protocols of the six ongoing trials including, the landmark trials namely PREMIER INSULIN (perioperative non-ICU, $n=180$), ULTRAFLEXI1 (T1DM) are cumulatively recruiting 1416 patients; across Japan (4 trials) and Austria (1 trial) and 1 trial as global multicentric (North America and Europe). The study designs include randomised, parallel, cross-over, designed studies. Three trials are evaluating the comparative efficacy patients in T1DM ($n=110$) and other three in T2DM ($n=1306$). Insulin glargine U300 along with insulin degludec is being compared with Insulin icodec - a novel once-weekly basal insulin analog. The comparative trials include age range from 7 to 90 years, including a dedicated trial in elderly ($n=30$). The mean number of participants being enrolled is 236 (SD $\pm$ 425, maximum 1096, minimum 25, 95% CI -210 to 682). The trial duration range from 1 day in post-operative non-ICU setting to 52 weeks. Trials evaluate the glycemic control (HbA1c), time spent in hypoglycaemia in post exercise regimen, mean amplitude of glycemic excursion, nocturnal glucose fluctuation index by flash glucose monitoring, and frequency of hypoglycemia.

Conclusion

We evaluated emerging outcomes based on clinical, comparative glycemic indices including CGM based precise evaluation parameters, qualitative non-glycemic and quality of life parameters, patient reported outcome comparing Insulin glargine U300 with insulin degludec.

Risk of developing type 2 diabetes in young adults with a psychiatric disorder: a nationwide population-based cohort study

Lee Min-Kyung[1], Seo-Young Sohn[1], Jiyeon Ahn[1], Kyungdo Han[2] & Jae-Hyuk Lee[1]
[1]Myongji Hospital, Hanyang University Medical Center, Division of Endocrinology and Metabolism, Department of Internal Medicine, Rep. of South Korea; [3]Soongsil University, Department of Statistics and Actuarial Science, Rep. of South Korea

Objective

Having a psychiatric disorder may increase the risk of developing type 2 diabetes (T2D) and we aimed to determine whether young adults with a psychiatric disorder have an increased risk of developing T2D.

Research Design and Methods

We conducted a nationwide cohort study to evaluate the association of different psychiatric disorders with the risk of T2D in the young population. Records of 6.457.991 adults aged $20-39$ years without a history of T2D were retrieved from database of the South Korean National Health Insurance between 2009 and 2012. Service and followed up for incident T2D cases until December 2018. Five categories of psychiatric disorders were included: schizophrenia, bipolar disorder, depressive disorder, anxiety disorder, and insomnia. Hazard ratios (HRs) and confidence interval (CI) for developing T2D were estimated using Cox proportional hazards regression models.

Results
Over a median follow-up period of 7.59 years (range 6.47-8.23), a total of 122.603 patients with newly diagnosed T2D were identified. Cumulative incidence of T2D significantly increased with all five psychiatric disorders ($P < 0.001$). The multivariable-adjusted HRs was 1.146 (95% CI 1.106−1.189) for depression; 1.517(95% CI 1.319−1.745) for schizophrenia; 1.594 (95% CI 1.413−1.798) for bipolar; 1.226 (95% CI 1.183−1.271) for insomnia; and 1.134 (95% CI 1.07−1.62) for anxiety disorder.
Conclusions
All five psychiatric disorders were associated with increased risk of incident T2D in the young population. There was most significant increased risk of T2D in young adults with schizophrenia and bipolar disorders.

Hyperglycemia, but not previous diagnosis of diabetes mellitus, is an independent indicator of poor outcome in patients hospitalized for severe COVID-19

Elisa Eletto[1], Alessandra Dei Cas[1], Antonio Nouvenne[2], Andrea Ticinesi[1], Beatrice Prati[2], Valentina Spigoni[1], Raffaella Aldigeri[1], Gloria Cinquegrani[1], Silvia Schirò[1], Livia Ruffini[3], Nicola Sverzellati[1], Tiziana Meschi[1] & Riccardo C. Bonadonna[1]
[1]University of Parma, Department of Medicine and Surgery, Parma, Italy; [2]Azienda Ospedaliera-Universitaria di Parma, Department of General and Specialistic Medicine, Parma, Italy; [3]Azienda Ospedaliera-Universitaria di Parma, Department. of Medical Imaging, Parma, Italy

Background
Both diabetes mellitus and hyperglycemia are reported to be strong risk factors for poor outcome(s) in patients hospitalized for COVID-19. However, their relative roles in affecting patient prognosis are under debate.
Aims
To evaluate the independent influence of known diabetes mellitus and hyperglycemia on death/admission to intensive care unit (ICU) in patients hospitalized for COVID-19 during the first wave of SARS-Co-V2 pandemic.
Experimental Design
We retrieved the clinical data/records of the patients admitted with COVID-19 between 23rd February 2020 and 31st March 2020 to the Covid-1 macro-unit of the University Hospital of Parma. Known diabetes was defined by self-reported history, electronic medical records or ongoing medications. The readout of hyperglycemia was fasting plasma glucose at admission. The primary outcome (follow-up: 6 weeks) was a composite of transfer to the Intensive Care Unit or death. Logistic regression analysis was used to identify independent risk indicators of the primary end-point by univariable and multivariable models. We used Receiver Operating Characteristic (ROC) curves to assess the overall predictive power of the different regression models.
Results
757 subjects were included, 143 of whom (19.2%) had known diabetes. Patients with diabetes were older and had more frequently comorbidities associated. The primary outcome occurred in 61.5% of patients with diabetes compared to 43.1% in those without (log-rank test < 0.001). Among variables associated with COVID-19 severity, age, obesity, arterial hypertension, previous CV event, eGFR, glucose levels at admission (but not known diabetes), C-reactive protein and HR-CT visual score of pneumonia extension, were independent risk indicators of poor outcome in logistic regression models undergoing progressively more and more adjustments for potential confounders. The ROC curves showed remarkably good accuracy (up to AUC = 0.89) in predicting the primary composite end-point in all models, including the one which used the simplest, most immediate clinical parameters.
Conclusions
Known diabetes indicated poor COVID-19 outcomes, but not when adjusted for other baseline clinical variables and comorbidities, suggesting that its impact was mostly driven by concomitant factors and complications. Fasting hyperglycemia was a powerful and independent predictor of poor outcomes, together with age and biomarkers of inflammation (CRP) and lung tissue damage (HR-CT visual score). The molecular mechanism(s) underlying the tight association between high glucose and poor COVID-19 outcome remain(s) to be elucidated.

Circulating levels of endothelial progenitor cells (EPCs) and sexual function in fertile women with type 1 diabetes

Antonietta Maio[1], Maria Tomasuolo[2], Chiara Porcellini[3], Annalisa Sarnataro[2], Vlenia Pernice[1], Laura Castellano[3], Paola Caruso[3] & Katherine Esposito[3]
[1]University of Campania "L. Vanvitelli", Department of Advanced Medical and Surgical Sciences, University of Campania "Luigi Vanvitelli", Naples, Italy, [2] University of Campania "L. Vanvitelli", PhD in Translational Medicine, Department of Experimental Medicine, University of Campania "Luigi Vanvitelli, Naples, Italy, [3] University of Campania "L. Vanvitelli", Division of Endocrinology and Metabolic Diseases, University Hospital "Luigi Vanvitelli", Naples, Italy

Introduction
Female sexual dysfunctions (FSD) are complex conditions characterized by impairment of the female sexual cycle. Higher prevalence of FSD has been found in women with diabetes, as compared with matched healthy controls. Endothelial progenitor cells (EPCs) are circulating mononuclear cells participating in the neo-angiogenesis. There is evidence that circulating levels of EPCs are reduced in diabetic patients compared with age-matched subjects. The relationship between EPCs and sexual function during menses in women with diabetes has never been investigated.
Aim
The aim of this study is to assess circulating levels of EPCs in different phases of the menses in young women with type 1 diabetes. The relationship between EPCs levels and sexual function will be also investigated.
Matherials and methods
Sexually active women, aged 18-30 years, with type 1 diabetes (T1D) and age-matched healthy controls with a stable couple relationship and no oral contraceptive use were included in the study. Blood samples were drawn in the follicular, ovulatory and luteal phases of the same menses to assess sexual hormones levels, including FSH, LH, progesterone and estradiol. EPCs were quantified by flow cytometry. Sexual function was investigated using the Female Sexual Function Index (FSFI) and the Female Sexual Distress Scale (FSDS) during the three phases of menstrual cycle; FSD was diagnosed by a FSFI score $<$ 26.55 and a FSDS score $>$15. Women with hypogonadism, polycystic ovarian syndrome or irregular menses were excluded.
Results
A total of 18 women with T1D and 8 healthy controls were enrolled. Mean age was 25 years and mean BMI was 23.4 Kg/m2. In the overall population FSD prevalence was 7%. There were no differences in sexual hormone levels during the different phases of menses in the 2 groups. The FSFI total score as well as the scores related to desire, arousal, lubrication and pain were lower in diabetic women as compared with those of control subjects. Moreover, circulating levels of CD34+ and CD34+KDR+ cells EPCs were significantly lower in the ovulatory phase ($P = 0.03$) and ovulatory/luteal phases ($P = 0.04$;$P = 0.02$) respectively in women with diabetes as compared healthy controls. No significant difference was observed in the other EPCs phenotypes.
Conclsion
Young fertile diabetic women showed a worse sexual function and lower levels of EPCs as compared with healthy age-matched women during the different phases of menstrual cycle.

Somatostatin analogue treatment for hyperinsulinemic hypoglycemia with glucokinase activating mutation (GCK), c.295T>C (p.Trp99Arg)

Anna Boguslawska, Ewelina Rzepka, Lukasz Kluczyński, Alicja Hubalewska-Dydejczyk & Aleksandra Gilis-Januszewska
Department of Endocrinology, Endocrine Oncology and Nuclear Medicine, Jagiellonian University Medical College, Cracow, Poland

Somatostatin analogues (SSA) are used to treat different forms of hyperinsulinemic hypoglycemia (HH) in children and adults and therapeutic effect is achieved by suppressing insulin secretion from pancreatic β-cells by complex mechanisms. These treatments might be associated with several side effects, can even cause the worsening of severity of hypoglycemia. This is a report of the treatment of HH with SSA in patient with Activating Mutation (GCK), c.295T>C (p.Trp99Arg). We

present a 58-year-old male with HH, which was diagnosed at the age of 20 years. However, symptoms of hypoglycemia were present from the postnatal period. Fasting was mainly the trigger for hypoglycemia episodes. Additionally, epilepsy was diagnosed at the age of 10 years and he is currently treated with carbamazepine. At the age of 54 years, the patient underwent genetic testing and a heterozygous variant in Glucokinase (*GCK)* c.295T>C was confirmed. The severity of hypoglycemia ranged from mild to serious with the lowest glucose of 1.88 mmol/l during fasting. In early adulthood, the patient did not consent to pancreatectomy. At the age of 20 years, diazoxide treatment was introduced. It resulted in decreased both the number and severity of hypoglycemic episodes, however, poor patient compliance was observed in terms of regular medical follow-ups and regular diazoxide intake. In 11.2021 SAA treatment was introduced at the age of 57. At that time, his HbA1c level was 4.1%, fasting glucose level 2.59 mmol/l with c-peptide level 2.1 ng/ml, and insulin level 7 uU/ml. Initially patient received 10 mg short-acting octreotide with a good response. He is now treated with 20 mg octreotide monthly. In self-monitoring mean fasting and after meal glycemia values increased by 20-30 mg%. His most recent 4-h oral glucose tolerance test (OGTT), performed after three months of treatment with SSA, showed fasting glucose level 3.22 mmol/l with insulin level 3.82 uU/ml and c-peptide 1.1 ng/ml. The lowest glucose level (1.58 mmol/l) was observed in 180 min in OGTT. Currently, the patient reports no symptomatic and self-monitored hypoglycemia as well as no side effects of SSA. The SSA treatment of HH with activating *GCK* mutation, c.295T>C improved both fasting and after meal glucose levels by 20-30 mg% with complete remission of hypoglycemia. However, hypoglycemia during OGTT suggests that glucose load is a very strong trigger of insulin oversecretion despite SSA treatment. Therefore efficient treatment with SSA analogues should be combined with the low glycemic diet.

Transient Refractory Hyperinsulinemic Hypoglycemia

John Berquist & Matthew Wahl
University of Utah Hospital, Endocrinology, Salt Lake City, United States

Fasting hypoglycemia in the setting of hyperinsulinemia typically is persistent and often progressive. We present a case where fasting hypoglycemia with hyperinsulinemia was transient in nature over a fortnight. This occurred in the setting of recurrent seizure-like activity. Seizures are a well known sequela of hypoglycemia; however, the reverse is not nearly as well documented. A 20 year old male with a history of developmental delay, chronic PEG tube, and nonverbal at baseline presented for breakthrough seizures after a 17 year seizure-free period. On day 3 of admission, his fasting glucose levels fell to less than 65 mg/dl. He required D10 infusion, and experienced return of hypoglycemia when D10 was stopped. Labs obtained during a hypoglycemic episode showed blood glucose 47 mg/dl, insulin 12 uU/ml, beta-hydroxybutyrate 0.07 mmol/l, C-peptide 7.9/ml, sulfonylurea screen negative, and negative insulin antibodies. Octreotide was started in addition to D10 for persistent hypoglycemia. MRI abdomen did not reveal pancreatic lesions and 68 Gallium-DOTATAE PET scan showed normal pancreatic structure. Over a two week period, octreotide and D10 infusion were slowly weaned off without return of hypoglycemia. During his admission, he underwent EEG assessment, which showed a moderate degree of diffuse or possibly multifocal cerebral dysfunction warranting clinical correlation. True hypoglycemia needs to fulfill Whipple's Triad: Documented venous hypoglycemia, symptoms consistent with hypoglycemia, and resolution of symptoms with correction of hypoglycemia. In this case, the triad was presumed to be positive based on laboratory evaluation and a report of behavioral changes with hypoglycemia from patient's parents. Laboratory assessment met criteria for endogenous hyperinsulinemia. Imaging did not reveal a source for excess insulin. He went from requiring D10 and octreotide to being euglycemic off both medications. Critical illness is also implicated in fasting hypoglycemia, particularly in end-organ failure or sepsis. The patient did not have any organ damage to this degree, but there was recurrent seizure-like activity. Status epileptics causes a massive release of catecholamines, which increases serum glucose. The latter then leads to a large insulin release from the pancreas, which can lead to a period of hypoglycemia. Although clear epileptiform activity was not noted on EEG, the patient's clinical presentation with seizures raises the possibility that the hypoglycemia was related to recurrent seizures. This case highlights the need to consider epiletiform activity as a cause of hyperinsulinemic hypoglycemia.

The impact of changes to Joint British Diabetes Societies' diabetes-related ketoacidosis management guidelines on trends of complications and outcome

Gobeka Ponniah[1], Amy Birchenough[2], Megan Owen[3], Carina Synn Cuen Pan[4], Shamanth Soghal[4], Emily Warmington[1], Haaziq Sheikh[5], Muhammad Ali Karamat[6], Sanjay Saraf[7] & Punith Kempegowda[4]
[1]University of Birmingham Medical School, Birmingham, United Kingdom; [2]Sandwell and West Birmingham Hospitals NHS Trust, Birmingham, United Kingdom; [3]Walsall Manor Hospital, Walsall, United Kingdom; [4]Queen Elizabeth Hospital, Birmingham, United Kingdom; [5]Haberdashers' Adams' Grammar School, Newport, United Kingdom; [6]Heartlands Hospital, Birmingham, United Kingdom; [7]Good Hope Hospital, Birmingham, United Kingdom

Background
Serious complications of diabetes-related ketoacidosis (DKA) and its management with fixed rate insulin infusion (FRIII) include hypoglycaemia, hyperkalaemia and hypokalaemia. Revised Joint British Diabetes Societies for Inpatient Care (JBDS) guidelines in July 2021 recommended a reduced rate FRIII of 0.05 units/kg/hour from 0.1 units/kg/hour once blood glucose levels fall to $\leq$14.0 mmol/l to alleviate the risk of these complications.
Aim
To study the impact on trends of hypoglycaemia, hyperkalaemia, and hypokalaemia in DKA prior to and following the JBDS guideline update.
Method
We performed a retrospective analysis of all DKA admissions between February and November 2021 across six hospitals in the UK. Three out of the six hospitals have updated their management guidelines to reflect the new national recommendations. The trends in hypoglycaemia, hyperkalaemia, and hypokalaemia episodes pre- (February to June) and post-guideline update (July to November) was compared.
Results
220 (February-June) and 188 (July-November) DKA admissions were identified. 23 (10.5%) patients experienced hypoglycaemic episodes prior to the guideline update compared to 29 (15.4 %) patients post-guideline update ($P=0.116$). 55 and 58 episodes of hypoglycaemia were identified pre- and post-guideline update, respectively. 82 (37.3%) admissions pre-guideline update experienced episodes of hyperkalaemia compared to 51 (27.1%) admissions post-guideline update ($P=0.306$). Additionally, 67 (30.5%) patients experienced hypokalaemic episodes pre-guideline update compared to 72 (38.3%) patients post-guideline update ($P=0.033$). Overall, 141 and 142 episodes of hypo- and hyperkalaemia were identified pre-guideline update in comparison to 189 and 72 hypo- and hyperkalaemic episodes post-guideline update. The median DKA duration was 13.5(IQR9.0-20.6) hours in February-June vs 14.1(IQR 9.6-19.7) hours in July-November ($P=0.424$). Median length of stay was 4.4(IQR 2.3-8.2) days in February-June vs 3.4(IQR 2.0-6.7) days in July-November ($P=0.58$) respectively. Lack of awareness and understanding was listed as the reason for minimal changes in complications and outcome post-guideline update.
Conclusion
With an exception a higher number of hypokalaemic episodes was observed after the guideline revision, there was no significant changes in the complications or outcomes of DKA. These findings suggest more work needs to be done in implementing and educating the end-user to improve the anticipated outcomes from the revised guidelines.

Impact of Bariatric Surgery on the liver - An adolescent cohort

Madalena von Hafe[1], Joana Chaves[1], João Sérgio Neves[2], Marta Borges-Canha[2], Catarina Vale[1], Inês Lourenço[1], Susana Corujeira[3] & Miguel Campos[4]
[1]Faculdade de Medicina da Universidade do Porto, Departamento de Cirurgia e Fisiologia, Porto, Portugal; [2]Centro Hospitalar Universitário de São João, Serviço de Endocrinologia, Diabetes e Metabolismo, Porto, Portugal; [3]Centro Hospitalar Universitário de São João, Serviço de Pediatria, Porto, Portugal; [4]Centro Hospitalar Universitário de São João, Serviço de Cirurgia Pediátrica, Porto, Portugal

Introduction
Obese patients are at an increased risk of develop nonalcoholic fatty liver disease. Evidence supports that bariatric surgery might have an important impact on hepatic profile in obese adults. Literature suggests that bariatric surgery in adolescents might decrease the prevalence of some comorbidities, but information about its impact on liver profile and steatosis and fibrosis risk remains scarce.
Aim
To evaluate the impact of bariatric surgery on liver parameters and on Hepatic Steatosis Index (HSI, predictor of hepatic steatosis) and AST to Platelet Ratio Index (APRI, predictor of hepatic fibrosis) in adolescents.
Material and methods
We conducted an observational retrospective cohort study in obese adolescents who underwent sleeve gastrectomy in our center between 2013 and 2021. Clinical and laboratorial parameters were evaluated before surgery, and at 6 months, 12 months, and 24 months after surgery. The variation after surgery of anthropometric parameters, lipid profile, liver parameters, HIS and APRI were evaluated with paired t-tests.
Results
The population included ($n=22$) had an average age of 18.0 [17.0; 18.0] years at the time of the surgery, a body mass index of 47.0 ± 5.4 Kg/m^2 and 70.4% were female. In the pre-operative study, 44.4% used metformin, 37.0% had hypertension, and 48.1% dyslipidemia. Six months after the surgery, there was a clinically significant decrease in weight (127.8 ± 17.5 vs 96.6 ± 16.3 Kg, $P<0.01$), body mass index (46.9 ± 5.3 vs 34.9 ± 5.2 Kg/m^2, $P<0.01$), and percentage of fat mass (47.7 ± 7.6 vs 38.0 ± 12.1 %, $P<0.01$). There was also a decrease in GGT (34.0 ± 22.5 vs 20.0 ± 12.0, $P<0.01$). HSI score, which predicts hepatic steatosis, was also markedly decreased (60.0 ± 6.7 vs 45.5 ± 7.6, $P<0.01$). One year after surgery, there was still a noticeable decrease in weight, body mass index, percentage of fat mass and HSI score. There was also an increase of HDL ($P=0.03$) and a decrease of triglycerides (116.4 ± 57.6 vs 81.7 ± 36.8 mg/dl, $P<0.01$). After a two-year follow-up period years after the surgery, the reduction of HSI, weight, body mass index, and percentage of fat mass remained significant ($P<0.01$). There were no statistically significant differences in the hepatic fibrosis score (APRI), AST, ALT, FA, total bilirubin, direct bilirubin, total cholesterol, and LDL levels during follow-up.
Conclusions
Among severely obese adolescents, sleeve gastrectomy is associated with an improvement of steatosis and triglycerides levels, and this might have a long-term impact on the progression of nonalcoholic fatty liver disease.

Effect of bariatric surgery on metabolic profile − a pediatric cohort

Madalena von Hafe[1], Joana Chaves[1], João Sérgio Neves[2], Marta Borges-Canha[2], Catarina Vale[1], Susana Corujeira[3] & Miguel Campos[4]
[1]Faculdade de Medicina da Universidade do Porto, Serviço de Pediatria, Porto, Portugal; [2]Centro Hospitalar Universitário São João, Serviço de Endocrinologia, Diabetes e Metabolismo, Porto, Portugal; [3]Centro Hospitalar Universitário de São João, Serviço de Pediatria, Porto, Portugal; [4]Centro Hospitalar Universitário de São João, Serviço de Cirurgia Pediátrica, Porto, Portugal

Introduction
Obesity is a complex multifactorial disease and its prevalence in pediatric age has increased. Obesity prejudices the individual metabolic profile due to the adipotoxicity involved in this condition. Bariatric surgery improves the weight of obese patients along with metabolic comorbidities, being today one of the most effective treatments for obesity. Time of exposure to adipotoxicity appears to be an important risk factor for the development of metabolic complications.
Objective
To assess the impact of bariatric surgery in the metabolic profile of adolescents.
Methods
Observational cohort study in obese adolescents selected to the criteria for sleeve surgery between 2013 and 2021. Clinical and laboratory parameters were evaluated before retro surgery and at 6 and 12 months after surgery. The effects of surgery were used to test the functioning test and the McNemmar test.
Results
The population included ($n=24$) had a mean age of 17.5 [17.0; 18.0] years at the time of surgery and 70.8% were female. The mean body mass index (BMI) at the time of surgery was 46.0 ± 6.0 kg/m2; 45.8% arterial hypertension, 50.0% dyslipidemia and 54.2% used metformin. After 6 months of follow-up, there was a significant reduction in weight (127 ± 20.5 vs 96.2 ± 17.3 kg, $P<0.001$), BMI (46.7 ± 5.7 vs 35.6 ± 5.4 Kg/m2, $P<0.01$) and percentage of fat mass (47.6 ± 8.3 vs 39.0 ± 12.0%, $P<0.001$). At the end of one year, the decrease in weight gain, BMI and percentage of fat mass remained statistically significant. Glycated hemoglobin levels significantly decreased compared to baseline (5.4 ± 0.2%), at 6 (5.2 ± 0.3%, $P=0.01$) and 12 months ($5.2\pm0.0.3$%, $P=0.01$). Also, a significant reduction in HOMA-IR was observed, compared to the initial value (5.7 ± 2.6 mg/dl), at 6 (2.3 ± 0.9 mg/dl, $P<0.001$) and at 12 months (2, 1 ± 1.2, $P=0.002$) after surgery. These changes culminated in a reduction in metformin use, from 54% to 6% ($P=0.05$), 6 months after surgery.
Conclusion
These results evidence that bariatric surgery has a beneficial effect on the metabolic profile. Knowing the cumulative effects of obesity, performing this surgery earlier will reduce the time exposed to adiposity and glucotoxicity, and may mitigate the long-term consequences of obesity. Longer follow-up is needed to assess these benefits.

Esr1 and Esr2 estrogen receptors have different functions in Glut4 expression of 3t3-l1 cells

Caroline Pancera Laurindo, Karen Cristina Rego Gregorio & Ubiratan Fabres Machado
University of São Paulo, Department of Physiology and Biophysics, Institute of Biomedical Sciences, São Paulo, Brazil

Diabetes mellitus (DM) is an important cause of morbidity and mortality on a global scale. The pathophysiology of DM involves insulin resistance, even in insulin-treated type 1 DM, which in turn is related to the amount of glucose transporter GLUT4 (*Slc2a4* gene). Estrogen activity can be mediated by two distinct receptors (ESR1 and ESR2) and may involve genomic and non-genomic mechanisms. Estrogen has been described as involved in glycemic homeostasis, but the related mechanisms are only now beginning to be investigated. Previous studies conducted by our group have demonstrated that estradiol (E2) can modulate the *Slc2a4*/GLUT4 expression in muscle and adipose cells and have suggested that the ESR1- or ESR-mediated effects may be different. The present study seeks to demonstrate the ESR1- and ESR2-induced effects upon the *Slc2a4*/GLUT4 expression in adipose cells. Differentiated 3T3-L1 adipocytes were treated with 10 nM E2, 10 nM PPT (ESR1 agonist), 1μ MPP (ESR1 antagonist) and 100 nM DPN (ESR2 agonist) alone, or E2 + PPT, E2 + MPP and E2 + DPN (in the same concentrations), for 24h. Oil Red (OR) staining for analysis of cell differentiation, RT-qPCR for *Slc2a4* mRNA quantification and Western blotting for GLUT4 protein quantification were used. Differentiation of 3T3-L1 cells was successfully achieved and similarly preserved after the treatments. E2 and PPT promoted a similar increase (2 to 3 folds, $P<0.05$) in *Slc2a4*/GLUT4 expression; and their association did not induce any additional effect. The presence of MPP or DPN in E2-treated cells abrogates the E2 enhancer effect upon the *Slc2a4*/GLUT4 expression ($P<0.05$). Curiously, MPP alone was capable of reducing ($P<0.01$) the *Slc2a4*/GLUT4 expression as compared to that of control cells (cultivated without E2), suggesting some enhancer effect of ESR1 even in the absence of the ligand. Therefore, E2 increases the *Slc2a4*/GLUT4 expression in adipocytes by an ESR1-mediated mechanism; an effect that can be counterbalanced by the hyperactivation of ESR2. These data indicate that the E2-induced and ESR1-mediated effects increase the GLUT4 expression, contributing to the improvement of cellular glucose uptake, which can explain a beneficial effect of estrogen upon glycemic homeostasis. On the other hand, the hyperactivity of ESR2, by repressing the GLUT4 expression, may play a diabetogenic effect

Isoflavones genistein and daidzein enhance the expression of Slc2a4 mRNA and GLUT4 protein in adipocytes

Karen Cristina Rego Gregorio, Caroline Pancera Laurindo & Ubiratan Fabres Machado
University of São Paulo, Department of Physiology and Biophysics, Institute of Biomedical Sciences, São Paulo, Brazil

According to the world Health Organization, about 422 million people worldwide have diabetes mellitus (DM), and this number is growing rapidly. DM, mainly type 2, is associated with insulin resistance, which involves reduced expression of glucose transporter GLUT4 (*Slc2a4* gene). It is known that estrogen can modulate glycemic homeostasis and seems to involve changes in the *Slc2a4*/GLUT4 expression. There has been an increased interest in plant-derived phytoestrogens, which can bind to estrogen receptors (ESR1 and ESR2), mimicking or inhibiting some estrogen effects. It is believed that these compounds have beneficial health properties, acting against various diseases, however, that must be carefully analyzed. Phytoestrogens can have different affinity for ESR1 or ESR2 and can reveal variable estrogen or antiestrogen effects. Little is known about the effect of phytoestrogens upon the GLUT4 expression, and about their possible role in cellular glucose disposal. The present study investigates the effects of some abundant phytoestrogens, isoflavones genistein (G) and daidzein (D), as compared to estradiol (E2), upon the *Slc2a4* mRNA and GLUT4 expression (respectively by RT-qPCR and Western blotting), in isolated adipocytes. Differentiated 3T3-L1 cells were cultivated for 24 h with 10 nM of E2, G and D, alone or in combination. Alone, E2, G and D showed a similar increase (by ~50%, $P<0.05$) in the expression of both *Slc2a4* mRNA and GLUT4 protein, as compared to untreated cells. Besides, in combination with E2, both G and D promoted an additional increase ($P<0.005$) in the *Slc2a4* mRNA, which was not accompanied by a similar increase in GLUT4, suggesting the presence of a posttranscriptional regulation. Based on these results, we conclude that phytoestrogens genistein and daidzein can increase *Slc2a4*/GLUT4 expression as efficiently as estradiol does. These results indicate that, concerning the adipocyte capacity of glucose uptake, the isoflavones studied can effectively substitute estradiol.

Mediterranean Diet and 12 months weight loss result in complex serum metabolomic and fecal metaproteomic changes in paediatric obesity

Daniele Spadaccini[1], Virginia Vita Vanella[2], Elettra Barberis[2], Roberta Ricotti[3], Simonetta Bellone[3], Elisa Bona[4], Valentina Antoniotti[3], Marina Caputo[1], Valentina Mancioppi[3], Ivana Rabbone[3], Marcello Manfredi[2] & Flavia Prodam[1]
[1]University of Piemonte Orientale, Department of Health Sciences, Novara, Italy; [2]University of Piemonte Orientale, Department of Translational Medicine, Novara, Italy; [3]University of Piemonte Orientale, SCDU of Pediatrics, Department of Health Sciences, Novara, Italy; [4]University of Piemonte Orientale, Department of Sciences and Technological Innovation, Alessandria, Italy

Background
The relationship between composition and function of microbiota, obesity and nutrition has been increasingly studied and is still a challenge.
Aims
To test whether in a group of 12 pediatric patients with obesity the treatment with a structured hospital and in-home Mediterranean Diet intervention had an impact on gut microbiota composition, function, and metabolite production, including Short chain fatty acids (SCFAs).
Methods
An untargeted metaproteomics analysis through nano-LC chromatography coupled to high-resolution mass spectrometer (Triple TOF 5600+, Sciex), for the identification of phyla, and GC-MS for the analysis of SCFA and small molecules in serum and stools were carried out. All identified peptides were annotated (UniProtKB database, KEGG) and their functions were identified by UniPept software. Phylogenetic analysis was also performed. Subjects were evaluated at baseline, and after 6 and 12 months.
Results
At metaproteomic, we identified more than 250000 peptides, and 70000 proteins. We were able to identify common features between patients from the same time group. We detected changes associated with an improvement of the gut inflammatory state directly dependent on the diet. Bacterial phylogenetic and functional changes were observed in relation to the dietary intervention, BMI reduction, and adherence to the Mediterranean diet. Both after 6 and 12 months, patients lost weight and contemporarily showed a reduction of fecal SCFA (acetic, butanoic, pentanoic, and propanoic) and an increase of the Bacteirodetes/Firmicutes ratio. Acetic acid and butyric acid were also decreased in serum after 6 and 12 months. Functionally, we observed an increase in pectin catabolism. We also identified fecal sugars and amino acid changes associated to the dietary intervention.
Conclusions
This preliminary data confirm that also pediatric obese individuals losing weight reverse their microbiota, increasing their Bacteirodetes/Firmicutes ratio. At the same time, most SCFA were found to be reduced both after 6 and 12 months after the intervention. Obese individuals could have an impaired utilization of SCFA that translates into a higher lipogenic effect compared to lean individuals who might better take advantage of the anti-inflammatory role. More intervention studies should be performed in this promising area by utilizing similar innovative techniques.

Ghrelin deficiency sex-dependently alters food intake, locomotor activity, and white adipose tissue gene expression in a binge-eating mouse model

Karina Prins, Patrick Delhanty, Martin Huisman, Rosinda Mies, Anke McLuskey & Jenny Visser
Erasmus MC, Department of Internal Medicine, Rotterdam, Netherlands

Binge-eating disorder is the most prevalent eating disorder diagnosed, affecting three times more women than men. It is characterised by binge-eating episodes: the rapid consumption of a large amount of food, without needing the calories. The gut hormone ghrelin stimulates appetite and reward signalling, and loss of its receptor reduces binge-eating behaviour in male mice. We aimed to examine the influence of ghrelin itself on binge-eating behaviour in mice of both sexes. 5-week-old wild-type (WT) and ghrelin-deficient (GKO) mice were housed individually in an indirect calorimetry system for 9 weeks. Binge-like eating in mice given *ad libitum* chow was induced by time-restricted access to Western-style diet (WD; 2h access, 3 days/week) in the light phase (BE); control groups received *ad libitum* chow (CO), or *ad libitum* access to both diets (CW). Food intake, locomotor activity, body composition, and white adipose tissue (WAT) gene expression were assessed. All groups of BE mice showed binge-eating behaviour, eating up to 60% of their 24h intake during the WD access period. Subsequent dark phase chow intake was decreased by 12.4% in GKO mice ($P=0.029$) and remained similarly decreased, especially in GKO females, on non-binge days ($P=0.015$). As a result, on binge days, chow comprised a smaller portion of the 24h caloric intake of GKO BE ($48\pm4\%$) compared with WT mice ($60\pm2\%$;$P=0.02$). This reduction in chow preference was also observed in CW mice (GKO: $3\pm1\%$; WT: $8\pm2\%$;$P=0.029$). Compared to males on the same diet, dark phase locomotor activity was increased by 97.6% in CO females ($P<0.0001$), 107.0% in CW females ($P<0.0001$), and, on binge days, by 46.0% in BE females ($P=0.003$). Interestingly, on non-binge days, locomotor activity remained increased in WT females but was reduced to the level of the males in GKO females (interaction:$P=0.03$). Upon sacrifice, GKO BE mice weighed 7.8% less ($P=0.001$) and had a 2.2% lower lean body mass percentage than WT BE mice ($P=0.014$). In inguinal white adipose tissue of BE and CW groups, ghrelin deficiency and female sex were associated with suppression of macrophage polarization-regulatory genes, and increased expression of genes that modulate thermogenesis. We conclude that, in contrast to ghrelin receptor deficiency, ghrelin deficiency does not hamper the development of binge-like eating. Moreover, ghrelin deficiency sex-dependently alters food intake timing, locomotor activity, and inguinal white adipose tissue function. These results add to the growing body of evidence that ghrelin signalling is sexually dimorphic.

Glucocorticoids enhance browning and thermogenic functions of mouse and human white adipocytes

Ramesh Kasarla[1], Iacopo Gesmundo[1], Noemi Congiusta[1], Greta Sabbia[1], Barbara Pardini[2], Maria Alessandra Bocchiotti[3], Ezio Ghigo[1] & Riccarda Granata[1]
[1]Division of Endocrinology, Diabetes and Metabolism, Department of Medical Science, University of Turin, Turin, Italy; [2]Italian Institute for Genomic Medicine (IIGM), Candiolo, Italy, Candiolo, Italy; [3]Department of Clinical and Biological Sciences, University of Turin, Turin, Italy

White adipose tissue (WAT) stores excess energy as triglycerides, while brown adipose tissue (BAT) dissipates energy through heat, acting as a defence against cold and obesity and as a positive regulator of metabolic functions. BAT thermogenic functions are mainly induced by mitochondrial uncoupling protein-1 (UCP-1), which induces uptake of lipids and glucose to sustain oxidation and thermogenesis in both brown and beige adipocytes. Beige/brite adipocytes arise in WAT depots and morphologically and functionally resemble to brown adipocytes. The glucocorticoid receptor (GR) agonist dexamethasone plays an important role in energy homeostasis, regulation of insulin sensitivity, lipid metabolism and adipose tissue distribution. Indeed, *in vivo* studies suggest that Dex increases the effects on UCP-1 mRNA expression in BAT. However, the role of Dex in adipose browning and BAT function is yet not fully known. Thus, we aimed to assess the role of Dex on browning of white adipocytes and brown adipocyte thermogenic functions. 3T3-L1 murine preadipocytes and human mesenchymal stem cells (hMSCs), isolated from bariatric surgery of lean subcutaneous and visceral adipose tissues, were differentiated into white adipocytes for 9 and 21 days respectively. Browning was induced for 72 h with rosiglitazone (Rosi) and insulin, in the presence or absence of Dex. Our results showed that in 3T3-L1 adipocytes Dex increased both mRNA and protein expression of BAT markers UCP-1, PRDM16, and PGC-1α. Moreover, the GR antagonist RU486 completely blocked Dex-induced mRNA expression of *Ucp-1*, indicating the involvement of GR on these effects. Dex also strongly enhanced the mRNA expression of the beige markers transmembrane protein 26 (TMEM26) and sirtuin 1(SIRT1), while inhibited the WAT marker *C/ebpα*. Interestingly, oil red O staining revealed that Dex increased the number of small lipid droplets and enhanced Iso-induced lipolysis, promoting the expression levels of adipose triglyceride lipase (ATGL) and hormone sensitive lipase (HSL). Furthermore, Dex enhanced mitochondrial biogenesis, determined by staining with Mito-Tracker dye, increased the expression of the fat oxidation marker *CPT1*, and modulated the oxygen consumption rate (OCR), assessed by Seahorse analysis, in transdifferentiated 3T3-L1 adipocytes. Finally, Dex increased the mRNA levels of browning genes in transdifferentiated adipocytes obtained from hMSCs of both subcutaneous and visceral human adipose tissues. Overall, these findings indicate that Dex enhances the differentiation of 3T3-L1 and human white adipocytes into beige adipocytes, by regulating the expression of genes characteristics of browning and increasing beige thermogenic functions.

The effects of Long-term (five years) prednisone therapy in frequently relapsing nephrotic syndrome of childhood: impact on glycemia and the different components of the metabolic syndrome (MetS)

Mostafa Elbaba[1], Noor Hamed[1], Ashraf Soliman[1], Fawzia Alyafei[1], Maya Itani[1,2], Fatima Al-Naimi[1,2], Doaa Al Yousef[2] & Mona Shaat Dalees[2]
[1]Hamad Medical Center, Pediatrics, Doha, Qatar; [2]Hamad Medical Center, Nutrition and Dietitic Department, Doha, Qatar

Although widely prescribed for their anti-inflammatory and immunosuppressive properties, glucocorticoids have various common metabolic side effects including hypertension, dysglycemia and diabetes.

Aim

This study was carried out to investigate the prevalence of different metabolic components and dysglycemia in children with steroid sensitive nephrotic syndrome (SSNS) with multiple relapses for 5 years in relation to the cumulative dose of steroids.

Methods

Data of 30 children with SSNS was analysed retrospectively. They received prednisolone only in the standard dose for the initial episode at 2 mg/kg/day for six weeks followed by 1.5 mg/kg on alternate days for six weeks and relapses were treated with 2 mg/kg/day till remission followed by 1.5 mg/kg/day for four weeks. The cumulative dose of steroids over the period of 5 years was calculated for each child. The growth data was recorded along the treatment period. The different metabolic criteria including impaired fasting glucose (IFG), high LDL and cholesterol, lower HD and high blood pressure for age and sex were studied over this period of time.

Results

The mean cumulative prednisone = 125 +/- 28 mg /kg/year given over an average duration of 5 years. Obesity (OB) and overweight (OW) increased from 25% pre-treatment to 59.2% after 5 years of treatment. After 3 and 5 years of treatment IFG was found in 24 and 36 % respectively, high LDL in 89% and 80% respectively, high cholesterol in 85% and 100% respectively. Hypertension was detected in 12.5% and 23% of patients after 3 and 5 years of treatment. The mean serum cholesterol and LDL levels were significantly higher than normal in treated children after 3 and 5 years of treatment.

Conclusion

Long term prednisone therapy (for 5 years) with a mean cumulative dose of prednisone = 125 +/- 28 mg/kg/yr. was associated with increased prevalence of OW and obesity as well as with higher risk of developing hypertension and dyslipidemia.

Table 1

Variables	Beginning	3 yr	5 yr	*P* value
Number	30	30	30	
IFG (FBG > 5.6 mmol/l	15.93%	24.14%	35.71%	0.1
LDL > 2.7 mmol/l	88.89%	88.89%	80.00%	0.35
HDL < 1.03 mmol/l	10.53%	10.00%	0.00%	0.07
TG >1.7 mmol/l	77.27%	33.33%	60.00%	0.23
Cholesterol > 4.5 mmol/l	100.00%	85.71%	100.00%	1
Hyperten-sion BP > 95th centile for age	23.30%	12.50%	23.00%	0.9

The ecology of the microbiome in children with congenital generalized lipodystrophy type 4 (CGL4) is quickly modified after metreleptin treatment

Tommaso Daffara[1], Valentina Mancioppi[2], Marina Caputo[1], Simonetta Bellone[2], Nadia Massa[3], Alice Caramaschi[3,4], Flavio Mignone[3,5], Martina Romanisio[1], Ivana Rabbone[2], Mara Giordano[6], Gianluca Aimaretti[1,6], Elisa Bona[3,4] & Flavia Prodam[1,6]
[1]Novara, Endocrinology Unit, Department of Translational Medicine, Novara, Italy; [2]Novara, SCDU Pediatrics, Department of Health Sciences, Novara, Italy; [3]Alessandria, Department of Sciences and Technological Innovation, Alessandria, Italy; [4]Vercelli, Department for Sustainable Development and Ecological Transition, Vercelli, Italy; [5]Novara, SmartSeq s.r.l., spin-off of the Università del Piemonte Orientale, Novara, Italy; [6]Novara, Department of Health Sciences, Novara, Italy

Introduction

Lipodystrophy syndromes are characterized by a progressive metabolic impairment secondary to adipose tissue dysfunction and genetic background. The role of microbiota is still uninvestigated.

Objective

Evaluate the gut microbiome ecology in relation to dietary and clinical parameters in two infant siblings with congenital generalized lipodystrophy type 4 (CGL4) before and after treatment with recombinant leptin.

Methods
Two siblings (male, 5.5 years; female 2.5 years) with CGL4 caused by a new homozygous PTRF mutation (NM_012232 eson1:c T21A:p. Y7X) were identified and followed after the starting of leptin treatment. We collected auxological, metabolic, nutritional parameters, and stool samples at baseline and every 3 months. Two baseline stool samples were pooled. DNA was extracted directly from 0.25 g of stool using the QIAamp PowerFecal Pro DNA Kit. DNA was amplified with primers for the V3 and V6 regions of 16S rDNA tagged with Multiplex Identifier sequences using Microbiota Solution B Kit optimized for Illumina Miseq sequencing. Raw FastQ sequences were analyzed using MicrobAT Software. Statistical analyses were performed using MicrobiomeAnalyst and R software.
Results
At baseline, reduced subcutaneous fat, muscular hypertrophy, distinct facial features, myopathy, atlantoaxial instability were observed. Stature and BMI were normal. Blood tests showed elevated CK, mildly elevated levels of liver enzymes and triglycerides, low leptin and adiponectin levels. Fasting glucose and HbA1c were normal; HOMA-IR was mildly elevated in the female, and continuous glucose monitoring often detected glucose higher than 180 mg/dl after meals in male. They were hyperphagic, mainly for foods rich in fats and sugars. The 2 subjects showed a Bacteroides enterotype (F/M): 46%/44% Bacteroidetes, 49%/42% Firmicutes, 0.02%/0.04 other Bacteria, 3.2%/1.9% Actinobacteria, 0.7%/0.4% Proteobacteria; 0%/11%Verrucomicrobia. Treatment with metreleptin was started at standard dose according to age and weight. All the metabolic parameters and hyperphagia improved, and they were more adherent to dietary indications. The male subject lost 0.8 kg after 3 months, female weight was stable. We present microbiome ecology after 3 months of treatment, before starting also medium-chain triglyceride oil formulas. Alfa-diversity increased in both children. Ecology was modified ($P<0.06$) with a reproducible signature with decreased and increased relative abundance of species linked to metabolic homeostasis.
Discussion
These preliminary results highlight as dietary adherence and leptin treatment were soon followed by improvements in metabolic alterations and changes in microbiome ecology. Whether microbiota composition and function have a role in the lipodystrophy phenotype needs further investigation. Our preliminary data should be validated in a wide cohort.

An audit of management of severe hyperlipidaemia in secondary and primary care services in greater london area

Bhavna Sharma & Anees Fatima
Northwick Park Hospital, United Kingdom

Hyperlipidaemia services in the UK are guided by National Guidance for Lipid Management for primary and secondary prevention of cardiovascular disease. Our audit studied a total of 71 patients in primary and secondary care in the greater London area with total Cholesterol levels greater than 7.5 mmols/l. In patients admitted to hospital ($n=22$); 27.8% patients were ITU admissions with 56% being under surgical team for acute pancreatitis. Only 45.4% of these patients were reviewed by the diabetes/endocrine team (most reviews being for management of diabetic ketoacidosis). 54.5% of patients were initiated and continued on insulin therapy (11% were on IV insulin only for management of hyperlipidaemia). 9% of patients had to have plasmapheresis. With regards to work up only 9% of these patients received lifestyle advice or screening for further co-morbidities. 45.5% were referred onwards to a lipid clinic. None of the acute admissions had inpatient investigations sent to screen for familial causes. Selected Patients attending GP practice ($n=49$) had an average total cholesterol level of 11.28 mmols/litre. About 70% of these patients received formal lifestyle advice. 18.3% of these patients were referred to a dietician. Around 77% of these patients were on statins and 67% of these patients were on two or more medications. 33.7% of these patients were diabetic and under follow up with Endocrine. 18.3% of these patients were classified as increased cholesterol secondary to alcohol use (it was unclear whether these patients were always referred to alcohol liaison services). Only 4% of these patients were referred to endocrine after screening for diabetes highlighting a significant gap in secondary screening. 34.7% of these patients underwent screening for familial hypocholesteraemia and were referred to a specialised lipid clinic. Our audit highlighted the gap in management of patients getting followed up in primary care vs being admitted in the hospital. The authors felt that dual guidelines emphasising on discharge based planning from hospital and a more secure safety net for patients with significant cardiovascular risk is needed. A GP guided approach with early referrals to lipid clinic/endocrine may achieve positive outcomes in such cases.

Dysregulation of cytochrome P450 oxidoreductase (POR) in NAFLD and hepatocellular carcinoma; evidence from clinical, rodent and cellular models

Ismael da Conceição[1], Nikolaos Nikolaou[2], Laura Gathercole[3], Shelley Harris[1], Niall Dempster[1], Ahmad Moolla[1], Leanne Hodson[1] & Jeremy Tomlinson[1]
[1]University of Oxford, Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, United Kingdom; [2]University of Cambridge, Department of Pathology, Cambridge, United Kingdom; [3]Oxford Brookes University, Department of Biological and Medical Sciences, Oxford, United Kingdom

The incidence of non-alcoholic fatty liver disease (NAFLD), the hepatic manifestation of the metabolic syndrome, continues to rise. NAFLD is associated with significant liver-specific and cardiovascular morbidity and mortality, including hepatocellular carcinoma (HCC). Currently, there are no licensed therapies, highlighting the importance of understanding the pathogenic mechanisms that drive the condition. Cytochrome p450 oxidoreductase (POR) plays an essential role in activation of all microsomal cytochrome p450s (CYPs) by electron transfer. Rodent models of POR deletion develop hepatic steatosis, but the underpinning mechanisms remain poorly understood. The role of POR in human models to modulate hepatic metabolic phenotype has not been explored in detail. We have tested the hypothesis that POR contributes to NAFLD progression through dysregulation of major metabolic pathways using clinical samples from patients with NAFLD and HCC, *in vivo* rodent models (American Lifestyle-Induced Obesity Syndrome, ALIOS) and human hepatoma cells. In liver biopsies of NAFLD patients, relative POR mRNA expression was significantly lower compared to non-NAFLD controls ($P<0.01$). In addition, POR activity as measured by the analysis of urine steroid metabolites, decreased with advancing NAFLD severity (control vs F0-F2, $P<0.0001$; control vs F3-F4, $P<0.0001$). In patients with cirrhosis or HCC, POR activity was also decreased when compared to healthy controls ($P<0.0001$). Mice fed the ALIOS diet (12-months) developed significant hepatic steatosis and fibrosis. In both male and female ALIOS mice, POR mRNA expression was significantly decreased in comparison with normal chow-fed animals ($P=0.01$, FDR$=0.04$). In human hepatoma cells (HepG2), lipid loading was associated with decreased POR expression. To determine the cellular impact of decreased POR expression, siRNA knockdown experiments were performed. RNA-sequencing analysis combined with real-time PCR identified multiple metabolic pathways that were dysregulated. Changes in fatty acid metabolism were indicative of futile cycling with increased expression of fatty acid synthesis (AMPK, ACC, FASN) and oxidation (*CPT1A*) markers. These findings were endorsed with biochemical analysis demonstrating increased triacylglycerol ($P<0.01$) and 3-hydroxybutyrate ($P=0.03$) levels in cell culture media, and increased rates of *de novo* lipogenesis in cellular triacylglycerol ($P<0.01$). Moreover, there were significant changes in glucose metabolism suggesting increased gluconeogenesis and reduced glucose uptake. Finally, bile acid synthesis was impacted with increased expression of rate limiting synthetic enzymes and altered cellular bile acid production. Altered POR expression and activity has the potential to contribute to the complex metabolic phenotypes associated with NAFLD. Further studies are needed to determine whether this represents a putative cause or consequence of disease.

Modern method of diagnosing of cerebral microangiopathy in patients with diabetes mellitus type 2 by doppler ultrasound

Madina Adkhamova, Dilfuza Karimova & Rakhshona Mirzaeva
Tashkent Medical Academy, Department of Endocrinology, Tashkent, Uzbekistan;

Background
To identify opportunities for Doppler ultrasound in the diagnosis of cerebral microangiopathy in patients with diabetes mellitus type 2 and hypertension.
Methods
The study included the diagnosis of 72 patients with type 2 diabetes and hypertension who were hospitalized in the 2 and 3 clinics TMA. The control group consisted of 25 patients aged 61.9 $\pm$ 2.6 years, suffering from type 2 diabetes. The study group included 47 patients (19 men and 28 women), older age groups with diagnosed type 2 diabetes and hypertension history, besides the patients of the second group were divided into two groups - those with diabetes complications flow - 23 patients without microvascular complications - 24 patients. Time monitoring of patients ranged from 3 to 8 years. All patients underwent Doppler ultrasound of the main arteries of the head and neck - the internal carotid artery. Evaluated the speed of blood flow indices, the PI index (which determines the stiffness and elasticity of the arteries), the RI index (reflecting peripheral resistance), systolic and diastolic index (the ISD), assessed cerebrovascular reactivity (according to tests with breath-holding and hyperventilation).
Results
Changes dopplerographic index in the BCA were observed in 19 patients in the subgroup with diabetes complications compared with 2 patients of the subgroup without complications. In the subgroup with diabetes complications 21 patients had signs of nephropathy and in 18 of them were identified changes in dopplerographic indicators BCA, which may indicate vascular remodeling processes in the body of patients with type 2 diabetes. Significant moderate and strong correlation LED current duration of type 2 and the presence of diabetic retinopathy and nephropathy, altered dopplerographic indices PI and RI. So a critical increase in the ICA RI index was observed after 6.8 years after the diagnosis of type 2 diabetes. It was revealed that the predictors of microcirculatory disorders in patients with type 2 diabetes mellitus were the duration of 8 years. It is shown that microcirculatory disorders, diagnosed by means of ultrasound diagnostics, develop an average of 7 years after the onset of diabetes. Changes in dopplerographic indices were observed mainly in patients with type 2 diabetes complications. At the same time in all patients with a diabetes study group for the duration of 2 years, more than 7 marked changes in cerebrovascular reactivity by reducing vasodilatation reserve.
Conclusions
These results suggest that Doppler ultrasound diagnoses cerebral microangiopathy in patients with type 2 diabetes.

Impact of the COVID-19 pandemic on diabetic foot

Sara Ragbi, Mjabber Amal, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
Uhc Ibn Rochd, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction
The COVID-19 pandemic has presented many challenges in the management of diabetics around the world. While many people can be managed using new methods such as tele-consulting, the diabetic foot presents unique challenges due to the frequent need for "face-to-face" consultation and treatment. The pandemic has thus made the management of diabetic feet, already complex, even more difficult. This study aims to assess the impact of the COVID-19 pandemic on the diabetic foot.
Methods and results
It's a retrospective study conducted at the endocrinology and diabetology department of the Ibn Rochd University Hospital, including patients who consulted in the emergency room for diabetic foot ulcer starting from the announcement of confinement in March 2020 until September 2021. Our study included 340 patients. The average age was 59 years, 62.35% were male and type 2 diabetics accounted for 93.23% with an average duration of diabetes of 12.3 years. Among the patients, 64.7% were on insulin, 22.6% on ADO and 7.3% on mixed treatment. Patients at very high cardiovascular risk represented 46.7% of which 6.9% were followed for ischemic cardiomyopathies and 40.8% for peripheral arterial disease. About microangiopathy, 27.3% had diabetic retinopathy and 25.3% diabetic kidney disease. Compared to the years 2018-2019, the number of patients who consulted was 1.9 times higher, the number of ulcers and cellulitis was 32.9% each, i.e. 6.8% more ulceration and 4% more cellulitis. The percentage of necrotizing fasciitis also increased by 18.4% as well as dry gangrene (22.6% vs 17%). 39.7% had to be referred for immediate surgical management due to the advanced stage of the lesions, which was 5.7% higher than in previous years. This increase in the number of emergencies was contrasting with a decrease in the number of outpatient consultations because of confinement.
Conclsion
The severity and increasing of the diabetic foot ulcers observed during the period of COVID-19 confirms the need for appropriate and rapid management to avoid dramatic results. Telemedicine and the use of new technologies are needed to provide optimal wound care while minimizing the exposure risk.

Influence of dopamine receptor d2 and dopamine transporter polymorphisms in angiopathy in patients with type 2 diabetes mellitus

Marta Neves[1], Ana Carolina Santos[1,2], Joana Ferreira[1,2], João F. Raposo[3], Ana Valente[4] & Manuel Bicho[1,2]
[1]Faculty of Medicine, University of Lisbon, Genetics Laboratory, Ecogenetics and Human Health Group, Institute for Environmental Health, Lisbon, Portugal; [2]Scientific Research Institute Bento da Rocha Cabral, Lisbon, Portugal; [3]Associação Protectora dos Diabéticos de Portugal, Lisbon, Portugal; [4]Atlântica - Escola Universitária de Ciências Empresariais, Saúde, Tecnologias e Engenharia, Barcarena, Oeiras, Portugal

Introduction and Aim
Dopamine receptor D2 (DRD2) polymorphism (rs1800497) appears to be associated with increased susceptibility to the development of type 2 diabetes mellitus (T2DM). The dopamine transporter (DAT) determines dopamine signalling, responsible for the reuptake of its active form from the synapse. Polymorphism in the DAT gene (rs2836317) can increase dopamine reuptake in the synaptic cleft. However, its association with T2DM is still controversial.
This study aimed to evaluate the relationship between genetic polymorphisms of DAT and DRD2 and the susceptibility to the development of angiopathy in T2DM and its influence on the biochemical parameters.
Design and Methods
150 patients with T2DM were divided into: G1-75 patients with angiopathy and G2-75 patients without angiopathy. The DRD2 and DAT polymorphism were determined by endpoint analysis method and PCR, respectively. Blood levels of malondialdehyde (MAD), ascorbic acid, homocysteine and cysteine, vitamins B6 (vit.B6), B12 (vit.B12) were measured by HPLC methods, and standardized methods determined the other biochemical parameters. Statistical analysis was performed using SPSS with statistical significance for $P<0.05$.
Results
There were differences only in the DRD2 polymorphism between G1 to G2 ($P=0.016$). Carriers of allele A of DRD2 had a 3.18-fold increased risk to angiopathy (OR = 3.18 [1.40-7.21], $P=0.006$). Analyzing the relationship of biochemical parameters between groups was found an increase in systolic blood pressure (SBP) ($P=0.023$), MAD ($P=0.010$) and retinol ($P=0.011$) in G1. Regarding DRD2 polymorphism, there was an increase in HDL cholesterol (HDL-C) ($P=0.035$) for genotype GG and of vit.B12 in carriers of the allele G ($P=0.013$). For DAT polymorphism, it was found an increase in weight ($P=0.042$) and waist circumference ($P=0.050$) and a decrease in ascorbic acid ($P=0.039$) for genotype 10/10 and an increase in LDL cholesterol (LDL-C) ($P=0.027$) in genotype 9/10. Biochemical parameters were compared between groups, but dividing the population by the studies polymorphisms, for DAT it was found higher values of SBP ($P=0.014$), triglycerides ($P=0.019$) and retinol ($P=0.031$) and lower HDL-C values ($P=0.050$) for carriers of allele 10 in G1; for DRD2 it was found in carriers of the allele A, higher values of homocysteine ($P=0.038$), cysteine ($P=0.035$) and retinol ($P=0.007$) and in the genotype GG higher values of SBP ($P=0.020$) and triglycerides ($P=0.011$) in G1.
Conclusions
DRD2 polymorphism appears to influence susceptibility to angiopathy in T2DM patients directly. DAT and DRD2 polymorphism may modulate disease-associated biochemical parameters.

Introduction
Correct titration of basal insulin is one of the most important conditions allowing Type 2 Diabetes Mellitus patients to reach correct and personalised fasting plasma glucose. The persistence of the pandemic, together with the persistence of the SARS-CoV2 virus made titration process more complex, and pushed the Lombardy diabetologists to develop solutions which could be handled by the patient independently, or with the remote online assistance of diabetes team.
Patients, materials and methods
The Lombardy diabetologists participating in a training program shared their titration experiences of degludec basal insulin and its association with liraglutide (iDegLira). These physicians collected aggregated data of 387 subjects with T2DM (W:60%; M: 40%); homogeneous distribution in age groups 50 and 65 (31%); 65 and 75 (32%), and over 75 (28%), with 9% of the patients below 50; duration of illness <5 years (15%), 5 and 10 years (17%), 10 and 20 years (39%), over 20 years (29%). The patients had not adequate glycaemic control (90% with HbA1c>7.0%) with overweight or obesity (84.5% with BMI>25 kg/m2). Degludec was introduced for 129 patients, iDegLira for 258, titration was set up through modifications recommended by the diabetes team (244 patients); through the program "Titolando" (www.titolando.it) (132 patients); with no education to titration (11 patients).
Results and discussion
Thanks to the diabetes centres support, the patients reached an adequate FPG (average 174.7 mg% at baseline; 122 mg% after 6.1 weeks of controlled titration, increase of basal insulin dose by 4.7 Ul/die); the self-titration with the program "Titolando" obtained overlapping results (average FPG 178.5 mg% at baseline; 127 mg% after 7 weeks of self-managed titration, increase of basal insulin dose equal to 7UI/die). Less satisfactory the evolution of FPG in those who have independently modified the dosages of basal insulins (average FPG 199 mg% vs 140 mg% at six months follow-up, with increase of 5.9 UI of daily doses). The main limit and drawback of this retrospective observation consists in the fact of not having collected hypoglycaemia episodes.
Conclsions
During the pandemic, the remote support by Lombardy diabetes centres allowed to obtain satisfactory FPG after introduction of Degludec or iDegLira. Similarly, the process of self-titration led by the "Titolando" program proved adequate, easy to understand and manage, and such as to offer a valid alternative in all the situations where it is not possible to provide clinical regular feedback to patients who are in therapy with basal insulins.

Use of continuous glucose monitoring for treatment adjustment in type 2 diabetes patients

Tzvetelina Totomirova & Mila Arnaudova
Military Medical Academy, Clinic of Endocrinology and Metabolic Diseases, Sofia, Bulgaria

Continuous Glucose Monitoring (CGM) is proved to be useful for dose adjustment in patients treated with multiple insulin injection regimens or with continuous subcutaneous insulin infusion. CGM give precise information about glucose variability in type 1 diabetes but are rarely used in type 2 patients. We assessed continuous glucose monitoring systems (CGMs) as control assessment tool in patients with type 2 diabetes receiving different treatment regimens. We studied 85 patients (50 men, 35 women; mean age 43.93 ± 10.87 years, mean disease duration 21.91 ± 6.07 years) with type 2 diabetes (31 receiving non-insulin therapy, 33 treated with pre-mixed insulin, 21 on multiple insulin injections. Continuous glucose monitoring by using iPro^{TM} was performed for seven days and HbA1c was measured at the end of this period. High positive correlation was found between HbA1c (7.46 ± 1.19%) and average glucose level during CGM period (7.45 ± 1.57 mmol/l) ($r=0.73$), AUC above limit ($r=0.75$) and percentage of time spent with glucose above 7.8 mmol/l (38.26 ± 26.38%, $P<0.05$, $r=0.69$). There was similar but negative correlation between HbA1c and percentage of time within the limit 3.9-7.8 mmol/l for all groups (56.07 ± 24.28%, $P<0.05$, $r=-0.63$). Comparing CGM results in different treatment groups we found similar correlations of HbA1c and percentage of time spent within limit (non-insulin treated group 55.65 ± 25.99%, $phi_1=-0.48$; premixed insulin treated group 54.33 ± 24.85%, $phi_2=-0.67$; intensified insulin treatment group 59.62 ± 21.36%, $phi_3=-0.58$). No correlations were found between HbA1c and number of all, positive and negative excursions. These results do not differ for age and gender. We conclude that performing CGM in patients with type 2 diabetes could give more precise information about the overall control nevertheless short time reflected and could present details about glucose deviations and hypoglycemic episodes and thus be useful for current treatment adjustment.

Dopaminergic system and adipose tissue: in vitro effect of cabergoline on white, brown and beige adipogenesis and lipogenesis processes

Mariarosaria Negri[1], Claudia Pivonello[1], Feliciana Amatrudo[1], Roberta Patalano[1], Tatiana Montò[1], Cristina de Angelis[1], Chiara Simeoli[1], Renata Simona Auriemma[1], Annamaria Colao[1,2] & Rosario Pivonello[1,2]
[1]Federico II University, Department of Clinical Medicine and Surgery, Naples, Italy; [2]Federico II University, UNESCO Chair for Health Education and Sustainable Development, Naples, Italy

Adipose tissue is an endocrine organ releasing adipokines and expressing specific markers and intracellular mediators, which regulate whole-body energy by balancing lipid accumulation and utilization through adipogenesis, the differentiation of preadipocytes into mature adipocytes associated with gradual lipid storage, and lipogenesis, the additional lipid accumulation in mature adipocytes. Adipogenesis and lipogenesis, strongly induced by insulin, occur in white adipocytes, specialized in excess energy storage as fat depots, and in brown and beige adipocytes, specialized in energy storage dissipation. Decreasing white and increasing brown and beige adipogenesis and lipogenesis, may represent therapeutic tools for obesity. This study aims at investigating the effects of the dopamine agonist cabergoline (CAB) on white, brown and beige adipogenesis as well as on basal and insulin-induced lipogenesis. At this purpose, CAB (10^{-10} -10^{-6} M) was administered in 3T3L1 preadipocytes induced to differentiate, in order to evaluate its effect on white, brown and beige adipogenesis, and in white, brown and beige mature 3T3L1, in order to evaluate its effect on lipogenesis. Adipogenesis and lipogenesis were investigated measuring lipid accumulation using Oil red O staining. Messenger and protein levels of leptin, adiponectin and PPARγ, as white lipogenesis markers and mediators, and of UCP1, PPARγ and PKA, as brown lipogenesis markers and mediators, were analyzed by RT-qPCR and/or WB. During white adipogenesis, CAB10^{-8} M and 10^{-6} M significantly inhibited lipid accumulation (27-37%; $P<0.05$) and lipogenesis in absence (63-64%; $P<0.001$) and presence (85-51%; $P<0.0001$) of insulin administration, compared to controls, with significant decrease of leptin protein and messenger levels ($P<0.01$), slight increase of adiponectin protein and slight decrease of PPARγ protein. During brown adipogenesis, CAB10^{-10} M-10^{-6} M slightly stimulated lipid accumulation (18-24%) and lipogenesis in presence of insulin (15-30%), compared to controls, with slight increase of UCP1 and PPARγ messenger and PPARγ and PKA protein levels. Finally, during beige adipogenesis, CAB10^{-10} M-10^{-6} M slightly inhibited lipid accumulation (34-38%) and lipogenesis (38-43%), with slight increase of UCP1 and PPARγ messenger levels. In conclusion, the current study demonstrated a novel CAB effect on adipose tissue modulation, defining a pivotal role of dopaminergic system in the obesity pathophysiology.

Is age-related hepatic elevation of endogenous SERM 27-hydroxycholesterol associated with hepatocellular degeneration female-specific? – Results from Rat study

Branka Šošić-Jurjević[1], Ljubiša Jovanović[2], Ljiljana Marina[3], Natasa Ristic[4], Marko Miler[4], Vladimir Ajdžanović[4], Branko Filipović[4] & Dieter Luetjohann[5]

[1]University of Belgrade Institute for Biological Research "Siniša Stanković" National Institute of Republic of Serbia, Citology, Beograd, Serbia; [2]Clinical Center of Serbia, Faculty of Medicine, University of Belgrade, 11000 Belgrade, Serbia, Department of Pathology and Medical Cytology, Beograd, Serbia; [3]Clinical Center of Serbia, Faculty of Medicine, University of Belgrade, 11000 Belgrade, Serbia, Clinic for Endocrinology, Diabetes and Diseases of Metabolism, Beograd, Serbia; [4]Institute for Biological Research "Siniša Stanković" - National Institute of Republic of Serbia, University of Belgrade, Citology, Beograd, Serbia; [5]Institut für Klinische Chemie und Klinische Pharmakologie, Universitätsklinikum Bonn, Sigmund-Freud-Str. 25, D-53127 Bonn, Germany

The cholesterol oxidation product 27-hydroxycholesterol (27OHC) is enzymatically produced from cholesterol by CYP27A1 in an alternative pathway of cholesterol degradation to bile acids. This oxysterol also acts as an endogenous selective estrogen receptor modulator (SERM). In healthy humans its concentration in circulation increases in hypercholesterolemia and with age, and is associated with increased risk of atherosclerosis, cardiovascular diseases and breast cancer. Several drugs with SERM activity used for treatments of breast cancer or osteoporosis have been reported to have sporadic hepatotoxic effects. Women suffer from some liver diseases more commonly (acute liver failure, autoimmune hepatitis, benign liver lesions, or primary biliary cirrhosis). For all of these the incidence increases with advancing age. To the best of our knowledge, there is no information in the literature, clinical or experimental, relating changes in hepatic 27OHC with incidence of liver disease in the context of aging and sex. To address this problem, we examined the effect of age and sex on liver and serum concentrations of 27OHC, as well as the immunostaining pattern of CYP27A1 in the liver of four-month and 24-month-old Wistar rats (experiments were repeated twice with similar results, $n=5$-6 animals/group) using LC MS/MS and immunohistochemistry, respectively. Furthermore, we examined changes in total cholesterol and concentration in liver and serum, liver histopathology, as well as serum concentration of hepatic enzymes, alanine (ALT) and aspartate aminotransferase (AST). The effect of age ($P<0.05$) on increase of serum and hepatic 27OHC was obtained both in males and females ($P<0.05$) and followed the same pattern of age-related total cholesterol increase ($P<0.05$). However, the intrahepatic increase of 27OHC was dramatically more pronounced only in old-aged females ($P<0.0001$). CYP27A1 immunostaining intensity was similar in all experimental groups, being the strongest in the cytoplasm of centrilobular hepatocytes, but the immunopositivity was diffusely spread throughout the liver lobule. Histopathological analysis revealed age-related hepatocellular degeneration (swelling and hydropic degeneration, increased fraction of binuclear hepatocytes and focal fatty changes) only in females. Moreover, age-related elevation of alanine transaminase (ALT) was observed only in female rats ($P<0.01$). In conclusion, the obtained results confirmed age-related female-specific increase of hepatic 27OHC as well as hepatocyte degeneration obsereved only in the liver of rat females. These age-related adaptive changes in cholesterol metabolism may atenuate hepatoprotective estrogen-like effects in the liver.

Ketogenic diet is protective against atherosclerosis development in Apolipoprotein E Knockout Mice

Vincenzo Marzolla[1], Caterina Mammi[1], Alessandra Feraco[1], Stefania Gorini[1], Andrea Armani[1,2] & Massimiliano Caprio[1,2]

[1]IRCCS San Raffaele Roma, Laboratory of Cardiovascular Endocrinology, Rome, Italy; [2]San Raffaele Roma Open University, Department of Human Sciences and Promotion of the Quality of Life, Rome, Italy

Objective

higher aldosterone (aldo) levels are associated with increased risk of cardiovascular ischemic events and mortality. It has been demonstrated that aldo accelerates the development of aterosclerosis in apolipoprotein E knockout mice (ApoE KO). Ketogenic diet (KD) positively impacts several cardiovascular risk factors, yet its effect on atherosclerosis, is elusive. We hypothesize that, KD protects from development of atherosclerotic plaques in ApeE KO mice, a murine model of atherosclerosis.

Methods

eight-week-old male ApoE KO mice were fed an *ad libitum* KD (90.5-fat, 0.4-carbohydrate, 9.1-protein; $n=12$) or a moderate high fat diet (HFD) (42-fat, 42.7-carbohydrate, 15.2-protein; $n=12$) and treated with aldo (6 μg/mouse per day) or vehicle through osmotic mini-pumps. Cholesterol content was comparable in KD and HFD. After 4 weeks of treatment, intraperitoneal glucose tolerance test was performed, and peripheral blood samples were collected and used to quantify beta-hydroxybutyrate (OH-But). At the endpoint, mice were euthanized and their cryosections of embedded aortic root were used to quantify the atherosclerotic plaque size, lipid and collagen content in all experimental groups. Vascular inflammation was assesed in speciments of thoracic aorta trough mRNA analisys of pro-inflammatory (ICAM-1, VCAM-1, IL-6, TNF-α and MCP-1) and anti-inflammatory (Arg-1, RETNLA, CCL5) genes.

Results

in ApoE KO mice treated with aldo, KD determined a significant improvements in glucose tolerance compared to mice fed a HFD without any significant effect on body weight. OH-But levels were always significantly higher in KD-mice than in AD-mice, confirming nutritional ketosis in KD-mice. Histological sections of aortic root showed that aldo treatment determined a significant increase in atherosclerotic plaque size and lipid content in HFD-mice. Such effects were significantly reduced in KD mice, suggesting a positive impact of ketosis in the prevention of atherosclerosis development. Plaque fibrosis, as measured by collagen content, did not differ among treatment groups. Finally, we observed a significant reduction in vascular inflammatory markers in KD-mice, when compared to HFD-mice. In particular, KD determined a significant reduction of gene expression of pro-inflammatory markers (ICAM-1, VCAM-1, IL-6, TNF-α and MCP-1) with the concomitant up-regulation of anti-inflammatory markers (Arg-1, RETNLA, CCL5), compared to AD.

Conclusion

the present study identifies KD as a potential non-pharmacological approach to prevent the development of atherosclerotic disease in subjects with high cardiovascular risk. Indeed, we demonstrated that KD determines decreased vascular inflammation and reduced atherosclerotic lesions in ApoE KO mice.

place of plasma injections rich in autologous platelet in the management of diabetic foot ulcer (preliminary results)

Lionel Stève Kamgain Simeu, Mjabber Amal, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli

Ibn Rochd University Teaching Hospital, Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Casablanca, Morocco

Introduction

Diabetic foot ulcer (DFU) is one of the leading causes of non-traumatic lower extremity amputations worldwide. Conventional treatment is expensive and often requires a long hospital stay, placing a heavy burden on any healthcare system. Using autologous platelet-rich plasma (PRP), which is rich in various growth factors, can approximate the natural healing process.

Objective

Evaluate the place of PRP injections and its interest in the management of DFU.

Material and methodology

Prospective descriptive study including 21 patients hospitalized in the endocrinology department of the Ibn Rochd UTH in Casablanca for DFU, having received PRP injections, from September 2016 to September 2019. We excluded those with positive hepatic or HIV serologies and hemostasis disorders.

Results

The mean age was 56 years (34-75 years). A male predominance with an M/F sex ratio of 1.5. The average duration of diabetes was 13 years (3 to 30 years). The mean HbA1c was 10.9% (8.6-14.9%). The majority (86%) had grade 2 feet according to the TEXAS classification. The patients benefited from 4 to 7 sessions of PRP injections at the rate of one per week. The evolution was marked by good

healing in 92% of patients with budding and epidermization. No incident of blood or infection were noted.
Conclusion
PRP injections offer a promising alternative in the management of DFU. It is less expensive, less invasive, promotes safe and natural healing by reducing healing time. This is a method of the future taking place in the therapeutic arsenal of DFUs.

Impact of teaching communication techniques to family member on quality of life score in patients with T2DM

Bharat Saboo[1], Shweta Saboo[1] & Aniket Inamdar[2]
[1]Prayas Diabetes Center, Indore, India; [2]Samarpan Clinic, Omerga, India

Introduction
Impact of teaching communication techniques to family member on quality of life score in people with T2DM.
Communication holds an important place in Diabetes management. People with diabetes usually have low self esteem. Proper communication with them can help in improving quality of life of people with diabetes. Family plays an integral part in Diabetes management. Benefits of proper communication has long been seen in various studies.
Aim
To see the Impact of teaching communication techniques to family member on quality of life score in people with T2DM.
Method
234 patient with diabetes were selected from Central India. They were divided in two groups of 117 each. Family members of one group were taught about communication techniques (called communication group)along with standard treatment while the second group was treated as such. The patients were surveyed for Quality of life and Depression at 30 days and 90 days. Results were analysed using MS excel.
Results
The Communication Group showed a decrease in Depression and improved quality of life score as compared with routine group. ($P<0.0001$), the communication group also showed better disease control (Target HBA1C <7 % in 72 % vs 43 % in routine group)
Conclusion
Communication is an integral aspect in Diabetes Care and most of the times it's with family members. The family members should be taught proper Communication techniques for better outcomes in terms of quality of life in patients with Diabetes. A guideline should be set in place to make communication a core part of overall Diabetes Management. The family members should be motivated to be a part of communication technique programs to improve their communication.

Injection of epidermal growth factors in the treatment of diabetic foot ulcers

Sara Ragbi, Mjabber Amal, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
Uhc Ibn Rochd, Endocrinology and Metabolic Disorders, Casablanca, Morocco

Introduction
Diabetic foot ulcer (DFU) is one of the major complications of diabetes mellitus. It can be a cause of amputation. A multidisciplinary approach is essential to promote wound healing and decrease amputation rates. Epidermal growth factor (EGF) is used as an adjuvant to close the wound in addition to standard care in diabetic foot ulcers.
Methods
This is a prospective study carried out between February 2019 and April 2021 in the department of endocrinology and metabolic diseases, involving 7 patients admitted for DFU and who received intralesional EGF injections.
Results
The mean age was 51 years (4 men and 3 women). There were patients with type 1 and type 2 diabetes mellitus with a mean duration of 15 years. All the patients had high levels of HbA1c with an average of 8.5%. The ulcers were mainly located on the plantar aspect of the foot, complicated in 4 cases by osteitis, with an evolution ranging from 2 months to 3 years. The standard care included blood glucose regulation, debridement of necrotic tissues, treatment of infections and offloading. The patients received an average of 3 injections of EGF until a complete granulation response was achieved. There was a case of overgranulation causing treatment to be stopped. The average length of stay was 21 days. Complete granulation was achieved in 5 patients, with an average healing time of 65 days.
Conclusion
The intralesional application of EGF is an effective adjuvant treatment in addition to standard care. The clinical evolution of patients treated with intralesional EGF together with its safety make it a promising product to treat DFU.

Diabetes and spontaneous miscarriage

Meriam Dalhoum, Zohra Hadj Ali, Ines Bani, Faika Ben Mami & Yosra Htira
National Institute of Nutrition, Department C, Tunis, Tunisia

Introduction
Early spontaneous miscarriage is common in diabetic women and has an unknown mechanism. This rate of spontaneous miscarriage is directly correlated to the glycemic control at the beginning of pregnancy.
Objective
To assess the frequency of spontaneous miscarriage in women with diabetes.
Patients and Method: This is a retrospective study including 50 diabetic women followed at department C of the National Institute of Nutrition of Tunis.
Results
The average age of our patients was 30 ± 7 years. The average duration of diabetes was 9 ± 7 years. Our population included: 46% type 2 diabetes, 42% type 1 diabetes and 12% gestational diabetes. the mean glycated hemoglobin (HbA1c) was 8.2%. The frequency of spontaneous miscarriage was 34% with a higher incidence in type 2 diabetics:82% vs 18% in type 1 diabetics. Patients with a history of spontaneous miscarriage had less controlled diabetes than others (mean hemoglobin glycated hemoglobin : 8.8% vs 7.9%).
Conclusions
Given the high frequency of spontaneous miscarriage in diabetic women, the practitioner is encouraged to provide adequate management of diabetic women before pregnancy.

Phase angle, a raw bioelectrical impedance analysis (bia) variable, as a prognostic factor for mortality at 90 days in patients with covid-19

Isabel Cornejo-Pareja[1], Isabel M[a] Vegas-Aguilar[1], Jose Manuel Garcia-Almeida[1], Andrea Fernández Valero[1] & Francisco J Tinahones[1]
[1]Department of Endocrinology and Nutrition, Virgen de la Victoria Hospital (IBIMA), Malaga University, Malaga, Spain

Introduction
COVID-19 has taken on pandemic proportions. Phase angle (PhA) and Standardized phase angle (SPhA) have been related to mortality and severity in several diseases.

Objetives: To determine the predictive role of PhA and SPhA on 90 days survival of adults with COVID-19.
Methods
A longitudinal cohort study with 127 consecutive patients diagnosed with COVID-19. We collected PhA, SPhA, body composition (fat mass, fat free mass, hydration) and laboratory markers (CRP, D-dimer or albumin).
Results
COVID-19 patients in the lowest SPhA quartile (Q1) had increased ($P<0.001$) mortality and hospital stay ($P=0.009$). Q1 patients have hyperhydration status ($P<0.001$), decreased nutritional parameters [body mass cell index [BCMI ($P<0.001$)]and increased inflammation biomarkers [CRP ($P<0.001$), albumin ($P<0.001$), D-dimer ($P=0.002$)]. Multivariate analysis (Cox regression) revealed that PhA, adjusted for age, sex, BMI, and comorbidities (diabetes, hypertension, dyslipidaemia or heart disease), were associated ($P<0.001$) with increased mortality. The HR was 2.48 (95% CI, 1.60-3.84, $P< 0.001$). PhA $<3.95°$ was the cut-off for predicting mortality in acute COVID-19 with 93.8% sensitivity and 66.7% specificity. Non-surviving COVID-19 patients had significantly lower PhA and SPhA values ($P<0.001$) and increased hydration ($P<0.001$) compared to surviving patients.
Conclusions
PhA may play a role in assessing mortality risk in COVID-19, independently of age, sex, BMI, and comorbidities. The HR was 2.48 times for each degree that PhA decrease. SPhA quartiles are related to median survival (70 days in Q1 vs. more than 90 days in Q2 and Q3). PhA $<3.95°$ could be considered as a cut-off point for mortality risk prognosis in acute SARS-CoV2 infection.

Disturbances in melatonin, leptin and ghrelin rhythms in women with metabolic syndrome with and without polycystic ovary syndrome

Presiyana Nyagolova[1], Mitko Mitkov[1], Vanya Peneva[2] & Dora Terzieva[2]
[1]Medical University Plovdiv, Endocrinology and Metabolic diseases, Plovdiv, Bulgaria; [2]Medical University Plovdiv, Department of Clinical Laboratory, Plovdiv, Bulgaria

Background
Polycystic ovary syndrome (PCOS) is a highly prevalent heterogeneous disease associated with ovulatory dysfunction and hyperandrogenemia. Recent data support a critical role of neuroendocrine dysfunction and metabolic disturbances in the pathophysiology of the syndrome, including hyperleptinaemia. Accumulating evidence suggests that circadian desynchrony is linked to obesity and metabolic syndrome (MetS). Both prevalence and incidence of the metabolic syndrome is very high in women with PCOS.
Objective
To examine daily fluctuations in serum levels of melatonin, leptin and ghrelin in women with PCOS and MetS
Patients and methods
The study included 12 women with PCOS and MetS and age-and BMI-matched 12 women with MetS without PCOS. The diagnosis PCOS was made according to the Rotterdam criteria. MetS was verified against IDF criteria (2009). Anthropometric measurements and circulating levels of melatonin, leptin and ghrelin at 3AM and 8AM, fasting insulin, fasting blood glucose, cholesterol, triglyceride, high-density lipoprotein (HDL) and low-density lipoprotein (LDL) levels were evaluated. Statistical analyses were performed using SPSS Ver. 26.0. A *P*-value less than 0.05 was considered statistically significant.
Results
Women with PCOS and MetS had significantly higher levels of 8AM leptin ($P=0.02$), fasting insulin ($P=0.05$) and HOMA-IR ($P=0.05$) compared to the patients with MetS only. In both groups we did not find significant difference between day and night melatonin and ghrelin levels. In women with PCOS and MetS we found significant difference between day and night leptin levels ($P=0.37$) while such difference was missing in women with MetS only. In both groups there was preserved cortisol rhythm.
Conclusions
Our results indicate that leptin is increased, but with preserved circadian rhythm in women with PCOS. Circadian misalignment of melatonin and ghrelin rhythms might be associated with metabolic dysregulation in women with PCOS and metabolic syndrome.

Metabolic Syndrome (MetS) Criteria in children with steroid-sensitive Nephrotic syndrome (SSNS) and frequent relapses treated with long-term prednisone therapy (LTPT) vs normal obese children

Ashraf Soliman, Mostafa Elbaba, Noor Hamed, Mona Shaat Dalees, Maya Itani & Fatima Al-Naimi
Hamad Medical Center, Pediatrics, Doha, Qatar

Steroid-associated adverse events (SAAE) include hypertension, hyperglycemia, and diabetes, overweight and obesity and short stature.
Aim
The goal of this study was to assess the occurrence of steroid-associated metabolic and clinical adverse events (SAAE) in patients with NS and frequent relapses treated with long-term prednisone compared to another high-risk group (obese children BMISDS $>$ 2)
Methods
Data of 30 children with SSNS was analysed retrospectively. They received prednisolone only in the standard dose for the initial episode at 2 mg/kg/day for six weeks followed by 1.5 mg/kg on alternate days for six weeks and relapses were treated with 2 mg/kg/day till remission followed by 1.5 mg/kg/day for four weeks. The cumulative dose of steroids over the period of 5 years was calculated for each child. The growth data was recorded along the treatment period. The different metabolic criteria including impaired fasting glucose (IFG), high LDL and cholesterol, lower HD and high blood pressure for age and sex were studied over this period of time and compared with the data for 66 age-matched obese non-nephrotic children.
Results
Comparison between the NS group treated for an average of 5 years with prednisone (cumulative dose$=$125 $+/-$ 28 mg/kg/yr.) and the non-nephrotic obese group showed that short stature (HtSDS $<$ -2), impaired fasting glucose (IFG), high cholesterol, triglycerides (TG) and LDL levels occurred more significantly in the NS group. Hypertension was detected in 28 % of the NS group vs 12.5% in the obese group. (Table)
Conclusion
In children with SSNS and frequent relapses, long-term steroid therapy was associated with higher rate of obesity, short stature as well as the occurrence of different MetS abnormalities including hypertension, dysglycemia, and dyslipidaemias compared to age matched obese children.

Table Metabolic risk factors among NS children on Long-term Prednisone therapy for $>$ 5 years vs age matched obese children.

Variables	NS on Pred $>$5 yr.	Obese 6-12 yr.
Number	30	66
Age	8.9+/-3.8	9.8 +/- 2.5
Overweight and obese	50%	100%*
Short stature HtSDS $<$-2	22%	6%
IFG$>$5.6 mmol/l	35%*	17.8%
LDL $>$ 2.7 mmol/l	77.7%*	8.0%
HDL $<$ 1.03 mmol/l	10%	20.8%
TG $>$1.7 mmol/l	33.3%*	8.0%
Cholesterol $>$ 4.5 mmol/l	80%*	20.8%
Hypertension BP $>$ 95th centile for age and sex	28.1%	12.5%

The action of WAY163909, central selective serotonin receptor, in obese and diabetic Wistar rats

Ivaylo Bogomilov[1], Vesela MIhneva[2], Ivona Daskalova[2], Rumen Nikolov[3] & Nadka Boyadjieva[3]
[1]Military Medical Academy-Sofia/Medical University-Sofia, Endocrinology/Pharmacology, Sofia, Bulgaria; [2]Military Medical Academy-Sofia, Endocrinology, Sofia, Bulgaria; [3]Medical University-Sofia, Pharmacology, Sofia, Bulgaria

Background and aims
Obesity can be cause because of reduction in energy expenditure and /or increased caloric intake. Total calorie intake has increased in recent decades and studies on eating behavior have reported increased intake of foods rich in fats and sugars. Many regulatory pathways for food intake, including those that use serotonin as a neurotransmitter, are affected by obesity or by hypercaloric diets. Summarizing the data known so far, it can be said that reduced serotonergic signaling and low availability of SERT are associated with hyperphagia and obesity. In addition, obesity has increased eating motivation and decreased D2/3 receptor binding, and lower DAT binding can be detected as well. Because of these facts, it is important to know brain serotonin mediation.
Materials and methods
WAY-163909 is a novel 5-hydroxytryptamine (HT)(2C) (serotonin) receptor-selective agonist that we used in our study. We used forty Wistar rats separate in 2 groups-rats with obesity and diabetes and healthy rats (control group). Each of this groups was separated in other 2 - one with daily intraperitoneal injection (i.p.) of WAY-163909 (for 1 mg/kg increasing till 32 mg/kg, 1 mg/kg per day) and one without. In 4 weeks period we were tracking blood glucose level, insulin secretion and rats weight. The differences in the mean values among the groups are greater than would be expected by chance; there is a statistically significant difference ($P = < 0.001$) using SPSS program.
Results
It was shown that after application of WAY-163909, the weight of the rats in diabetic and obese group rats decreased by 55.2% ($P < 0.05$), and by 25.3% ($P < 0.05$) in the control group using and no significant dynamic in the groups without daily intraperitoneal injection of WAY-163909. In the diabetic and obese rats group in which WAY-163909 was applied we had registered reduction of hyperglycemia (blood glucose over 7.0 mmol/l) by 35.4% ($P < 0.05$) compering the results before the start of using WAY-163909, which is greater in the rats which reduce more body weight. The research also shows decreasing of insulin resistance by 42.3 % ($P < 0.05$) in diabetic and obese rats group using WAY-163909.
Conclusion
Using WAY-163909 for treatment of obesity and obesity-induced diabetes in male Wistar rats, WAY-163909 significantly reduces body weightm hyperglycemia and peripheral insulin resistance. In the study was registered reducing of body weight not only in the obese and diabetic rats group, but also in the control group.

The role of endocrine disruptors, obesity, and cytokines in PCOS

Michaela Duskova[1,2], Jana Vítků[1], Lucie Kolátorová[1], Jana Vrbíková[3], Michala Vosátková[3], Josef Včelák[3] & Marketa Šimková[1,4]
[1]Institute of Endocrinology, Department of Steroids and Proteofactors, Praha, Czech Republic; [2]General Teaching Hospital, Third Medical Department – Department of Metabolism and Endocrinology, Praha, Czech Republic; [3]Institute of Endocrinology; [4]University of Chemistry and Technology, Praha, Czech Republic

As genetic and environmental components contribute to the PCOS expression, we compared levels of endocrine disruptors, steroid hormones, cytokines, and metabolic parameters in twenty healthy, nine normal-weight PCOS women, and ten obese PCOS women. Steroid hormones, bisphenols (BPA, BPS, BPF, BPAF) and parabens (methyl-, ethyl-, propyl-, butyl-, benzyl-parabens) were measured by liquid chromatography-tandem mass spectrometry. Differences between the groups were assessed using the Mann-Whitney U test. Spearman correlation coefficients were calculated for the individual parameters relationship. Significantly higher levels of BPA, Anti-Müllerain hormone, lutropine, lutropine/folitropine ratio, testosterone, androstenedione, 7β-OH-epiandrosterone, and cytokines (IL-6, VEGF, PDGF-bb), were found in normal-weight PCOS women compared to controls. In PCOS women concerning the weight, there were no differences in hormonal, but in metabolic levels. Obese PCOS women had significantly higher insulin resistance, fatty-liver index, triglycerides, cytokines (IL-2, IL-13, IFN-γ). In healthy, but not in PCOS, women, there was a positive correlation of BPA with testosterone, SHBG with lutropine, and folitropine, while testosterone negatively correlated with SHBG. In obese women with PCOS, insulin resistance negatively correlated with SHBG and estradiol. No differences were observed in the paraben exposure. Levels of BPA were higher in PCOS women, indicating its role in the etiology. Obesity significantly worsens the symptoms.

MODY 6: To be, or not to be, that is the question

Leonor Lopes[1], Catarina Roque[2], Carlos Bello[1], Maria Clotilde Limbert[1] & João Sequeira Duarte[1]
[1]Hospital Egas Moniz, Endocrinology, Lisboa, Portugal; [2]Hospital Fernando Fonseca, Endocrinology, Lisboa, Portugal

Introduction
Maturity-Onset Diabetes of the Young (MODY) is a rare cause of Diabetes Mellitus (<5%), resulting from autosomal dominant monogenic defects.
NEUROD1 gene is expressed in pancreatic and neuronal cells, being associated with MODY type 6. Mutations in NEUROD1 gene are reported in 20 families worldwide to date. Heterozygous variant c.616C>A, p.(His206Asn) has never been described.
Case Report
The authors report a case of a 38-year-old woman, with normal BMI, medical history of *Hashimoto*'s thyroiditis and family history of presumed Type 2 Diabetes (mother and maternal uncles), as well as pancreatic cancer (maternal grandmother). Patient presented with *de novo* Diabetes: A1C 7.2%, fasting glucose of 146 mg/dl and serum C-peptide 1.8 ng/ml. She did not complain about polydipsia, polyuria, or weight loss. Being a young adult, without classical clinical features of type 1 or type 2 diabetes, and with a strong family history, MODY gene panel was evaluated. An extremely rare mutation on NEUROD1 gene was documented – Heterozygous c.616C>A, p.(His206Asn) variant. Patient's mothers was also a carrier of the same mutation. Medical Genetics found the mutation pathogenicity doubtful and considered its clinical influence uncertain. The peculiarity of the case led to further analytical investigation: antibodies to GAD65 were positive (113.0 U/ml). Glycaemic control was achieved with a low dose of long-acting insulin (12 units glargine). It has been 4 years since the initial diagnosis and patient is metabolically stable (A1c 6.7%). Serum C-peptide was revaluated: 0.4 ng/ml (with fasting glucose of 98 mg/dl). The family is being genetically studied at the time of this report.
Conclusion
Current International guidelines consider the presence of antibodies GAD65 an exclusion factor for MODY's diagnosis. We present a case of a 38 year-old-woman with heterozygous mutation (c616C>A p.(His206Asn)) of the NEUROD1 gene and concomitant antibodies GAD65. Patient had detectable C-peptide at the diagnosis but after 4 years C-peptide is below the normal range. However, glycaemic control was achieved with a single daily dose of long-acting insulin. The most probable diagnosis is a type 1 diabetes with long "honey-moon period" being the genetic mutation in NEUROD1 gene an analytical incidentaloma.
Further genetic evaluation is necessary to define de main cause of metabolic disorder in this patient.

Anxio-depressive disorders in diabetic pregnant women on the circumstances of the COVID 19 pandemic

Sara Charkaoui, Bensbaa Salma, Siham El Aziz, Nassim Essabah Haraj & Asma Chadli
Ibn Rochd University Hospital, Department of Endocrinology, Diabetology and Metabolic Diseases, Casablanca, Morocco

Introduction
The COVID 19 pandemic is causing a considerable degree of fear and concern among the general population. In diabetic pregnant women, this risk is even higher given the physiological and psychological changes that occur during pregnancy.
Goal of the study
To evaluate the prevalence and risk factors for the onset of anxiety-depressive disorders in pregnant women with diabetes during the COVID 19 pandemic in comparison with those followed outside this period.
Materials and methods
Case-control study on diabetic pregnant women followed in the endocrinology department of CHU Ibn Rochd (March 2020 - May 2021), based on the Hamilton anxiety and depression scale Arabic version.
Results
The study included 117 patients with an average age of 30.9 years. 60% had pregestational diabetes.70% were on insulin. Mean HbA1c was 8.7%. 19% had complicated diabetes. 18% reported an unwanted pregnancy. Only 15% of patients had planned their pregnancy. 30% of patients had a history of maternal-fetal complications. 31% had a history of SARS cov 2 infection. 31% of patients thought that the virus is more serious in diabetics and more than 50% had fears about the risk of materofetal transmission and the risk of fetal malformations. Anxiety was objectified in 74% of patients against 65% in controls and depression was found in 45% against 30% in controls. Anxio-depressive disorders were significantly associated with insulin therapy, the presence of maternal-fetal complications and the belief of patients vis-à-vis the virus. Depression was significantly associated with pregestational diabetes. Anxio-depressive disorders were less marked in patients with a history of SARS cov 2 infection.
Conclusion
Our study demonstrated a significant increase in the prevalence of anxiety-depressive disorders in diabetic pregnant women during the COVID 19 pandemic compared to the control group. This is mainly due to the beliefs of the patients vis-à-vis the virus. This justifies the need for screening and management of these disorders in this population during this period.

Type 1 diabetes and autoimmune diseases

Meriam Dalhoum, Zohra Hadj Ali, Ines Bani, Yosra Htira & Faika Ben Mami
National Institute of Nutrition, Department C, Tunis, Tunisia

Introduction
Type 1 diabetes (T1DM) is an autoimmune disease in 90% of cases and is frequently accompanied by other autoimmune diseases.
Objective
To assess the frequency of autoimmune diseases in type 1 diabetics and study the particularities of this association.
Patients and Method
This is a retrospective study including 120 type 1 diabetic patients hospitalized in department C of the National Institute of Nutrition in Tunis.
Results
The mean age of our patients was 30± 12 years with a sex ratio M/F = 0.7. The average duration of diabetes was 12± 8 years. The mean glycated hemoglobin (HbA1c) was 10.3%. The frequency of autoimmune diseases was 20% with a higher incidence in women: 79% vs 21% men. Hypothyroidism topped the list with a frequency of 13.3%. The frequency of hyperthyroidism, celiac disease and Addison's disease was 4.3%, 3.3 % and 1.6% respectively. The frequency of Biermer's disease was the same as that of vitiligo : 0.83%. The following associations were noted: Hypothyroidism and celiac disease with a frequency of 0.83%. Hyperthyroidism and celiac disease with a frequency of 0.83%. Hypothyroidism, celiac disease and Addison's disease with a frequency of 0.83%. Diabetes type 1 preceded dysthyroidism in 85% of cases and other autoimmune diseases elicited in 100% of cases. Patients with associated autoimmune diseases were older (34.4 ± 12 vs. 29.1 ± 13 years; $P = 0.008$) and had older diabetes (14 ± 11 vs. 10 ± 9 years; $P = 0.005$).
Conclsion
The coexistence of autoimmune diseases in the type 1 diabetic patient is not rare, the practitioner is encouraged to screen them at least, as soon as diabetes is discovered and in front of evocative signs.

Deep soft tissue masses as a manifestation of type 2 diabetes

Cristiana Gomes da Costa[1], Francisca Jácome Morgado[2] & Sónia Vale[1,3]
[1]Hospital Santa Maria, Lisbon, Portugal; [2]Centro Hospitalar e Universitário de Coimbra, Coimbra, Portugal; [3]Faculdade de Medicina da Universidade de Lisboa, Lisbon, Portugal

Introduction
Xanthomas are defined as aggregates of lipid-laden histiocytes. They are generally present in superficial soft tissues such as skin and subcutis but can occasionally involve deep soft tissues. Xanthomas are classically associated with hyperlipidemia, that can be primary or secondary to numerous disorders such as diabetes. This case highlights an atypical manifestation of T2D.
Case report
A 61-year-old women was referred to our endocrinology outpatient clinic in July, 2020, due to new-onset diabetes. The patient mentioned weight loss, polyuria, polydipsia and blurred vision for 10 months before diagnosis. Importantly, she mentioned the appearance of several subcutaneous nodules on the buttocks, thighs and forearms 2 months before diagnosis. Her past medical history revealed hypertension controlled with metoprolol. There was no history of alcohol or tobacco use. Laboratory findings showed an elevated fasting blood glucose 444 mg/dl and HbA1c 15.2%, and an altered lipid profile (total cholesterol 249 mg/dl, HDL cholesterol 50 mg/dl, triglycerides 252 mg/dl). Other laboratory findings were unrevealing. On physical examination we outline the presence of multiple firm deep soft tissue masses, with irregular margins and no pain on palpation on the patient's gluteal region, thighs and forearm. She also had thin yellow to orange plaques on the left lower eyelid compatible with xanthelasma. Subsequent ultrasonography of these lesions revealed multiple hypoechogenic and heterogenous expansive lesions, with undefined borders, they were in touch with aponeurosis but did not infiltrate it, the biggest with the diameter of 56 mm in the gluteal region. The x-ray excluded bone involvement. She started glargine 10U/day with self-adjustment of dosage and metformin 500 mg tid. Three months after introduction of anti-diabetic therapy the masses started to reduce in size and after four months, they had totally disappeared. Biopsy was not performed due to the complete involution of masses. Furthermore, HbA1c decreased to 6% and the lipid profile had improved (total cholesterol 190 mg/dl, HDL cholesterol 58 mg/dl, triglycerides 96 mg/dl).
Discussion
Poor glycemic control has a negative impact on lipid profile. We report a unique case where deep soft tissue masses developed in association with newly diagnosed diabetes with spontaneous resolution after institution of anti-diabetic therapy. The fact that the patient had already a xanthelasma and the complete resolution of the nodules with glycemic and lipid profile improvement favours the diagnosis of deep soft tissue xanthomas.

Dylipidemia in type 1 diabetic patients

Ines Bani, Zohra Hadj Ali, Meriam Dalhoum, Yosra Htira & Feika Ben Mami
National Institute of Nutrition of Tunis, Department C, Tunis, Tunisia

Introduction
Dyslipidemia in type 1 diabetic patients is a frequent situation and seems to be a risk factor for the occurrence of degenerative complications. The aim of this study is to evaluate the lipid profile of type 1 diabetic patients and to study the relationship between dyslipedmia and the occurrence of degenerative complications.
Method
This is a retrospective study conducted at the National Nutrition Institute of Tunis including 110 diabetic patients during the year 2021.
Results
The population consists of 45 men and 65 women, with mean age of 30+/- 12 years. The average duration of diabetes was 12 +/- 8 years. The majority of patients had poorly controlled diabetes with a mean HB1AC of 10.3 +/- 2%. Hypertriglyceridemia was present in 25.5% of patients. Moreover, hyper-LDL cholesterol and hypo-HDL cholesterol were noted in 42.7% and 32.4% of patients respectively. A significant association was noted between hypo-HDL cholesterol and diabetic nephropathy ($P = 0.035$), diabetic retinopathy ($P = 0.025$) and diabetic neuropathy ($P = 0.017$). In addition, hper LDL cholesterol was associated with diabetic nephropathy ($P = 0.003$). However, no association was found between hypertriglyceridemia and microangiopathic complications.

Conclusion
Dyslipidemia is common in type 1 diabetes and the lipid profile in type 1 diabetic patients influences the occurrence of degenerative complications of diabetes.

Predictive factors of glycaemic control in type 2 diabetic patients during the COVID-19 crisis

Anis Grassa, Bel Hadj Sliman Chayma, Ameni Terzi, Nadia Khessairi, Meriem Yazidi, Ibtissem Oueslati & Melika Chihaoui
Rabta Hospital, Endocrinology, Tunisia

Introduction
Glycaemic control is still difficult to achieve despite advances in the pharmacotherapy of type 2 diabetes. Moreover, the COVID-19 crisis led to a disruption in medical consultations and in the access to medications. The aim of our study was to identify factors associated with poor glycaemic control in Tunisian type 2 diabetic patients during the COVID-19 crisis.
Methods
This is a cross-sectional study, carried out in December 2021, on type 2 diabetic patients followed up at the outpatient clinic of the department of endocrinology in Rabta University hospital. Three hundred patients with type 2 diabetes mellitus followed up for at least two years were included. Each patient underwent a clinical examination. Data on glycaemic control during 2019 and 2021 were collected from the medical file.
Results
Patients were 117 males and 183 females with a mean age of 61.6±9.7 years (22-91). One or more micro or macrovascular complications were present in 47.3%. Twenty-nine percent were previously infected with COVID-19 and 87% were vaccinated. More than half (52%) had poor socio-economic conditions and 46.7% were unable to buy their medications if unavailable in the public structures. The visits were irregular in one third of the patients, of whom 73.3% took regularly their medication. The mean annual HbA1c in 2021 was 8.2±1.8%. HbA1c was within the personalized targets in 42.7%. Uncontrolled diabetes was positively correlated with disease duration ($P=10^{-3}$), poly-medication ($P=0.031$), poor compliance to treatment ($P=0.002$), and the lack of drugs availability ($P=0.002$) . No correlation was found with the gender ($P=0.805$) or the occurrence of a COVID-19 infection ($P=0.204$). In multivariate analysis, independent risk factors were a duration of the disease longer than 6.5 years (OR=3.83; $P< 10^{-3}$), poor compliance to treatment (OR=2.37, $P=0.029$), and a mean annual HbA1c in 2019 higher than 7% (OR=9.09; $P< 10^{-3}$).
Conclsion
The management of diabetes should be patient-centred and multifactorial. It is therefore necessary to work on socio-economic factors and therapeutic education in order to improve the health status of our patients and limit the early onset of vascular complications.

Assessment of glycaemic control in type 2 diabetic patients before and during the COVID-19 crisis

Chayma Bel Hadj Sliman, Anis Grassa, Ameni Terzi, Nadia Khessairi, Fatma Chaker, Ibtissem Oueslati & Melika Chihaoui
Rabta Hospital, Endocrinology Department, Tunis, Tunisia

Introduction
Chronic hyperglycemia in type 2 diabetic patients is associated with an increased risk of micro and macrovascular complications. Therefore, glycemic control is the cornerstone of its management. The aim of this study was to evaluate glycemic control in patients with type 2 diabetes before and during COVID-19 crisis.
Methods
A cross-sectional study was conducted during December 2021, in the outpatient clinic of the department of endocrinology in Rabta University hospital. The study included 300 patients with type 2 diabetes mellitus followed up for at least two years. Each patient underwent clinical examination and data on glycaemic control during 2019 and 2021 were collected from medical files.
Results
Patients were 117 men (39%) and 183 women (61%), with a mean age of 61.6 ± 9.8 years (22-91). The mean duration of the disease was 9.6±6.1 years (2-35). The main cardiovascular risk factors were smoking (21%), hypertension (56.7%) and dyslipidaemia (57.3%). Eighty-eight percent of the patients were treated with metformin as a monotherapy in one quarter of the cases and in combination with other oral antidiabetic agents, mainly sulfonylurea in 41% or insulin therapy in 35%. The mean number of medical visits per patient was 1.78±0.67 in 2019 and 1.9±0.74 in 2021 ($P=0.005$). A poor compliance with medication during the past three months was noted in 27% of the patients and was explained by a lack of availability of the drugs in 46.7%. Hypoglycemia was reported by 18% of the patients. It occurred more than once a week in one quarter of the cases and it was severe in 9.8% of them. The mean annual HbA1c was 8.1±1.7 % in 2019 and 8.2±1.8 % in 2021 ($P=0.12$). The mean annual fasting blood glucose was 1.71±0.56 g/l in 2019 and 1.79± 0.72 g/l in 2021 ($P=0.22$). Compared to 2019, glycaemic control in 2021 was stable in 36.4%, worsened in 33.6% with an increase in HbA1c of 0.11%, and improved in 30% of the patients.
Conclsion
Glycaemic control was not worsened during the COVID crisis despite the difficulties in the availability of the drugs.

Metabolic emergencies during the month of Ramadan

Lionel Stève Kamgain Simeu, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
Ibn Rochd University Teaching Hospital, Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Morocco

Introduction
Fasting in the month of Ramadan is one of the pillars of Islam. The diabetic subject, whether he practices it or not, if not prepared expose him to acute complications. The objective of our study was to determine the frequency of occurrence of acute complications during the month of Ramadan.
Objectives
To establish the epidemiological profile of diabetics seen in the emergency room during the month of Ramadan. Determine the frequency of occurrence of acute metabolic complications during this month.
Material and methodology
Descriptive observational study, conducted from April 13 to May 12, 2021, including 150 diabetic patients admitted to the emergency room of the Ibn Rochd UTH in Casablanca, for an acute metabolic complication during this sacred month.
Results
The mean age was 44.6 years (18-78). A female predominance with an M/F sex ratio of 2.22. T2DM was the majority (70%), the average duration of diabetes was 12 years (1-20), fasting was practiced by 44% of patients, including 9% of elderly subjects, degenerative complications of diabetes were present in 10% of patients, diabetic retinopathy was predominant (67%). Diabetic ketosis was the main reason for admission (57%), the frequency of hypoglycaemia remained low (2%). The mean HbA1c level was 12.4% (8.2-15.3), 64% of patients were on insulin. Forgetfulness of treatment was found in 51% of patients. Before Ramadan, 52% of T1DM patients and 64% of T2DM patients had not discussed with their healthcare professional, among them 93% of these T1DM patients ($P=0.0015$) and 50% of these T2D patients ($P=0. 07$), presented an acute complication.
Conclsion
Fasting during the month of Ramadan, if authorized in balanced patients, must be interrupted if diabetes is unbalanced. Therapeutic education and appropriate medical care are necessary to avoid acute complications.

Determinants and consequences of nonadherence among patients with type-2-diabetes

Caroline Raun Hansen[1], Helena Zander Wodschouw[1], Hans Perrild[1], Tomas Møller Christensen[1], Torben Jørgensen[2,3] & Mette Zander[1]
[1]Bispebjerg-Frederiksberg Hospital, Department of Endocrinology, Copenhagen NV, Denmark; [2]Bispebjerg-Frederiksberg Hospital, Center for Clinical Research and Prevention, Frederiksberg, Denmark; [3]University of Copenhagen, Copenhagen, Denmark

Objective
To determine the cumulative incidence of nonadherent patients with type-2-diabetes from an outpatient clinic, and to examine determinants and consequences of premature discharge.
Research design and methods
A cohort comprising patients with type-2-diabetes referred to a Diabetes Clinic from 2009-2012 was assessed. Patients were categorized as nonadherent if discharged within two years of referral due to nonattendance and/or nonadherence to medication and control. Medication and biochemical values at baseline and two years later were assessed. Data regarding co-morbidity, mortality and socio-economics were extracted from national registers, and determinants and consequences of nonadherence were assessed.
Results
1072 patients were identified, and of these 1008 met the inclusion criteria. The cumulated incidence of patients classified as nonadherent was 20.3 %. Nonadherent patients were younger at time of type-2-diabetes diagnosis and had poorer glycaemic control at referral and two years later. Both non-western ethnicity and low education were determinants of nonadherence, but the effect of ethnicity became insignificant when adjusting for education, whereas the effect of education was less influenced by ethnicity. Cohabitation had no influence on adherence. Nonadherence was significantly associated with increased mortality also after adjusting for ethnicity and education, whereas the significance disappeared when adjusting for cohabitation.
Conclusions
Significant differences in glycaemic control, socioeconomics, and mortality were found between an adherent and a nonadherent group of type-2-diabetes patients. Low education seemed to be the principal determinant of nonadherence, while living alone was a mediator of increased mortality. To reach nonadherent patients and to reduce their risk of complications and reduced life expectancy, differentiated efforts should be considered.

The importance of hepatocyte STAT5b, glucokinase and ChREBP in GH receptor-mediated regulation of steatosis and de novo lipogenesis is dependent on the nutritional state

Mari C. Vázquez-Borrego[1], Mercedes Del Rio-Moreno[1], Magdalena Wnek[1], Mariyah Mahmood[1], Jose Cordoba-Chacon[1], Michelle Puchowicz[2] & Rhonda Kineman[1,3]
[1]Department of Medicine, Section of Endocrinology, Diabetes, and Metabolism, University of Illinois at Chicago, United States; [2]Department of Pediatrics, Unversity of Tennessee Health Science Center, Memphis, United States; [3]Jesse Brown VA Medical Center, Research and Development Division, Chicago, United States

Fatty liver (steatosis) can progress to non-alcoholic fatty liver disease, increasing the risk of diabetes and cardiovascular disease. Growth hormone (GH) deficiency is associated with steatosis, while raising GH reduces steatosis. To date it remains to be determined how GH mediates this hepato-protective effect. To investigate the hepatocyte-specific actions of GH, a mouse model of adult-onset hepatocyte-specific GH receptor knockdown (aHepGHRkd) was generated by treating adult mice, homozygous for the GHR-floxed allele, with an adeno-associated viral vector expressing a thyroxin-binding globulin promoter driven Cre recombinase (AAV8-TBGp-Cre). Mice treated with an AAV8-TBGp-Null serve as GHR-intact controls. We reported that 7d-post aHepGHRkd, steatosis develops associated with enhanced expression of glucokinase (GCK), ketohexokinase (KHK) and *de novo* lipogenesis (DNL) genes, and increased rate of DNL which was measured by deuterated water labeling. New data demonstrate the aHepGHRkd-mediated alterations in liver phenotype persist under thermoneutral conditions (mice housed at 30C). Also, the increase in cytoplasmic GCK protein (active), but not KHK, occurs just 3d-post aHepGHRkd, suggesting enhanced glycolysis may be an initiating event to drive enhanced DNL, since the expression of KHK is upregulated by carbohydrate response element binding protein (ChREBP), a transcription factor activated by glycolytic metabolites. In fact, in preliminary studies we found that knockdown of hepatocyte ChREBP, in aHepGHRkd mice, prevented the rise in KHK, but did not prevent the rise in GCK or steatosis. Since GHR signals through JAK2/STAT5b to regulate many genes in hepatocytes, we sought to determine if restoration of STAT5b activity in aHepGHRkd would normalize the liver phenotype. To this end, we co-treated a subset of aHepGHRkd mice with an AAV expressing a constitutive active form of STAT5b (AAV8-TBGp-STAT5b^{CA}). Since regulation of hepatic lipid accumulation is dynamically mediated by multiple hormones and substrate availability, we compared the impact of aHepGHRkd, without or with STAT5b^{CA} under multiple nutritional conditions: natural fasting (10h after food withdrawal at 0600h), overnight fasting (16h), or overnight fasting with 6h refeeding. Data collected thus far show hepatocyte STAT5b, in the absence of GHR, can suppress GCK expression/activity, but this is not always associated with a reduction in steatosis or DNL, depending on the nutritional state. These findings imply that the GHR may signal independent of STAT5b to suppress DNL.

Novel panels of tissue microRNAs to diagnose adrenocortical malignancy based on artificial intelligence tools

Peter Turai[1], Zoltán Herold[2], Gábor Nyirö[1], Katalin Borka[3], Tamás Micsik[4], Judit Töke[1], Nikolette Szücs[1], Miklos Toth[1], Attila Patócs[5] & Peter Igaz[1,6]
[1]Semmelweis University, Department of Endocrinology, Department of Internal Medicine and Oncology, Budapest, Hungary; [2]Semmelweis University, Department of Internal Medicine and Oncology, Budapest, Hungary; [3]Semmelweis University, 2 nd Department of Pathology, Budapest, Hungary; [4]Semmelweis University, 1st Department of Pathology and Experimental Cancer Research, Budapest, Hungary; [5]National Institute of Oncology, Department of Molecular Genetics, Budapest, Hungary; [6]Semmelweis University, Deapartment of Endocrinology, Department of Internal Medicine and Oncology, Budapest, Hungary

Adrenocortical tumors are common, occuring in 5-7% of the population. Adrenocortical carcinoma (ACC) is rare (0.7-2/million/year) and it has a poor prognosis with a five-year survival of less than 30% in advanced stages. The histological differentiation of benign and malignant adrenocortical tumors is challenging.
Objectives
To explore the diagnostic utility of multiple microRNAs in various combinations as markers of adrenocortical malignancy by using artificial intelligence methods, based on machine learning and neural networks.
Materials and Methods
63 formalin-fixed, paraffin-embedded (FFPE) adrenocortical tissues were studied. The discovery cohort included 10 adrenocortical adenoma (ACA) and 10 ACC samples. An independent validation cohort encompassed another 21 ACC and 22 ACA samples. 16 microRNAs shown to be differentially expressed based on literature data were included. MicroRNA expression was studied by a 2-step TaqMan RT-qPCR. RNU48 was used as an internal, alongside with cel-miR-39 as an external control. Normalization of microRNAs was performed with the ΔCt method using R package NormqPCR. The order of microRNAs for the grouping of ACA and ACC samples was determined by the random forest classification method. The possibility of automatic classification of samples into ACA or ACC groups was tested by machine learning methods (R packages nnet and caret). Only models with more than 90% classification capability were selected for RT-qPCR validation and subsequent artificial intelligence-based classification. The best performing microRNA combinations (statistical models) were selected by neural network-based, 90-10% random learner-tester cross validation. 24 microRNA models were included in the validation performed in a blind manner.
Results
Hsa-miR-195, *hsa-miR-375, hsa-miR-483_3p, hsa-miR-483_5p* and *hsa-miR-503* were the best 5 microRNAs revealed by random forest algorithm to correctly classify the previously unkown samples. The following three, best performing statistical models were selected out of the former microRNAs: *hsa-miR-195 + hsa-miR-210 + hsa-miR-503*, *hsa-miR-210 + hsa-miR-375 + hsa-miR-503* and *hsa-miR-210 + hsa-miR-483-5p + hsa-miR-503* with sensitivity and specificity of 90.91-90.48; 90.91-90.48 and 90.91-95.24 %, respectively. The diagnostic performance of these three models was clearly superior over that of individual microRNAs.

Conclusion
We have established three microRNA combinations with outstanding diagnostic performance using artificial intelligence-based methods. These biomarker combinations can help histological analysis, and their use in small amount preoperative biopsy samples might also be envisaged.

Diagnostic evaluation of selected granin family proteins and INSM-1 (Insulinoma-associated protein 1) in patients with medullary thyroid carcinoma

Piotr Glinicki[1], Agnieszka Żyłka[2], Joanna Długosińska[2], Magdalena Ostrowska[1], Małgorzata Gietka-Czernel[1], Wojciech Zgliczyński[1] & Marek Dedecjus[2]
[1]Centre of Postgraduate Medical Education, Department of Endocrinology, Warsaw, Poland; [2]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Oncological Endocrinology and Nuclear Medicine, Warsaw, Poland

Introduction
Medullary thyroid carcinoma (MTC) accounts for 3.5-5% of thyroid cancers. The biochemical diagnosis of MTC is based on the determination of concentration of a sensitive and specific biomarker - calcitonin (CT) as well as CEA and procalcitonin (PCT). Neuroendocrine cells have the ability to produce various proteins and neuropeptides (e.g. granin proteins and INSM-1), which are secreted into the circulation with calcitonin and can be measured in the blood as so-called circulating tumor markers.
Purpose
The aim of the study was to assess the usefulness of determining levels of selected granin family proteins and INSM-1 in the diagnosis of patients with medullary thyroid cancer.
Material and methods
34 patients with medullary thyroid carcinoma (MTC) were enrolled in the study. Patients were divided into 2 groups:
1. MTC – active form (7 patients with newly diagnosed MTC and 8 patients with distant metastases (4-15 years after thyroidectomy),
2. MTC – stable form, with no recurrence nor metastases ($n=19$).
Forty healthy individuals were the control group. The following levels were determined in all patients: calcitonin, procalcitonin, CEA, INSM-1, proSAAS, chromogranin B (CgB), chromogranin A (CgA) and derivates peptides: Pancreastatin/chromogranin A (250-301), Serpinin/prepro-chromogranin A (429-454), WE-14/prepro-chromogranin A (342-355) and Catestatin.
Results
In MTC-active patients levels of: CT, CEA, PCT, INSM-1, WE-14, Catestanin and Serpinin were significantly different vs. control group, with higher level in MTC patients. No significant difference was confirmed for CgA, CgB, pro-SAAS and Pancreastatin between MTC-active and the control group. For MTC-stable patients, only CEA, INSM-1 and Serpinin levels were significantly higher compared to the control group. In the group of patients with the active form of MTC, the following indicators of the diagnostic evaluation of the analyzed biomarkers were obtained: CT: 93% sensitivity and 100% specificity (AUC 0.968), PCT: 100% sensitivity and specificity, INSM-1: 100% sensitivity and 95% specificity (AUC 0.997), WE-14: 86.7% sensitivity and 87.5% specificity (AUC 0.922), Catestatin: 80% sensitivity and 85% specificity (AUC 0.899), Serpinin: 53% sensitivity and 95% specificity (AUC 0.764). In the group of MTC-stable form patients, the highest diagnostic usefulness was the determination of INSM-1 level: 57.9% sensitivity and 82.5% specificity (AUC 0.720) and Serpinin: 47.4% sensitivity and 90% specificity (AUC 0.737).
Conclsion
In patients with active MTC, the greatest diagnostic usefulness was found for the determination of CT, PCT and CEA levels as well as of new biomarkers: INSM-1 and selected peptides from the granin family: WE-14, Catestatin and Serpinin.

The transcriptomic and methylomic landscape of POU1F1 pituitary tumors

Gloria Elena Silva Román[1,2], Ma Isabel Salazar[2], Keiko Taniguchi Ponciano[1], Juan Eduardo Peña Martínez[1], Sandra Vela Patiño[1,2], Sergio Andonegui Elguera[1], Erick Gomez Apo[3], Laura Chavez Macias[3,4], Etual Espinosa Cardenas[1], Claudia Ramirez Renteria[1], Aldo Ferreira Hermosillo[1], Ernesto Sosa[5], Moises Mercado[1] & Daniel Marrero-Rodríguez[1]
[1]Unidad de Investigación Medica en Enfermedades Endocrinas, Hospital de Especialidades, Centro Medico Nacional Siglo XXI, Instituto Mexicano del Seguro Social, Mexico City, Mexico; [2]Departamento de Microbiología, Escuela Nacional de Ciencias Biológicas, Instituto Politécnico Nacional, Mexico City, Mexico; [3]Área de Neuropatología, Servicio de Anatomía Patológica, Hospital General de México Dr. Eduardo Liceaga, Mexico City, Mexico; [4]Facultad de Medicina, Universidad Nacional Autónoma de México, Mexico City, Mexico; [5]Servicio de Endocrinología, Hospital de Especialidades, Centro Médico Nacional Siglo XXI, Instituto Mexicano del Seguro Social, Mexico City, Mexico

Pituitary adenomas (PA) are primarily benign lesions with monoclonal origins from the adenohypophyseal cells and represent 10-15% of all intracranial tumors. Tumors derived from POU1F1 cell lineage are GH-, TSH-, and PRL-secreting tumors that cause important syndromes such as acromegaly, hyperthyroidism, and sexual dysfunction, respectively. Surgical resection is the first line of treatment; the secondary treatment is pharmacological; despite having targets pharmacological in tumors derived of POU1F1 cell lineage, a high percentage of patient's present resistance to pharmacotherapy over time. The molecular alterations continue unclearly understood. We performed global transcriptome and methylome profiling in six non-tumoral pituitary glands and sixteen POU1F1 tumors distributed as follows ten GH-, four TSH- and two PRL-tumors identifying differentially expressed genes regulated by methylation, miRNA-mRNA regulation, and pathway alterations. Our results showed distinctive transcriptome and methylome profiles segregating control glands from tumor samples. The transcriptomic analysis further revealed better segregation clusters according to the hormone-secreting tumor. We identified up-regulated coding genes such as *DGKG*, *GRM5,* and *GPR173* common to the three tumors derived from the POU1F1 lineage. Interestingly, in each tumor identified up-regulated coding and non-coding genes such as *CDKA5R1*, *MET*, *GRIN3A* and *miR4771-1* in PRL-; *CHKA*, *TMEM233, miR95, LINC01347* and *LINC01524* in GH-; *NTRK3*, *GRIK4*, *miR4510, miR3925* and *LINC00662* in TSH-secreting tumors, that could serve for future specific targets for molecular therapy. In addition, inside up-regulated genes we also identified hypomethylated status genes such as *DGKG*, *miR590*, *miR4510*, *LINC00662*, *LINC01000*, *LINC01347*, *LINC01524*; DNA hypomethylation in CPG islands in these genes potentially participates in up-regulated gene expression. miRNA-target gene found an interaction between *miR590* with *ANXA1*, *S100A10*, *YAP1*, *STAT3*, *ATP13A3*, *PTPN14*, *PCDG11X* that also were identified down-regulated in our transcriptomic analysis. Pathway analysis revealed alterations in glycerophospholipids, phospholipase, and calcium signaling pathways. Overall, these results indicate potential molecular markers that could become specific targets for developing novel therapies.

Hirsutism as the first manifestation of a mesonephric-like adenocarcinoma of the ovary: the first case with positive androgen receptors

Iciar Martín Timón, Beatriz Ugalde-Abiega, Mikaela Zubillaga, Inmaculada Moreno-Ruiz, Isabel Huguet, Olalla Meizoso-Pita, Vanessa Triviño Yannuzzi & Cristina Sevillano-Collantes
Hospital Universitario Infanta Leonor, Endocrinology, Madrid, Spain

Mesonephric adenocarcinoma (MA) is an uncommon gynecologic tumor that are thought to arise from embryonal remnants of the mesonephric ducts, also known as Wolffian ducts. Mesonephric-like adenocarcinoma (MLA), despite absence of Wolffian origin, have similar morphology and immunophenotype and exhibit molecular aberrations like MA. These tumors are generally negative for estrogen and progesterone receptor.

Case Report

An 83-year-old Spanish female was referred to our outpatient clinic of endocrinology to study hirsutism. She had a history of 4 uncomplicated pregnancies and experienced menopause at age 42 years. She had not taken hormone replacement therapy and she didn't experience uterine bleeding. A drug history excluded anabolic steroid use or exposure to exogenous androgens. In the anamnesis she referred a recent-onset hirsutism, less than 3 months, without signs of virilization and constitutional syndrome with asthenia and anorexia. Ferriman-Gallwey score was not calculable by depilation of facial and body hair; it was only visible the presence of excess terminal hair growth in the abdomen. She had no stries. Laboratory testing revealed the following levels: total testosterone 4.46 ng/ml (normal range, <0.25), androstenedione >10 ng/ml (normal range, 0.3-3.3), 17-hydroxyprogesterone 17.80 ng/ml, dehydroepiandrosterone sulfate (DHEA-S) 183 mg/dl. Abdominopelvic CT revealed two tumors in the pelvis of 11.5x9 cm and 8.5x5.5 cm. The largest one had necrotic degeneration. No significant adenopathies where shown and adrenal glands were normal. A laparoscopic bilateral salpingo-oophorectomy was performed. Histopathology revealed two tumors of 13x11x7 cm, of 851 gr of weight, and another one of 9x8x2 cm. The first one was solid with gray-white solid areas associated with areas of necrosis with admixture of growth patterns (ductal and tubular), as well as intraluminal eosinophilic colloid-like material resembling mesonephric remnants, and atypical nuclear cells. No evidence of mesonephric remnants or endometriosis were observed. The other one was a fibrous fragment which included the other ovary and fallopian tube. There was no neoplastic infiltration of other tissues, and the peritoneal fluid was positive for malignancy. By immunohistochemistry, tumor cells were positive for GATA3, CD10 and androgen receptor and negative for calretinin, PAX8, estrogen and progesterone receptors, TTF1 and CDX2. The final diagnosis was MLA of the ovary pT2aNx (TNM, 8^a edic), FIGO IIA. After the surgery, testosterone level was <0.20, androstenedione <0.3 ng/ml, 17-hydroxyprogesterone 0.3 ng/ml and DHEAS 34.3 mg/dl.

Conclusion

Here we describe the first case of mesonephric-like adenocarcinoma of the ovary with positive androgen receptors

Introduction

Sphingosine-1-phosphate lyase (SGPL1) catalyses the final step in sphingolipid metabolism, irreversibly degrading the lipid signalling molecule sphingosine-1-phosphate (S1P). The relative abundance of S1P compared to its precursors sphingosine and ceramide finely tunes signal transduction for a wide range of cellular pathways including proliferation, apoptosis, migration and calcium handling. Loss-of-function mutations in SGPL1 cause a spectrum of disorders, including primary adrenal insufficiency (PAI). Adrenocortical carcinomas (ACCs) are invasive tumours arising in the adrenal cortex, and steroidogenic tumours are associated with worse prognostic outcomes. Given that loss of SGPL1 expression causes PAI, we hypothesised increased SGPL1 expression might increase steroidogenesis and therefore be linked to increase disease severity in ACC.

Methods

We analysed two ACC cohorts with survival data and corresponding RNA-seq/Microarray transcriptomic data, focusing on SGPL1 and other genes in the sphingolipid pathway. *In vitro,* we generated isogenic SGPL1-knockout and stable SGPL1-overexpressing H295R adrenocortical cells to better analyse the role of SGPL1 in cell signalling in ACCs. To investigate the effect of these perturbations on cell signalling and function we conducted assays for proliferation, migration, lipidomics, calcium signalling, apoptosis, autophagy, metabolism and gene/protein expression.

Results

We found increased *SGPL1* expression correlated with reduced patient survival in two ACC cohorts, and a correlation in SGPL1 and Ki67 expression in a small cohort of ACC tissue samples. We also found a similar correlation in patient survival and sphingosine-1 kinase expression and the opposite correlation with patient survival and sphingosine-1-phosphatase expression. We noticed a marked increase in proliferation in SGPL1-overexpressing cells and a concordant decrease in proliferation in knockout cells. Similarly, overexpressing cells migrated faster while knockout cells were slower. SGPL1 overexpression significantly reduced levels of pro-apoptotic ceramides, although no reduction in apoptosis was observed. RNA-seq revealed a global increase in the expression of genes in the electron transport chain in overexpressing cells, correlating with increased aerobic respiration and glycolysis in these cells. Furthermore, the opposite phenotype was seen in cells lacking SGPL1. We subsequently found the increased proliferation is linked to metabolic substrate availability. We therefore propose that SGPL1-overexpressing ACC tumours reduce patient survival by increasing anabolism and energy availability for growth and invasion.

Conclusions

SGPL1 expression correlates with growth and migration rates in H295R cells, with knockout reducing steroidogenic capacity and overexpression increasing metabolism.

Ultrasound and cytological features of thyroid nodules with aggressive behavior: from histology to clinic

Daniele Sgrò[1], Giuseppe Greco[2], Alessandro Brancatella[2], Nicola Viola[2], Mauro Casula[2], Liborio Torregrossa[2], Teresa Rago[2], Ferruccio Santini[2] & Francesco Latrofa[2]
[1]University of Pisa, Section of Endocrinology and Metabolic Disease, Department of Clinical and Experimental Medicine, Pisa, Italy; [2]University of Pisa, Section of Endocrinology and Metabolic Disease, Department of Clinical and Experimental Medicine, Pisa, Italy

Fine-Needle Aspiration Biopsy (FNAB) is the recommended diagnostic tool for differentiating malignant from benign thyroid nodules and provides indication for surgical decisions. According to the Italian system, thyroid nodules are classified as TIR 1/1C, TIR 2, TIR 3A, TIR3B, TIR4 or TIR5, which correspond to Thy I, Thy II, Thy III, Thy IV, Thy V and Thy VI categories of the Bethesda system. TIR 3 identifies the indeterminate nodules. Surgery is usually recommended for TIR 3B, TIR 4 and TIR 5 nodules. Among papillary thyroid carcinomas (PTC), the classic and follicular (CV-PTC and FV-PTC) are characterized by a good prognosis and require a less aggressive treatment, while the tall cell (TC-PTC) and the solid variants (SV-PTC) and others rarer (columnar, hobnail and diffuse sclerosing variants) have a worse prognosis. In addition, thyroid ultrasound often identifies thyroid nodules <1 cm, which are usually characterized by an indolent behavior and active surveillance may be advised. We aimed at identifying which ultrasound and cytological features enable to recognize, among TIR4-5 nodules, the aggressive variants and, among TIR3B nodules, the malignant ones. To this purpose we retrospectively analyzed the histopathological records of 1117 patients (for a total of 1668 nodules, 650 malignant) who underwent surgery in 2017 and who had previously undergone FNAB and thyroid ultrasound (available for 390 nodules). Of the 566 PTC, 18.7% were TIR3A, 20.7% TIR 3B and 51.6% TIR4-5, while of 50 FTC 42.0% were TIR3A, 42.0% TIR3B and 6.0% TIR4-5. Of

the 11 PDTC 54.5% had been diagnosed as TIR 3B. Of the 249 classic variant of PTC, 0.8% had resulted TIR3A, 14.1% TIR3B and 79.9% TIR4-5. Among 49 TC-PTC, none had resulted TIR3A, 2% had been diagnosed as TIR3B and 95.9% as TIR4-5. Of the 219 FV-PTC 42.0% had resulted TIR3A, 39.7% TIR3B and 12.3% TIR4-5. Among 34 SV-PTC, 32.4% had been diagnosed as TIR3A, 41.2% TIR3B and 0.6% TIR4-5. At ultrasound, blurred margins were the only feature associated with malignancy ($P=0.034$) in TIR3B category. The coexistence of hypoechogenicity and blurred margins in absence of microcalcifications were more common in the TC (7/28) compared to the CV (10/120) of PTC ($P=0.021$). In conclusion ultrasound helps to identify, among TIR4 and TIR5 nodules, the aggressive variants, and among TIR3B, the malignant ones, and therefore to choose the extent of surgical treatment and, when <1 cm, to confidently advise active surveillance.

Role of DKK1 in growth and migration of prostate cancer cells

Letizia Rinella[1], Mara Compagno[2], Gloria Fiorentino[1], Nicoletta Fortunati[3], Emanuela Arvat[1,3] & Maria Graziella Catalano[1]
[1]University of Turin, Department of Medical Sciences, Turin, Italy; [2]Fondazione Edo ed Elvo Tempia, Molecular Oncology Laboratory, Biella, Italy; [3]AO Città della Salute e della Scienza di Torino, Oncological Endocrinology, Turin, Italy

Androgen deprivation therapy is the choice treatment of metastatic prostatic tumors. Unfortunately, very often, resistance occurs and chemotherapy is needed. Results are however disappointing with frequent side effects. Therefore, new therapeutic approaches for metastatic and advanced prostate cancer are necessary. DKK1, an inhibitor of the Wnt signaling pathway, is increased in different types of cancer. In prostate cancer patients with bone metastases, an increase of DKK1 is observed both in the serum and in the prostate tissue, suggesting that DKK1 might be considered as a new molecular target in the metastatic prostate cancer therapy. The aim of this study was to evaluate the role of DKK1 in growth and migration of prostate cancer cell lines (PC3 and DU145), expressing high levels of DKK1. To this end, we carried out DKK1 gene silencing and knockout in PC3 and DU145 cells. Silencing was obtained by specific siRNA to DKK1; permanent knockdown was performed using a CRISPR/CAS9 system. Real-Time PCR, Western Blotting analysis, and secretion levels by ELISA confirmed DKK1 silencing and knockout, respectively. The effects of silencing (PC3-siRNA and DU145-siRNA) and knockdown (PC3-KO and DU145-KO) were evaluated in terms of cell growth by colorimetric WST-1 test and cell migration by transwell migration assay. A significant reduction of mRNA, protein levels and secretion of DKK1 was observed in both cell lines where DKK1 was silenced or knocked-down. Functionally, DKK1 inhibition resulted in a reduction of cell growth and migration. In conclusion, our data support a key role of DKK1 in the growth and migration of prostate cancer cells. Based on our study, DKK1 may represent a specific target for a new therapy intended to specifically block its function in metastatic and advanced prostate cancer.

Splicing machinery dysregulation in rare neuroendocrine tumors: pheochromocytomas and paragangliomas

María Trinidad Moreno Montilla[1,2,3], Ricardo Blázquez Encinas Rey[1,2,3], Ángel Mario Martínez Montes[4], Víctor García Vioque[1,2,3], Emilia Alors-Pérez[1,2,3], Federica Mangili[1,2,3,5], Antonio Agraz-Doblas[1,2,3], Mercedes Robledo[4,6], Justo P. Castaño[1,2,3,7] & Alejandro Ibañez Costa[1,2,3]
[1]Instituto Maimónides de Investigación Biomédica de Córdoba, Córdoba, Spain; [2]University of Cordoba, Department of Cell Biology, Physiology and Immunology, University of Cordoba, Córdoba, Spain; [3]Hospital Universitario Reina Sofia, Córdoba, Spain; [4]National Cancer Research Center, Madrid, Spain; [5]University of Milan, Department of Clinical Sciences and Community Health, Milano, Italy; [6]Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Madrid, Spain; [7]CIBER Physiopathology of Obesity and Nutrition (CIBERobn), Madrid, Spain

Pheochromocytomas and paragangliomas (PPGL) are commonly benign catecholamine-producing neuroendocrine tumors (NETs); however, up to 25 % of patients develop distant metastases or aggressive behavior. The current classification of PPGL comprises pseudohypoxia-profile, MAPK-pathway alteration, and Wnt-pathway dysregulation clusters according to their genomic characterization. However, to date, there are no biomarkers to help stratify patients based on their prognosis. Alternative splicing is an emerging cancer feature that has been linked to a more aggressive phenotype in a variety of neoplasms, including NETs. In this context, we have recently discovered alterations in the splicing machinery in other NETs, such as pancreatic and lung NETs. The splicing process has not been studied in detail before in PPGL, but there are reasons to expect that it could be altered. Thus, the aim of this study was to assess the profile of the splicing machinery in PPGL and study its potential relationship with clinical-molecular features. To this end, we studied the expression of 313 splicing-related genes in the data available in the TCGA dataset, which includes 151 patients (29 paragangliomas, PGL, and 122 pheochromocytomas, PCC). Most splicing-related genes were found to be similar in PCC and PGL, but 16 genes, including *RBM22*, *CELF4*, and *PABPC1*, exhibited significant differences. Interestingly, a detailed analysis among the three genomic clusters revealed considerable differences, standing out 143 of 313 splicing-related genes, which were found over- or under-expressed. It is also worth noting that just the expression of *CELF4* and *API5* was sufficient to clearly distinguish the three clusters: low expression of both genes in pseudohypoxia cluster, high in kinase signaling, and *CELF4* high and *API5* low expression in Wnt-altered cluster. Furthermore, 27 genes were shown to be associated with aggressive PCC; in particular, categorizing PCC samples based on high or low expression of specific genes, such as *LSM4* or *SMC1A*, allowed us to predict aggressive/metastatic behavior. In addition, aggressive PGLs had differential expression of 25 genes. Altogether, our findings show that the splicing machinery is disrupted in PPGL, which encourage us to explore the splicing process in a larger cohort of PPGL samples and investigate the functional importance of these splicing-related genes *in vitro*.

Keywords: pheochromocytoma, paraganglioma, metastasis, splicing dysregulation, splicing machinery. This work was supported by MICINN (PID2019-105201RB-I00), Beca GETNE 2019, Fundación Eugenio Rodríguez Pascual, ISCIII (CD19/00255).

The impact of pregnancy on disease outcome in patients with persistent differentiated thyroid carcinoma

Noemi Giancola[1], Carla Colombo[1,2], Simone De Leo[1], Matteo Trevisan[1], Luca Persani[1,3] & Laura Fugazzola[1,2]
[1]Division of Endocrine and Metabolic Diseases, Istituto Auxologico Italiano IRCCS, Milan, Italy; [2], Department of Pathophysiology and Transplantation, University of Milan, Milan, Italy; [3], Department of Medical Biotechnology and Translational Medicine, University of Milan, Milan, Italy

Background
Pregnancy does not cause differentiated thyroid cancer (DTC) recurrence in patients without structural or biochemical evidence of disease at the time of conception. However, data regarding pregnancy's impact in patients with persistent DTC before conception are still controversial.
Aim
The aim of the study was to determine whether pregnancy could significantly influence the outcome in DTC patients in persistence before pregnancy, but with a biochemical and structural stable disease.
Methods
This was a retrospective evaluation of all women followed for DTC at a tertiary Italian thyroid cancer center who had a pregnancy after initial treatments between 2003 and 2020. Subjects included were required to have biochemical and/or structural persistence within 12 months before pregnancy.
Results
we enrolled 8 patients with papillary thyroid carcinoma (PTC) with a mean age at diagnosis of 27.6 years and a mean time between PTC diagnosis and pregnancy of 60 months. Among the 7 patients with structural disease, five patients had lung metastases, two lymph node metastases and one patient biochemical persistence. Patients were treated with total thyroidectomy, lymphadenectomy and radioactive iodine ablation (RAI). According to 8 th edition of the American Joint Commission on Cancer (AJCC) and 2015 American Thyroid Association (ATA) 2015 guidelines, 75% of women had AJCC stage I and intermediate

risk of recurrence and 25% had AJCC stage II and high risk of recurrence. Evaluation of Dynamic Risk Stratification (DRS) during the 24 months of follow-up showed 88% patients with structural incomplete response and 12% with a biochemical incomplete response. During a mean follow-up of 153 months, none of the patients showed biochemical and radiological progression of disease during pregnancy or within 6 months of delivery and no further treatments were required. One patient with lung metastases had an increase of thyroglobulin during pregnancy, which returned to the pre-pregnancy levels after delivery.
Conclusions
Our data demonstrate that pregnancy is not associated with significant progression in patients with stable persistent DTC before conception. However, further studies are needed to verify the effect of pregnancy on the outcome of patients with persistent and progressive disease.

Origins of progesterone in male mice

Hannah Colldén[1], Malin Hagberg Thulin[1], Andreas Landin[2], Anna-Karin Norlén[3], Henrik Ryberg[3], Jianyao Wu[1], Karin L Gustafsson[1], Louise Grahnemo[1], Karin Nilsson[1], Klara Sjögren[1], Matti Poutanen[1], Liesbeth Vandenput[1] & Claes Ohlsson[1]
[1]Gothenburg University, Sahlgrenska Academy, Insitute of Medicine, Gothenburg, Sweden; [2]Sahlgrenska University Hospital, Clinical Pharmacology, Gothenburg, Sweden; [3]Sahlgrenska University Hospital, Clinical Chemistry, Gothenburg, Sweden

The role of progesterone in male physiology is mainly unknown. We recently observed that progesterone was the most abundant sex hormone in orchiectomized (ORX) mice with most of it stored in white adipose tissue (WAT) (1). The aim of the present study was to use a sensitive and validated gas chromatography/tandem mass spectroscopy method to determine the origins of progesterone in male mice. Tissue levels of progesterone were high in adrenals of male mice, indicating that male progesterone may be predominantly adrenal-derived. To determine if progesterone only originates from the adrenals in males, we compared WAT levels of progesterone in ORX + adrenalectomized (ADX) and intact mice. Surprisingly, combined orchiectomy and adrenalectomy did not reduce progesterone levels in WAT (mean ± SEM, 1.638 ± 239 pg/g vs. 1.871 ± 124 pg/g, non-significant). In both groups, we also observed high levels of progesterone along the gastrointestinal tract including the gastric contents. To evaluate food as a potential progesterone source, we analyzed progesterone levels in 20 types of mouse chow and found varying but substantial levels in all tested types (2.319-17.702 pg/g). To identify main sources of food-derived progesterone, we analyzed progesterone levels in several food items, reveling no/low levels in non-animal-derived food items, medium levels in meat and very high levels in dairy products such as cream (123.162 ± 1.282 pg/g). To functionally test if orally ingested progesterone could contribute to tissue levels, we administered isotope-labeled progesterone or vehicle by oral gavage for 10 days to adult ORX + ADX male mice, and data indicated some uptake of labeled progesterone into the WAT. Interestingly, a recent metagenomic study showed an association between gut microbiota (GM) functional traits and circulating progesterone levels in humans (2). Accordingly, we determined the impact of the GM for progesterone levels in WAT and found that germ-free male mice, completely lacking GM, had substantially increased progesterone levels in WAT compared with conventionally raised mice (+ 132% ± 25%; $P<0.001$). In conclusion, in the absence of adrenal-derived progesterone in male mice progesterone levels are maintained by an alternative progesterone source. We propose that food-derived progesterone may be taken up and maintain close to normal progesterone levels in ORX + ADX male mice. Furthermore, GM composition may regulate this uptake of progesterone.

Neuropeptide Y (NPY) and Human cocaine- and amphetamine-regulated transcript (CART) in patients with adrenal pheochromocytoma

Piotr Glinicki, Magdalena Ostrowska, Lucyna Papierska, Alicja Szatko & Wojciech Zgliczyński
Centre of Postgraduate Medical Education, Department of Endocrinology, Warsaw, Poland

Introduction
Pheochromocytoma is a rare tumor that develops from chromaffin cells of the adrenal medulla. In about 90% of cases, it is a benign tumor. Along with catecholamines, neuroendocrine cells of the adrenal medulla have the ability to produce various proteins and neuropeptides and secrete them into the blood. Among the known biologically active substances are: neuropeptide Y and human cocaine- and amphetamine-regulated transcript (CART).
Purpose
The aim of the study was to assess the usefulness of the determination of levels of neuropeptides: neuropeptide Y and CART in the diagnosis of patients with adrenal pheochromocytoma.
Material and methods
Patients were divided into 4 groups:
1. Patients with pheochromocytoma ($n=51$),
2. Patients with adrenal incidentaloma ($n=23$),
3. Patients with primary arterial hypertension ($n=20$),
4. Control group – healthy volunteers ($n=52$).
The following biochemical determinations were performed in all patients: plasma levels of metanephrine and normetanephrine, concentration of chromogranin A (CgA), neuropeptide Y (NPY) and human cocaine- and amphetamine-regulated transcript (CART). Biochemical determinations were made using the LC-MS/MS technique and immunochemical techniques (IRMA, ELISA) were used.
Results
Concentrations of the analyzed biomarkers: CgA, NPY and CART were significantly higher ($P<0.001$) compared to control groups (adenoma, primary hypertension and healthy subjects). Sensitivity, specificity and AUC indices of the analyzed biomarkers: CgA, NPY and CART were compared in the group of patients with pheochromocytoma vs. control groups: adenoma, primary hypertension and healthy subjects. Pheochromocytoma vs. adenoma: CgA: 84% sensitivity and 96% specificity (AUC 0.932); NPY: 80% sensitivity and 78% specificity (AUC 0.808) and CART: 43% sensitivity and 100% specificity (AUC 0.768). Pheochromocytoma vs. primary hypertension: CgA: 78% sensitivity and 100% specificity (AUC 0.945); NPY: 47% sensitivity and 100 specificity (AUC 0.615) and CART: 72% sensitivity and 85% specificity (AUC 0.797). Pheochromocytoma vs. healthy subjects (blood donors): CgA: 84% sensitivity and 98% specificity (AUC 0.923); NPY: 90% sensitivity and 86% specificity (AUC 0.897) and CART: 60% sensitivity and 49% specificity (AUC 0.403).
Conclsion
Among the analyzed biomarkers, CgA concentration determination presented the highest discriminant value between patients with pheochromocytoma and other study groups. Neuropeptide Y showed a high specificity between the analyzed groups, especially in the differential diagnosis of patients with adenoma and patients with essential hypertension.

Somatostatin receptor splicing variant SST5TMD4 overexpression in glioblastoma is associated to poor survival, increased aggressiveness features and somatostatin analogs resistance

Jesus Perez Gomez[1,2,3,4], Antonio C. Fuentes-Fayos[1,2,3,4], Miguel E. G-Garcia[1,2,3,4], Annabel Peel[5], Cristóbal Blanco Acevedo[1,2,6], Juan Solivera Vela[1,2,6], Alejandro Ibáñez Costa[1,2,3,4], Manuel David Gahete Ortiz[1,2,3,4], Justo P. Castaño[1,2,3,4] & Raúl M. Luque[1,2,3,4]

Glioblastoma (GBM; grade IV astrocytoma) is the one of the most malignant and lethal endocrine-related cancers worldwide. Current standard treatment consists of surgery followed by radiotherapy and/or chemotherapy; however, this is only a palliative approach with a mean post-operative survival of scarcely ~12-15 months. Therefore, the identification of novel therapeutic targets to treat this devastating pathology is urgently needed. In this context, the truncated splicing-variant of the somatostatin receptor subtype 5 (SST_5TMD4), which is produced

by aberrant alternative splicing, has been demonstrated to be overexpressed and associated with increased aggressiveness features in several endocrine-related cancers/tumors. However, the presence, functional role, and associated molecular mechanisms of SST_5TMD4 in GBM have not been yet explored. Therefore, we performed herein a comprehensive analysis to characterize the expression and pathophysiological role of SST_5TMD4 in human GBM. We demonstrated that SST_5TMD4 was significantly overexpressed (at mRNA and protein levels) in human GBM tissues ($n=47$) compared to non-tumor brain tissues (control; $n=15$) and grade III-astrocytoma patients ($n=9$). Remarkably, SST_5TMD4 expression was significantly associated with poor overall survival and recurrent tumors in GBM patients. Moreover, *in vitro* SST_5TMD4 overexpression (by specific plasmid) increased, whereas SST_5TMD4 silencing (by specific siRNA) decreased, key malignant features (i.e., proliferation and migration capacity) of GBM cells (U-87 MG/U-118 MG models). Furthermore, SST_5TMD4 overexpression in GBM cells altered the activity of multiple key signaling-pathways associated with tumor aggressiveness and progression (AKT, JAK-STAT, NF-κB and TGFβ routes), and its silencing sensitized GBM cells to the antitumor effect of pasireotide (a somatostatin analog). Altogether, these results demonstrated that SST_5TMD4 is overexpressed and associated with enhanced malignancy features in human GBMs and revealed its potential utility as a novel and useful diagnostic and prognostic biomarker and as a potential target in the future development of therapeutic approaches in patients with this devastating endocrine-related cancer, offering a clinically relevant opportunity that should be tested for use in humans.

Rapidly progressive cases of ectopic adrenocorticotropic hormone syndrome

Lucía González Gracia, Gema López Gallardo, Bothayna Oulad Ahmed, Elena Dios Fuentes, Luis Beltrán Romero & Alfonso Soto-Moreno
Virgen del Rocío University Hospital, Sevilla, Spain

Introduction
Adrenocorticotropic hormone (ACTH)-dependent Cushing's syndrome (CS) secondary to an ectopic source is an uncommon condition, accounting for 4-5% of all cases of CS and between 9-18% of cases of ACTH-dependent CS. Although numerous malignancies have been associated with ectopic ACTH syndrome (EAS), lung neuroendocrine tumours (NETs) are the most common. Refractory hypokalemia can be the presenting feature in EAS and is seen in up to 80% of cases. We present two cases which first presented with hypokalemia, refractory to treatment with potassium supplementation and spironolactone.
Cases reports

Table 1

Gender:	Male	Female
Age: (years)	62	56
Clinical presentation	- Hypertension - Newly diagnosed hyperglycaemia - Hyperpigmentation - Peripheral edema	- Constitutional syndrome - Newly diagnosed hypertension and hyperglycaemia - Proximal myopathy - Peripheral edema
Biochemical parameters	Glucose 187 mg/dl K^+ 2.5 mEq/l (3.5 – 5)	Glucose 150 mg/dl K^+ 2.2 mEq/l (3.5 – 5) pH 7.56; $HCO3^-$ 49.1 mEq/l
Hormone parameters	UFC 14219.7 mg/24 h (35 – 135) ACTH > 1500 pg/ml (3.6 – 60.5)	UFC 1268 mg/24 h (35 – 135) ACTH 276.9 pg/ml (3.6 – 60.5)
Tumor localization	Ileum	Lung
Tumour size	32 mm	17 mm
Histopathology	Large-cell neuroendocrine carcinoma	Small-cell neuroendocrine carcinoma
Immunohistochemistry	Chromogranin and synaptophysin positive. ACTH negative	Chromogranin, synaptophysin, CD56 and TTF1 positive. ACTH negative
Ki-67	70-80%	90%
Metastasis	+	+
Treatment of hypercortisolism	Ketoconazole + somatostatin analogs	Ketoconazole
Outcome	Deceased	Deceased
Survival from time of diagnosis	19 days	12 days

UFC: 24 h-urinary free cortisol; Chromogranin, synaptophysin and CD 56: markers of neuroendocrine differentiation. TTF-1: primary site marker (lung and thyroid)

Conclusions
We present two cases of ectopic ACTH syndrome similar in their clinical presentation (newly diagnosed hyperglycaemia and hypertension and severe hypokalemia), tumour aggressiveness and rapidly fatal outcome. Furthermore, we present a case of EAS produced by a NET from the ileum tract. To our knowledge this is extremely rare and only described in isolated case reports

DOI: 10.1530/endoabs.81.P133

Serial liquid biopsies - the NETest - in gastroenteropancreatic NET surveillance

Mark van Treijen[1,2], Tiny Korse[2,3], Wieke Verbeek[2,4], Margot Tesselaar[2,5] & Gerlof D. Valk[1,2]
[1]UMC Utrecht, Endocrine Oncology, Utrecht, Netherlands; [2]AVL/UMC Utrecht Enets Center of Excellence; [3]The Netherlands Cancer Institute, Clinical Chemistry, Amsterdam, Netherlands; [4]The Netherlands Cancer Institute, Gastroenterology, Amsterdam, Netherlands; [5]The Netherlands Cancer Institute, Medical Oncology, Amsterdam, Netherlands

Introduction
The variable tumor behavior in patients with gastro-entero-pancreatic neuro-endocrine tumors (GEPNETs) is challenging. Current general biomarkers are insufficient to predict the disease course. An emerging biomarker is the NETest, a blood-based gene signature that can predict disease status based on the expression of genes involved in tumor biology. While promising, the accuracy and reproducibility of results in daily practice during years of follow up has never been assessed. Evaluation of serial NETest measurements in an individual is needed to determine its place in the clinical armamentarium.
Aims
To evaluate if serial NETest measurements can predict treatment response and reflect disease evolution during years of follow up.
Methods
Serial NETest scores were compared with RECIST1.1 defined disease status in 132 GEP-NET patients over 46 (6-71) months of follow-up. A median of 4 samples was collected in patients on a watch-and-wait strategy or undergoing systemic treatment. Pre- and post-treatment scores (<6 months) were compared with progression-free survival (PFS).
Results
Fluctuating scores [0-100%] were seen in patients with no evidence of disease (NED) and stable disease (SD). None of the 30 patients with NED and 1 of the 28 (4%) patients with SD had all outcomes within the low range. In patients with progressive disease (PD) and not receiving any treatment ($n=16$), ongoing tumor progression was confirmed in consecutive samples in 82%. Patients responding to treatment (PFS > 12 months) had higher pre-treatment NETest scores (76.5; $n=22$) compared to non-responders (33; $n=12$;$P=0.001$). Patients with low pre-treatment scores had a 21 months shorter PFS after treatment (10 vs 31

months;$P=0.008$). The accuracy for treatment response prediction was 0.73 ($P=0.009$). Post-treatment scores had no discriminative value.
Conclusion
Low NETest scores are associated with an indolent tumor behavior in the follow up of individuals, but scores fluctuate over time in patients with NED and SD. Elevated NETest scores in patients on watch-and-wait strategy had limited predictive value while elevated scores – measured before treatment initiation – predicted treatment response and might therefore be used for individualizing decisions on starting systemic therapy.

First case report of a natural killer T (NK/T) extranodal nasal lymphoma presenting as a diabetes insipidus

Karol Almendra Alvarado Rosas, Valeria Gonzalez Sacoto, Leticia Serrano Urzaiz, Macarena Lacarta Benítez, Cristina Contreras Pascual, Maria Elena Lopez Alaminos, Pablo Trincado, Patricia De Diego Garcia & Javier Acha Perez
Hospital Universitario Miguel Servet, Endocrinología y Nutrición, Zaragoza, Spain

A 52-year-old male patient with no past medical history of interest was admitted to our Endocrinology Unit with a clinical course developed in the last month of sudden polyuria, nocturia and polydipsia (8 liters/day) associated with bilateral low back and leg pain, a right-side nasal congestion with eye swelling and paresthesia. Physical examination revealed a doubtful thickening of the nasal mucosa and several two-cm- scattered erythematous disseminated skin lesions. Blood samples showed basal sodium levels between 146-148 mEq/dl. A Miller test confirmed the diagnosis of Central Diabetes Insipidus (CDI) with a urine osmolality of 444 mOsm/kg that raised to 720 mOsm/kg after desmopressin. Anterior pituitary hormone levels were within normal range. A pituitary MRI showed a focal 10x7x10 mm posterior lesion with extension towards to the pituitary stalk, along with bilateral mucous thickening in ethmoid cells and occupation of nostrils, especially in the right side. During admission, the patient presented worsening of nasal symptoms, solid and liquid dysphagia and advance of skin lesions, which were biopsied. Oral desmopressin was started at a dose of 90 mg/day and subsequently moved on to 240 mgc/day due to persistent polyuria. Infectious processes, germinoma, autoimmune and associated granulomatous disease were ruled out. Due to symptomatology and imaging tests, a diagnostic lumbar puncture was performed, showing infiltration of 66% NK cells by flow cytometry in CSF. Similar findings were observed in skin biopsy with cutaneous infiltration by T cells with CD3 epsilon, CD 7, CD56, granzyme and perforin positive immunophenotype, positive ISH EBER and ki-67 $>$ 90 %. An 18-FDG-glucose- PET-TC showed extensive supra and infradiaphragmatic nodal invasion with splenic, pituitary, nasosinusal, spinal cord and lumbosacral root cord and probable hepatic, adrenal, cutaneous and bone involvement. According to Pink Scale a diagnosis of high score extranodal T/NK lymphoma, nasal type stage IV with cutaneous and central nervous involvement was stated. The patient started a chemotherapy treatment (SMILE protocol) that included dexamethasone, methotrexate, ifosfamide, l.asparaginase and etoposide with clinical improvement and radiological resolution of brain lesions three months afte the diagnosis.
Conclusion
The diagnosis of central DI always makes it necessary to rule out infectious, autoimmune, infiltrative and hematological diseases. Extranodal NK/T lymphoma (nasal type) is a rare neoplasm with an aggressive behavior, first reported here in presenting with CDI, in which early diagnosis and treatment is essential.

Hormonal therapy in breast cancer patients and malignancy risk of thyroid nodules

Alexandra Abegão Matias, Bruno Bouça, Teresa Sabino, Paula Bogalho & José Silva-Nunes
Hospital de Curry Cabral, Department of Endocrinology, Diabetes and Metabolism, Lisbon, Portugal

Introduction
The bidirectional relationship of risk between breast cancer (BC) and thyroid cancer (TC) has been debated. Estrogens are proposed as agents implicated in the risk of developing TC promoting thyroid tumorigenesis. Therapies that reduce the effect of estrogens on their receptors in cancer cells are widely used.
Objective
To correlate the use of hormonal therapy in BC with the prevalence of TC.
Material and Methods
We performed a retrospective analysis of female patients with nodular thyroid pathology and BC followed in our consultation from January 2016 to January 2021. The variables were analyzed using the SPSS software; they are expressed as mean and standard deviation (with a 95% confidence interval).
Results
A total of 3253 patients with nodular thyroid disease were identified. In 4.1% of patients ($n=132$) BC was described in the medical records. Twenty-eight patients were excluded due to lack of data. Regarding the patients included ($n=104$), the mean age at diagnosis of BC was 56 ± 12 years. Patients underwent radiotherapy in 75.9% of cases ($n=79$), hormonal therapy in 72.1% ($n=75$) and chemotherapy in 52.9% ($n=55$). Considering the largest thyroid nodule, the mean diameter in thyroid ultrasound was 22.8 ± 8.5 mm. Fine needle aspiration cytology (FNAC) was performed in 88.5% of patients ($n=92$) and was repeated in 23.9% ($n=22$), mostly due to an initial non-diagnostic result. Considering both procedures, the result was benign in 82.6% ($n=76$), non-diagnostic in 9.8% ($n=9$), follicular lesion of undetermined significance in 2.2% ($n=2$), suspected of malignancy in 2.2% ($n=2$), Hürthle cell tumor in 1.1% ($n=1$) and follicular tumor in 2.2% ($n=2$). Thyroid surgery was performed in 18.3% of patients ($n=19$) with a prevalence of thyroid malignancy of 8.7% ($n=9$). Papillary thyroid carcinoma was diagnosed in eight patients and follicular thyroid carcinoma in one patient. Compared with patients who did not undergo hormonal therapy, patients undergoing hormonal therapy did not show a decrease in cytological (OR = 0.88 [0.16-4.88];$P=0.88$)) or histological (OR = 0.28 [0.07-1.15];$P=0.08$)) risk of TC.
Conclusion
An increased risk of thyroid cancer has been reported in breast cancer survivors. Despite the published evidence on the role of estrogens in the association of BC and TC, in our studied sample there was no relationship between the use of hormonal therapy and the prevalence of TC. Further studies with a larger sample size should be encouraged.

A metastatic ACC mouse model: Combined inactivation of Znrf3 & Tp53 results in consistent adrenocortical carcinoma formation

James Wilmouth[1], Julie Olabe[2], Laly Pucheu[2], Roucher Florence[3], Cecily Lucas Rodrigues[2], Christelle Soubeyrand-Damon[2], Kroiss Matthias[4,5], Laura-Sophie Landwehr[4], Martin Fassnacht[4], Anne-Marie Lefrancois-Martinez[2], Antoine Martinez[2] & Pierre Val[2]
[1]iGReD UMR CNRS 6293, INSERM U1103, Clermont-Ferrand, France; [1] iGReD UMR CNRS 6293, INSERM U1103, Clermont-Ferrand, France; [3]Hospices Civils de Lyon, Biochimie Biologie Moléculaire Grand Est - UM Pathologies Endocriniennes Rénales Musculaires et Mucoviscidose, Lyon, France; [4]Division of Endocrinology and Diabetes, University Hospital, University of Würzburg, Department of Internal Medicine I, Würzburg, Germany; [5]LMU Klinikum, Department of Internal Medicine IV, Munich, Germany

Adrenocortical carcinoma (ACC) is an infrequent and aggressive cancer that originates from steroidogenic cells within the adrenal cortex. Half of patients present with metastatic spread at initial diagnosis, and to date, there is no curative therapy for advanced disease. Recent genomic analysis has established that the most aggressive subgroup of ACC patients have overlapping alterations in the WNT/B-catenin pathway and the p53/RB pathway. We therefore set out to develop a metastatic ACC mouse model based on patient genomic alterations. Using Cre loxP technology, we inactivated both Znrf3, a negative regulator of the WNT/beta-catenin pathway, & p53, a potent tumor suppressor, in steroidogenic cells. By 6 months of age, mice with individual inactivation of p53 (PKO) or Znrf3 (ZKO) did not show tumor formation, while the combined inactivation of p53 & Znrf3 (DKO) resulted in aggressive carcinomas that metastasize at a rate of 36.8%. Using the ROSA26^{mTmG} reporter, we identified metastatic deposits in the lymph nodes, peritoneal cavity, lungs and liver of DKO mice. Importantly, metastatic DKOs show a significant increase in adrenal weight and Ki67 index, while having a significant decrease in overall survival. Furthermore, these tumors

are hormonally inactive, representing a subtype of ACC that has not been previously established in available mouse models. Taken together, these results establish that combined inactivation of Znrf3 & p53 in steroidogenic cells provides a habitable environment for the development of metastatic ACC. The timeline and consistent rate of metastasis in this mouse model highlights its importance for the study of metastatic ACC dissemination, immune-tumor interactions, and potential anti-cancer therapies.

Effect of metformin on the activity of the mTORC1 complex in patients with type 2 diabetes

Tamara Vatseba[1], Liubov Sokolova[2], Volodymyr Pushkarev[2], Viktor Pushkarev[2], Olena Kovzun[2] & Mykola Tronko[2]
[1]Ivano-Frankivsk National Medical University, Endocrinology, Ivano-Frankivsk, Ukraine; [2]V.P. Komisarenko Institute of Endocrinology and Metabolism of the National Academy of Medical Sciences of Ukraine, Kyiv, Ukraine

Introduction
The increased risk of cancer in patients with diabetes mellitus (DM) creates an interest in finding mechanisms of the possible association of antidiabetic drugs and carcinogenesis. Metformin has the most documented evidence of pleiotropic oncoprotective effects, including increased stabilization of tumour suppressor p53, inhibition of NF-κB activation, slowing of the cell cycle and inhibition of mitosis due to decreased expression of cyclin D and cyclin E, as well as the positive effect on intestinal microbiota. The study of the drug's ability to affect the activation of insulin signalling PI3K/Akt/mTOR, which is involved in the regulation of carcinogenesis and metabolism, continues. The aim of the study was to compare the activity of PI3K/Akt/mTOR in patients with type 2 diabetes on metformin monotherapy and other antidiabetic regimens.
Methods
To assess the activation of the PI3K/Akt/mTOR pathway in patients with type 2 diabetes by enzyme-linked immunosorbent assay in peripheral blood mononuclear cells, the content of natural inhibitor of mTORC1 - phosphorylated PRAS40 and the content of phosphorylated protein kinase p70S6K1 were determined. The amounts of phospho-PRAS40 (*P*-Thr246) and phospho-p70S6K1 (*P*-Thr389) were determined using a microplate reader of "Bio-tek Instruments" company (USA) at a wavelength of 450 nm with the diagnostic ELISA kits (KHO0421, 85-86053 respectively (Invitrogen, USA)).
Results
Significantly lower phospho-PRAS40 levels in patients with type 2 DM on metformin monotherapy compared with patients on combination therapy with sulfonylurea derivatives (SUD) and metformin ($t=2.34$;$P<0.05$); lower levels of phospho-p70S6K in patients on monotherapy with metformin in comparison to patients on combination therapy with SUD and metformin ($t=4.13$;$P<0.05$), combination therapy with SUD and insulin ($t=3.76$;$P<0.05$), combined therapy with SUD, metformin and DPP-4 inhibitors ($t=4.0$;$P<0.05$), on insulin monotherapy ($t=3.85$; $P<0.05$) were found. The decrease in the content of phospho-PRAS40 on metformin monotherapy can be explained by the ability of the drug to increase the interaction of PRAS40 with Raptor in the mTORC1 complex, which influences the phosphorylation activity of PRAS40. Decrease in the content of phospho-p70S6K (depending on the activity of the mTORC1 complex) may be explained by the ability of metformin to increase the level of AMPK, the negative regulator of mTORC1.
Conclsion
The obtained results confirm the property of metformin to inhibit the activity of the mTORC1 complex.
Key words
metformin, type 2 diabetes mellitus, PI3K/Akt/mTOR, phospho-PRAS40, phospho-p70S6K.

Circulating cell-free tumour DNA (ctDNA) utilisation in diagnosis and monitoring of thyroid cancer response to treatment - systematic review

Ali Al Jumaah[1,2], Miles J Levy[2], Narendra Reddy[2], Ragini Bhake[2] & Shailesh Gohil[2]
[1]University of Leicester, Leicester, United Kingdom; [2]University Hospitals of Leicester NHS Trust, Department of Endocrinology, Leicester, United Kingdom

Thyroid cancer is the most common endocrine malignancy accounting for 1% of new cancer cases each year. Even after treatment, one in five patients develop recurrence eventually. Therefore, close follow up is crucial after treatment. Current tumour biomarkers are not perfect, and there is a need for a more sensitive and specific way of detecting early recurrence. Liquid biopsies have emerged as a novel marker in tumour surveillance and monitoring response to treatment. In particular, Circulating cell-free Tumour DNA (ctDNA) have been investigated. Here, we review the available evidence regarding the use of ctDNA as a liquid biopsy in the diagnosis and monitoring of thyroid cancer response to treatment.
Methodology
Online database search of PubMed (Medline) was performed using keywords; Circulating Tum* DNA, ctDNA, cfDNA, liquid biopsy, thyroid cancer, thyroid neoplasm*, thyroid carcinoma, papillary, medullary, follicular, anaplastic. Reference lists were reviewed for relevant literature. Modified PRISMA model was adopted for article extraction. Due to significant heterogeneity in trial population characteristics, methodology and outcomes, meta-analysis was not feasible.
Results
After filtering our search to human only trials, some articles were excluded after title reading and screening the text. 11 relevant articles were identified from the online database. 8 more articles were identified from reference lists of relevant reviews raising the total number of articles to 19. Trials included a total of 1163 patients. Of the different tumour types, papillary thyroid cancer (PTC) was the most common type in 71% of patients followed by medullary (MTC) then anaplastic thyroid cancer (ATC) in 14.4% and 10.3% of patients respectively. $BRAF^{V600E}$ was the most commonly sought after ctDNA variant amongst others which included RET and TP53. Tissue mutant DNA detection was performed using digital droplet PCR (ddPCR) and real-time PCR (qPCR) in most trials. Few trials used targeted Next Generation Sequencing technique limited to previously reported mutational hotspot. Concordance rate of tissue-to-peripheral blood mutant DNA detection rate varied from 0% to 86% in trials of diagnosis and surveillance for disease recurrence. The main pitfall was that seeking mutations commonly reported in the literature in both tissue and blood risks missing ctDNA containing less common/unique mutations thereby reducing ctDNA analysis sensitivity.
Conclusion
cT-DNA offers a novel and minimally invasive tool for surveillance and monitoring of thyroid cancer. Research utilizing wider or individualised gene mutation panels is warranted to improve test sensitivity.

Appendiceal neuroendocrine neoplasms diagnosed during pregnancy-case series and review of the literature

Orit Twito[1,2], Akirov Amit[2,3], Rosenblum Rachel Chava[1,2], Dana Herzberg[1,2], Kira Oleinikov[4], Rotman-Pikielny Pnina[2,5] & Simona Glasberg[4]
[1]Edith Wolfson Medical Center, Endocrinology, Holon,; [2]Tel-Aviv University, Sackler Faculty of Medicine, Tel-Aviv, Israel; [3]Rabin Medical Center - Beilinson Hospital, Endocrinology, Israel; [4]Hadassah Medical Organization and Faculty of Medicine, the Hebrew University, Neuroendocrine Tumor Unit, Jerusalem, Israel; [5]Meir Medical Center, Endocrinology, Netanya, Israel

Introduction
Although appendicitis occurs in approximately 1:1000 pregnancies, appendiceal neuroendocrine neoplasm (ANEN) diagnosis during pregnancy is very rare. Data on presentation, treatment and prognosis is scarce.
Aim
To describe ANEN cases diagnosed during pregnancy.
Materials and Methods
A retrospective appraisal of 7 consecutive ANEN patients diagnosed during pregnancy from four Israeli tertiary medical centers and comparison with 17 cases described in the literature from 1965-2021.
Results
Age at ANEN diagnosis was 26.4 ± 3.5 years (range 21-33). Patients were diagnosed between gestational weeks 6-40, most frequently in the third trimester (53%). The most common presenting symptom was abdominal pain. Tumor size

was 14.3±8.9 mm (range 3-45 mm). In patients from our series appendiceal base involvement was reported in 2/7; mesoappendiceal invasion in 5/7; lympho-vascular invasion in 2/7. KI-67 staining was reported in 6/7 cases and ranged from 1-10%. Pathology details were lacking in most of the previously published cases. All 7 pregnancies in our series resulted in term delivery with no complications, whereas in historical cases there were one first trimester abortion, one ectopic pregnancy, and one stillbirth. Right hemicolectomy was performed in 5/7 patients in our series and reported in 2/17 historical cases. All hemicolectomies were performed after delivery, 3-16 months after appendectomy. Local metastases were reported in two cases. Follow-up duration was 7-98 months in our patients and 3-48 months in 5 previous cases. No disease recurrence, distant metastases or mortality were noted.

Conclusions

ANEN diagnosis during pregnancy is extremely rare. Pregnancy outcomes were usually favorable and long-term prognosis was excellent.

DOI: 10.1530/endoabs.81.P384

PD-1 and PD-L1 immune checkpoint expression - the prognostic impact on adrenocortical carcinoma

Laura-Sophie Landwehr[1], Iuliu Sbiera[1], Barbara Altieri[1], Hanna Remde[1], Stefan Kircher[2], Silviu Sbiera[1,3], Matthias Kroiss[1,3,4] & Martin Fassnacht[1,3,5]

[1]University Hospital Würzburg, Department of Internal Medicine I, Division of Endocrinology and Diabetes,; [2]University Würzburg, Institute of Pathology; [3]University of Würzburg, Comprehensive Cancer Center Mainfranken; [4]LMU Klinikum München, Medizinische Klinik und Poliklinik IV; [5]University Hospital Würzburg, Clinical Chemistry and Laboratory Medicine

Adrenocortical carcinoma (ACC) is a very severe endocrine malignancy with poor prognosis. While cancer immunotherapies have revolutionized the treatment of several cancer entities, the results of initial studies of different immune checkpoint inhibitors in ACC were heterogeneous and clinically substantial responses were observed only in a subset of patients. Expression of immune checkpoint molecules - programmed cell death 1 (PD-1) and its ligand PD-L1 - has been shown to predict response in different, but not all cancer entities. Using immunohistochemistry, a cohort of 129 ACCs was examined for PD-1 and PD-L1 expression. PD-1 and PD-L1 were present (threshold of $\geq$1% of cells) in 17.4% and 24.4% of samples, respectively, but expression was heterogeneous and in general rather low (median 3.9% (range 1-15) and 19.7% (range 1-90)). Interestingly, PD-1 expression was significantly associated with beneficial progression-free (HR: 0.30, 95% CI 0.13-0.72) and overall survival (HR: 0.21, 95% CI 0.53-0.84) independently of established prognostic factors, including ENSAT tumor stage, resection status, Ki67 proliferation index and glucocorticoid excess. In contrast, its ligand PD-L1 was not associated with clinical outcome in this ACC cohort. In addition, we analyzed the correlation of PD-1 and PD-L1 with tumor-infiltrating lymphocytes. Whereas PD-L1 correlated significantly with the number of $CD3^+$ -, $CD8^+$-, and $FoxP3^+$ T cells ($P=0.0003$, < 0.0001 and < 0.0001, respectively), PD-1 correlated only with $FoxP3^+$ T cells ($P=0.020$). When including both PD-1 and different T cell subtypes in the above-mentioned multivariate Cox regression, the presence of $PD1^+$ cells was the strongest predictor of favorable clinical outcome. In conclusion, this study provides several potential explanations for the heterogeneous results of the immune checkpoint therapy in advanced ACC. In addition, PD-1 expression serves as a strong prognostic biomarker that can easily be applied in routine clinical care as part of histo-pathological assessment.

Introduction

Gas chromatography mass spectrometry (GC-MS) is the gold standard method for urinary steroid profiling. However, GC-MS requires chemical derivatisation, long run times, is labour intensive, expensive, and unsuitable for rapid multi-sample analysis, limiting its use in routine clinical practice. GC-MS urinary steroid metabolomics, the combination of steroid profiling and machine learning (Generalized Matrix Learning Vector Quantization) was shown to have superior specificity and sensitivity for adrenocortical carcinoma (ACC) diagnosis compared to imaging technologies (1). The method has subsequently been transferred to liquid chromatography tandem mass spectrometry (LC-MS/MS), selecting 15 diagnostically relevant steroids, decreasing the complexity and the cost of the assay. This method was applied to the EURINE-ACT cohort, 2017 prospectively recruited adrenal tumours patients through an ENS@T collaboration (2). Here we compare GC-MS to LC-MS/MS to evaluate the differences in quantitation and ACC diagnostic ability.

Experimental and Results

After deconjugation the steroid extract was either derivatised for GC-MS analysis (Agilent MSD 5975 with a DB1 column) or run directly via LC-MS/MS (Waters-Xevo with Acquity uPLC, HSS T3 column). Correlation between the two technologies was investigated by comparing steroid quantitation in 481 urines from a range of endocrine conditions, including a healthy control cohort 129 urines (75/54 female/male, 20-81 years). Correlation plots and Bland-Altman plots were used to assess method agreement. To compare diagnostic ability urines from 40 patients with adrenal carcinoma (17/23 female/male, 22-79 years, tumour size 50-230 mm) and 99 patients with non-cancerous adrenal tumours (61/38 female/male, 29-83 years, tumour size 9-55 mm) were assessed. Diagnostic ability was determined via calculation of the area under receiver operated characteristic curve (AUROC). There were statistically significant correlations between the methods for all steroids. The diagnostic ability, AUROC for 31 steroids by GC-MS was 0.969, (SD=0.044), and for 15 steroids by LC-MS/MS, was 0.954 (0.067). The highest estimated sensitivity=specificity was LC-MS/MS for 15 steroids (0.901), followed by GC-MS 31 steroids (0.890).

Conclusions

Despite differences in sample preparation and mass spectrometer design GC-MS and LC-MS/MS showed significantly similar quantitation for all steroids. Reduction of the number of analytes from 31 by GC-MS to 15 by LC-MS/MS does not impact the diagnostic ability for ACC diagnosis. LC-MS/MS should now be introduced into clinical biochemistry laboratories as a routine test for the diagnostic work up for patients with adrenal tumours.

Prognostic role of targeted methylation analysis in formalin-fixed paraffin-embedded samples of adrenocortical carcinoma

Juliane Lippert[1], Barbara Altieri[1], Breanna Morrison[2], Sonja Steinhauer[1], Gabrielle Smith[3], Antonia Lorey[1], Urlaub Hanna[1], Stefan Kircher[4], Alice J Sitch[2], Martin Fassnacht[1] & Cristina Ronchi[1,3]

[1]Division of Endocrinology and Diabetes, University Hospital of Wuerzburg, Germany; [2]Institute of Applied Health Research, University of Birmingham, United Kingdom; [3]Institute of Metabolism and System Research, University of Birmingham, United Kingdom; [4]Institute of Pathology, University of Wuerzburg, Germany

Adrenocortical carcinoma (ACC) is a rare and aggressive endocrine neoplasia with heterogeneous molecular background and clinical outcome. Previous studies identified hypermethylation in specific genes to be associated with poor

prognosis. Here, we aimed to investigate the role of methylation pattern for prognostic stratification of patients with ACC as compared to clinical parameters, using methods easily applicable in clinical routine. We investigated a total of 237 ACCs (96 M/141F); data were obtained from a previously published retrospective cohort ($n=107$, Lippert *et al* 2018) with updated follow up data (median overall survival (OS)=65 months) and a novel independent cohort ($n=130$, median OS=53 months). Tumour-DNA was isolated from formalin-fixed paraffin-embedded specimens. Leukocyte-DNA was used as reference. Targeted pyrosequencing or Deep Bisulfite Sequencing was used to detect methylation in the promoter region of 5 selected genes (*G0S2, GSTP1, PAX5, PAX6,* and *PYCARD*). Genes were considered "hypermethylated" if percentage values were >25%. Clinical and histological parameters were collected for S-GRAS score calculation as previously published (Elhassan *et al* 2021). Survival analysis was performed for progression-free survival (PFS) and OS. A Cox survival model was applied to test the prognostic impact of hypermethylation in each gene and S-GRAS score, separately and combined. Analyses were also adjusted for cohorts. A total of 25%, 14%, 28%, 49% and 49% cases showed hypermethylation in *G0S2, GSTP1, PAX5, PAX6,* and *PYCARD,* respectively. Hypermethylation in all individual genes – except *GSTP1* - was significantly associated with both PFS and OS with Hazard Ratios (HR) between 1.4 and 2.3. However, overall the models did not perform well. In the model combining methylation of all genes and S-GRAS score, hypermethylation of *PAX5* was the only molecular parameter significantly and independently related to OS (HR=1.9, 95%CI 1.2-3.2). As a comparison, the best HRs for OS were obtained for S-GRAS score group 2 and 3 were 4.5 and 6.8, respectively, when compared to an S-GRAS score group 0.
In conclusion, this study confirms that hypermethylation in preselected genes is significantly associated with worst PFS and OS in ACC. However, only hypermethylation in *PAX5* was related to OS when accounting for S-GRAS score. Assessing targeted methylation is straightforward and feasible in the clinical setting. Therefore, the addition of methylation status of *PAX5* in the baseline evaluation of ACC patients could help to improve accuracy of prognostic classification and enable the direction of personalized management.

Endocrine-metabolic disorders in patients with gastroenteropancreatic and lung neuroendocrine tumors

Virginia Zamponi[1], Rossella Mazzilli[1], Flaminia Russo[1], Nevena Mikovic[1], Maria Rinzivillo[2], Ludovica Magi[2], Beatrice Trabalza Marinucci[2], Alessandra Siciliani[2], Francesco Panzuto[2] & Antongiulio Faggiano[1]
[1]Sant'Andrea University Hospital, Department of Clinical and Molecular Medicine, Rome, Italy; [2]Sant'Andrea University Hospital, Department of Medical-Surgical Sciences and Translational Medicine, Rome, Italy

Background
Neuroendocrine tumors (NETs) are characterized by long survival and slow progression. In the clinical practice adifferent types of endocrine-metabolic disorders can occur. Such disorders are either comorbidities related to the neoplasm or side effects of specific oncological treatments. The aim of this study is to evaluate type and prevalence of the endocrine-metabolic disorders in patients with gastroenteropancreatic (GEP) and lung NETs.
Materials and Methods
This single-center study evaluated 58 consecutive patients with sporadic NEN, referring to the ENETS Center in Rome (Sant'Andrea Hospital) from November 2020 to December 2021. Of them 31(53.4%) were affected by GEP NET and 27 (46.6%) by bronchial carcinoid. Twenty patients underwent surgical resection, 12 medical therapy and 26 combined therapies. All patients underwent clinical and biochemical screening for endocrine-metabolic disorders at the baseline and during the follow-up.
Results
Fifty-six over 58 patients (96.6%) were affected by at least one metabolic endocrine disorder. Thyroid dysfunctions were detected in 19 patients (33.9%), including primary hypothyroidism in 16 patients and central hypothyroidism in 1 patient. Six of them occurred after NET diagnosis: 1 after somatostatin analogues (SSA); 2 after targeted therapy and 3 after surgery. Subclinical hyperthyroidism occurred in 2 patients after SSA therapy. Impaired fasting glucose occurred in 23 subjects (41%) and was detected after NET diagnosis in 20 patients (5 after SSA, 4 after surgery, 1 after targeted therapy and 10 after combined therapy). Diabetes occurred in 12 subjects (21.4%) and was detected after NET diagnosis in 8 patients (3 after surgery, 1 after SSA, 1 after targeted therapy and 3 after combined therapy). Dyslipidemia occurred in 23 subjects (41%) and was detected after NET diagnosis in 9 patients (2 after surgery, 1 after targeted therapy and 5 after combined therapy). Hypovitaminosis D occurred in 36 subjects (64.3%) and was detected after NET diagnosis in 19 patients (5 after surgery, 5 after SSA and 9 after combined therapy). Primary hypogonadism occurred in 2 patients and central hypogonadism in 1 patient. Primary adrenal insufficiency occurred in 2 patients after surgery and after SSA respectively, 1 patient was affected by Cushing Syndrome detected after combined therapy.
Conclusions
NET patients represent a high-risk population for the development of endocrine-metabolic disorders. The most frequent alterations are hypovitaminosis D, dyslipidemia and glucose impairment, mainly occurring after medical therapy and/or surgery. In all patients with NET a screening of endocrine-metabolic disorders at diagnosis and during the follow-up is strongly recommended.

Adrenocortical carcinoma (ACC) is a rare and aggressive cancer that originates from steroidogenic cells within the adrenal cortex. The most common alteration in ACC patients is inactivation of the transmembrane E3 ubiquitin-ligase Zinc and Ring Finger 3 (ZNRF3), which is responsible for inhibiting the canonical WNT/Beta-catenin pathway. Using Cre/loxP strategy, we showed that inactivation of *Znrf3* in the adrenal cortex resulted in an initial hyperplasia by 6-weeks, after which sexually dimorphic phenotypes arose. We observed a senescent phenotype and a recruitment of macrophages with a higher phagocytic function in males, leading to regression of neoplastic cells and the absence of aggressive tumors in males. Moreover, androgen treatment of females inactivated for *Znrf3* led to a reverse phenotype with regression. Interestingly, in patients, the incidence of ACC is higher in women. The analysis of histologic and genomic data of ACC patients reinforced the idea of a sexually dimorphic phenotype associated with phagocytic function and macrophages infiltration. Our current aim is to use this mouse model and patient data to highlight the role of macrophages in immunosurveillance and tumor inhibition within the adrenal cortex.

Uncovering the immune profile in well-differentiated gastroenteropancreatic neuroendocrine tumors

Franz Sesti[1], Giulia Puliani[1,2], Francesca Sciarra[1], Tiziana Feola[1,3], Roberta Centello[1], Valentina Di Vito[1], Carla Pandozzi[1], Andrea Lenzi[1], Andrea Isidori[1], Mary Anna Venneri[1], Antongiulio Faggiano[4] & Elisa Giannetta[1]
[1]Sapienza University of Rome, Department of Experimental Medicine, Roma, Italy; [2]IRCCS Regina Elena National Cancer Institute, Oncological Endocrinology Unit, Roma, Italy; [3]IRCCS Neuromed Mediterranean Neurological Institute, Neuroendocrinology, Pozzilli, Italy; [4]Sapienza University of Rome, Department of Clinical and Molecular Medicine, Italy

Introduction
Immune tumor microenvironment plays a key role in tumors' growth and metastatic spread, while its role in the heterogeneous field of neuroendocrine

neoplasms (NENs) remains unclear. There is evidence that tumor progression in NENs is promoted by an immunosuppressed microenvironment created by a plethora of infiltrating immune cells. Changes in circulating leukocyte and peripheral blood mononuclear cell (PBMC) subpopulations can mirror the local alteration of the microenvironment, as demonstrated in different kinds of tumors but data in NENs are lacking.
Methods
A prospective controlled observational study was performed recruiting 15 consecutive patients naïve to treatment with histologically proven gastroenteropancreatic (GEP) neuroendocrine tumors (NETs) and 15 healthy controls (Ctrl), matched for age and sex. The primary aim was the quantification of PBMC subpopulations (profiled via flow cytometry).
Results
The mean age of the patients was 60.3 ± 9.7 years (73.3% males). G1 NETs were 46.7%, G2 were 53.3%. Locally advanced or metastatic disease represented the 80%. Immune cell profiling revealed a lower CD3-CD56+ natural killer (NK) cell count in patients with NET than in Ctrl (median [interquartile range], 124 [90-572 *vs* 402 [265-530] cells/μl; $p=0.04$). NK subset analysis showed a reduced percentage of CD56+CD16+ NK cells (81.8% [76.8-89.7%] *vs* 91.7 [88.9-97.6%]; $p=0.004$), a reduced absolute count of CD56+CD16+ NK cells (114 [73-468] *vs* 340 [247-480] cells/μl; $p=0.026$), and a reduced absolute count of CD56dim NK cells (105 [66-544] *vs* 362 [237-461] cells/μl; $p=0.04$) in patients than in Ctrl. Total monocytes count was not significantly different between the study groups. However, patients with NET had a higher percentage of CD14+ CD16++ non-classical monocytes (3.3% [2.1-9.1%] *vs* 1.7% [1.1-2.5%]; $p=0.01$), a higher absolute count of CD14+CD16++ non-classical monocytes (14 [6-23] *vs* 6 [3-10] cells/μl; $P=0.019$), and a lower percentage of CD14+CD16+ intermediate monocytes (5% [2.6-9.2%] *vs* 8.8% [6.1-11.6%]; $p=0.04$). Total CD3+ T lymphocyte count was not significantly different between the study groups. However, a decrease in percentage (mean ± standard deviation, 55.4 ± 8.1% *vs* 63.9 ± 6.6%; $p=0.004$) and in absolute count (554 ± 307 cells/μl *vs* 820 ± 285 cells/μl; $p=0.02$) of CD4+ T helper lymphocytes were found in NETs patients.
Conclusions
The study shows that patients with GEP-NETs have an immune alteration characterized by a low count of cytotoxic NK cells and a high count of anti-inflammatory non-classical monocytes, suggesting a deregulation of CD16 expressing cells. Moreover, a low count of T helper lymphocytes was found. This unfavorable and immunosuppressed immune profile could contribute to tumor growth and progression.

Effect of mitotane on male gonadal function

Federica Innocenti[1], Sara Di Persio[2], Marilena Taggi[2], Roberta Maggio[3], Pina Lardo[4], Maria Elena Aloini[4], Rita Canipari[2] & Antonio Stigliano[3]
[1]Unit of Histology and Medical Embryology, Sapienza University of Rome, Italy; [2]Unit of Histology and Medical Embryology, Sapienza University of Rome; [3]Endocrinology - Sant'Andrea Hospital, Sapienza University of Rome, Clinical and Molecular Medicine, Rome, Italy; [4]Endocrinology - Sant'Andrea Hospital, Sapienza University of Rome

Mitotane (MTT) currently represents the treatment of choice for adrenocortical carcinoma (ACC). Clinical evidence shows the occurrence of hypogonadism following treatment with this drug, observed more frequently in male patients. The aim of the study, therefore, was to evaluate the impact of MTT treatment on male gonadal function on adult CD1 mice. At the end of the 45 days of treatment, testes were collected for morphological examination, and a blood sample of each animal was retrieved to evaluate serum hormone levels. Serum testosterone was significantly lower in MTT-treated animals than the control siblings. The testis of the MTT-exposed group showed several degrees of damage: disorganization of the germinal epithelium, a pronounced alteration of the spermatogenic process with a reduction of spermatozoa in the lumen, absence of lumen and a less compact interstitial space and a thickness of the albuginea. Molecular analysis on the interstitial compartment revealed the expected significant decline in mRNA expression of *3βHsd* and *Insl3* in MTT-treated mice, confirming an impairment of androgens production. The expression of mRNA of *Fsh-R* was only slightly down modulated by treatment with MTT, but was not statistically different, proving that Sertoli cells are not the main target of the drug and the alteration of spermatogenesis is not related to Sertoli cell damage. Moreover, the evaluation of the specific gene expression for different stages of germ cell differentiation, stimulated by Retinoic Acid 8 (Stra8), expressed in differentiating spermatogonia and Heat shock protein A 2 (HspA2), a marker of meiotic cells, showed no alteration in the expression of Stra8 and a decrease of HspA2 mRNA in the testes of MTT-treated mice, demonstrating that differentiating spermatogonia are not affected by the drug treatment while impairment of the meiotic progression of germ cells was observed. Finally, the concentration of sperm collected from epididymis cauda was significantly lower in MTT treated animals than in the control group. Moreover, the administration of MTT caused a significant increase in the percentage of spermatozoa with abnormal chromatin structure defined by the DNA fragmentation index (%DFI) compared to the untreated animals. The testosterone replacement therapy only restored some of these parameters.
In conclusion, we demonstrate the negative effects of the MTT treatment on the male reproductive system, including changes in the morphology of testicular tissue and reduction of sperm concentration and sperm quality.

Struma ovarii with NIFTP tumor: case report

Ana Sofia Osório[1], Ricardo Fonseca[2], Catarina Roque[2], Gabriela Gasparinho[3] & Sara Abrantes[4]
[1]Hospital Prof. Dr. Fernando Fonseca, Endocrinology, Amadora, Portugal; [2]Hospital Prof. Dr. Fernando Fonseca, Endocrinology, Amadora, Portugal; [3]Hospital Prof. Dr. Fernando Fonseca, Anatomopathology, Amadora, Portugal; [4]Hospital Prof. Dr. Fernando Fonseca, Gynaecology, Amadora, Portugal

Struma ovarii is a form of mature teratoma, a rare germ cell tumor, containing more than 50% thyroid tissue. Malignancy is uncommon. Non-invasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP) inside struma ovarii was never described. A 32 y.o. female with previous history of ovarian cysts was admitted in the emergency room with painfull acute abdominal distention. The MRI revealed a right adnexal mass, predominantly cystic with 82x66x80 mm and surrounding oedema. Suspecting of right ovarian torsion, exploratory laparotomy was performed. The torsion was confirmed and the adnexal mass removed. Histopathologic examination showed mature thyroid follicles with abundant colloid in more than 50% of the tissue - consistent with struma ovarii - and a 1 cm area of NIFTP tumor. Thyroid ultrasound was normal and laboratory exams (thyroid function and thyroglobulin levels) within reference range. Malignant struma ovarii is a rare clinical entity that poses a therapeutic challenge, as there is no 'gold standard' of care. NIFTP is an encapsulated or clearly delimitated, noninvasive neoplasm with follicular growth pattern and nuclear features of papillary thyroid carcinoma, that has an excellent prognosis in thyroid gland, but with yet unknown/uncharacterized behavior as struma ovarii. Of our knowledge, this is the first reported NIFTP in a struma ovarii. The patient is being kept under surveillance by the mutidisciplinary team.

Sporadic and Von Hippel-Lindau disease-related pancreatic neuroendocrine tumors definitions are not consistent between the various classification criteria

Reut Halperin[1,2], Yehudit Eden-Friedman[1,2], Liat Arnon[1,2] & Amit Tirosh[1,2]
[1]Sheba Medical Center, Division of Endocrinology, Diabetes and Metabolism, Tel Hashomer, Israel; [2]Tel Aviv University, Department of Medicine, Tel Aviv, Israel

Background
von Hipple-Lindau (VHL) disease comprises hemangioblastomas, renal cell carcinomas (RCC), pheochromocytomas, and pancreatic neuroendocrine tumors (PNET). Diagnosis is based International (two hemangioblastomas, one hemangioblastoma and one visceral lesion, or VHL family history and hemangioblastoma or visceral lesion) or Danish criteria (any two clinical manifestations, one clinical manifestation and family background of VHL or self-genetic diagnosis). The nature of PNET in VHL appears to be distinct from sporadic PNET, as most VHL-related PNET are non-functioning, are lower grade and have a lower rate of metastases, yet head-to-head comparisons are scarce.

Aim
In the current study we wished to compare the characteristics of VHL-related and sporadic PNET. We also tested the hypothesis that diagnosis of VHL according to the International and Danish criteria may comprise two distinct patient populations.
Methods
Patients with a diagnosis of PNET were identified using the MD Clone platform and data including demographic and tumor specific characteristics were gathered. In addition, the presence of any clinical feature of VHL and presence of a family or genetic diagnoses was noted for each patient. Patients were grouped according to a diagnosis of VHL (following either International or Danish criteria) or sporadic PNET.
Results
Twenty-nine patients with VHL, 17 (58%) with PNET and 65 patients with sporadic PNET were identified. Patients with VHL were younger at PNET diagnosis compared with sporadic PNET (50.1±4.7 vs. 62.8±1.5 years, $P<0.001$). There was no significant difference between VHL-related or sporadic PNET in stage and grade, nor in progression or survival. Sporadic PNET were more often located in the body and tail of pancreas. In the subgroup comparison of International vs Danish criteria -based VHL diagnosis, age at diagnosis of PNET, RCC and VHL was younger in the International group. Hemangioblastomas were diagnosed in 90% of patients in the International compared with none in the Danish group. First manifestation of VHL was hemangioblastomas (47%) followed by pheochromocytomas (31%) in the International group compared with RCC (62%) and PNET (37%) in the Danish group. Finally, 50% in the International and none in the Danish group had a family or genetic VHL background.
Conclusions
Patients with PNET diagnosed with VHL according to the International and Danish criteria seem to form two distinct clinical groups, with a greater similarity of the Danish group to patients with sporadic PNET. Further comparisons in other cohorts are warranted, as this may call for different clinical management.

P638

TKI related adverse events in patients with progressive and metastatic thyroid carcinoma: a retrospective analysis of our experience with cabozantinib during EXAM and EXAMINER clinical trial

Virginia Cappagli, Valeria Bottici, David Viola, Laura Agate, Eleonora Molinaro & Rossella Elisei
Department of Clinical and Experimental Medicine, Endocrine Unit, University of Pisa, Pisa, Italy

Background
Vandetanib and Cabozantinib are the only two multitarget tyrosine kinase inhibitors approved for the management of metastatic and progressive medullary thyroid cancer. (MTC) Despite their efficacy in terms of progression free survival prolongation and overall response rate, the drug-related toxicity is still a clinical problem, impairing patient's quality of life and the compliance to the treatment. We retrospectively evaluate the adverse events (AEs) occurred during cabozantinib treatment in patient enrolled in the EXAM and EXAMINER clinical trial.
Matherials and Methods
We retrospectively analyzed data from 23 patients with metastatic MTC, follow-up at our department and enrolled in clinical trials with cabozantinib for radiological documented progression of disease. During follow-up a periodically clinical assessment and of tumoral markers (calcitonin and CEA) and hormonal-hematochemical parameters were performed every month, while a radiological assessment with total body CT scan with iodine contrast medium injection every 12 weeks. The clinical evaluation of AEs was performed according to the CTCAE (National Cancer Institute's Common Terminology Criteria for Adverse Events) dictionary.
Results
All patients experienced AEs during treatment, which were classified in laboratoristic (endocrine and not) and clinical ones. The most frequent endocrine AEs observed were hypothyroidism (78.3%), hypocalcemia (47.8%), high levels of ACTH (34.8%) and FSH/lH. The most frequent not endocrine laboratoristic AEs occurred were AST/ALT high levels (82.6%), increasing in amylase and lipase enzyme (39.1%), renal impairment (21.7%), electrolyte n (43.5%), hematological (60.9%) and coagulation (21.7%) alterations. None of endocrine and not endocrine AEs caused drug stopped or dose reduction since they were well managed with supporting therapies. The most frequent clinical AEs observed were gastrointestinal as mucositis (82.6%), diarrhea (73.9%), nausea/vomiting (34.8%), dysgeusia (30.4%), epigastralgy (26.1%), dysphagia (21.7%); thereafter, constitutional AEs as anorexia (21.7%) and weight loss (47.8%) and cutaneous AEs (47.8%). These AEs occurred early after the drug initiation and, despite preventing and supporting therapies, they were the main cause of drug withdrawal and dose reduction. The analysis of which AE could be a predicting factor of response in still ongoing.
Conclusions
Cabozantinib is an effective treatment for MTC patients. However, AEs occur in all patients during follow-up, but while the laboratoristic ones appear later and are well manageable, the clinical ones occur early and are the main responsible for dose reduction and discontinuation, impair patient's quality of life and disease control. The knowledge, prevention and early treatment of these AEs are fundamental for patients' compliance.

Does the length of a polyalanine tract in the FOXE1 gene impact the course of familial non-medullary thyroid cancer?

Bartosz Domagała[1], Michał Koziara[1], Malgorzata Trofimiuk-Muldner[2], Anna Skalniak[2] & Alicja Hubalewska-Dydejczyk[2]
[1]University Hospital in Krakow, Department of Endocrinology, Endocrine Oncology and Nuclear Medicine, Krakow, Poland; [2]Jagiellonian University Medical College, Chair and Department of Endocrinology, Krakow, Poland

Familial non-medullary thyroid cancer (FNMTC) constitutes about 3–9% of all thyroid cancers. One of the genes believed to predispose to non-syndromic FNMTC is *FOXE1*. It contains a polyalanine tract (polyAla) with a variable number (11 – 22) of alanine residues. This length polymorphism could lead to changes in the *FOXE1*-encoded protein (*FOXE1* transcription factor) structure and predispose to papillary thyroid cancer (PTC). The aim of the study was to investigate the relationship between the length of the polyAla tract and the stage of PTC at diagnosis (according to AJCC 8th edition) in patients with FNMTC. The study included 27 patients with familial PTC (at least two family members were diagnosed with the disease). The length of the polyAla tract of the *FOXE1* gene was analyzed. The following numbers of polyAla variants were detected: 11-Ala – 2, 12-Ala – 1, 14-Ala – 23, 16-Ala – 28 alleles. The staging at diagnosis was compared in two groups: less than 16-Ala and at least 16-Ala. The stages of pT1a and pT1a (m) were found in 20 alleles in the less than 16-Ala group, whereas in 16 alleles of the at least 16-Ala group, pT1b-pT2(m) was the most common ($P=0.039$). Lymph node metastases were found more frequently in the less than 16-Ala group than in the at least 16-Ala group but this difference was not statistically significant (10 vs. 3 respectively; $P=0.680$).
Conclusions
The analysis of the length of the polyAla tract may be a useful diagnostic tool in predicting the course of PTC in patients with a positive family history.

Short fasting test as reliable and effective tool to diagnose insulinoma

Nevena Mikovic, Virginia Zamponi, Rossella Mazzilli, Flaminia Russo, beatrice fazzalari & Antongiulio Faggiano
Sant'Andrea Hospital, "Sapienza" University, Unit of Endocrinology, Department of Clinical and Molecular Medicine, ENETS Center of Excellence, Rome, Italy

Introduction
Insulinomas are rare pancreatic NETs presenting with chronic hypoglycaemia. Current guidelines for diagnosis require a prolonged fasting test (72 h), which implies hospitalization and is difficult to perform, delaying prompt diagnosis and treatment. It has been reported that 65 to 85% of insulinomas could be diagnosed after less of a 24h fasting period and 94 to 95.7% within 48h, although a shorter test for diagnosis has not yet been standardized.
Objective
To predict weather a shorter outpatient fasting test initiated overnight and portrayed up until 24h could be a sensitive method for diagnosing insulinoma.
Materials & Methods
we conducted a retrospective monocentric study to evaluate the diagnostic performance of the short fasting test to achieve the diagnosis of insulinoma. All subjects admitted from 2019 to 2021 at the Unit of Endocrinology of the Sant'Andrea Hospital with clinical suspicion for insulinoma (documented

hypoglycaemia in absence of other known causes or intake of hypoglycaemic drugs) underwent the short fasting test ($n=9$). A comparison study was performed with subjects who underwent the standard prolonged fasting test from 2003 to 2018 ($n=22$). The short fasting test is initiated by the patient overnight at home and proceeds the following day in outpatient setting (Day Hospital). As in the standard protocol, symptoms and capillary blood glucose (CBG) are strictly monitored. Venous blood is drawn for glycaemia, insulin and C-Peptide at admission, in case of symptoms of hypoglycaemia or if CBG ≤ 45 mg/dl. Diagnostic values for insulinoma consist of glucose $<$ 55 mg/dl with insulin $\geq$ 3μU/ml and C-Peptide $\geq$ 0.6 ng/ml. In case of a negative result and a remaining high suspicion for insulinoma, the prolonged test would be performed subsequently.
Results
The final sample consisted of 31 patients, with mean age $\pm$ Standard Deviation (SD) of 44.5 $\pm$ 12.6 years (17-74). Diagnostic values for insulinoma were found in a total of 10 patients: in 6/22 who underwent the prolonged test and in 4/9 who underwent the short fasting test. Time counting from the last meal until diagnosis ranged from 4h to 30h, with average $\pm$ SD of 11 $\pm$ 7.3 h; however, only one patient showed diagnostic values at $>$24h (30h).
Conclusion
In our series, 9/10 (90%) patients with insulinoma were diagnosed within 14 h from the beginning of the fast. A short fasting test could be a valid, sensitive and reliable first-line workup in diagnosing insulinoma, without hospitalization.

Management and long term follow up of hyperparathyroidism in multiple endocrine neoplasia type 1: single center experience

Maria Yavropoulou[1], Sofia Vlachou[1], Marina Tsoli[1], Florentia Fostira[2], Gregory Kaltsas[1] & Eva Kassi[1]
[1]Medical School, National and Kapodistrian University of Athens, Greece, Endocrinology Unit, First Department of Propaedeutic and Internal Medicine, Athens, Greece; [2]Molecular Diagnostics Laboratory, INRaSTES, National Center for Scientific Research "Demokritos", Athens, Greece

Background and objective
Multiple Endocrine Neoplasia type 1 (MEN 1) is an autosomal dominant disease characterized by a broad clinical spectrum. Previous multi-center studies, that analyzed large groups of patients with MEN 1 have been reported before but long term follow up data of these patients focusing exclusively on primary hyperparathyroidism (PHPT) are scarce.
Patients and Methods
In this retrospective cohort study we include all patients with PHPT in the context of MEN1 that were under regular follow up in our institution.
Results
Our cohort consisted of 68 patients (39 males and 29 females), with a mean age at MEN1 diagnosis of 39 $\pm$ 13.06 years. Obvious family history of MEN1 was present in 76.7% of the patients. Besides PHPT, pancreatic neuroendocrine tumors were the most commonly neoplasm encountered in 80% of patients (62% non-functioning), followed by pituitary adenomas in 66% (micro 73%, non-functioning 49%). The mean age at PHPT diagnosis was 35.2 $\pm$ 14.0 years. Fifteen patients developed osteoporosis (22%), 22 (64.7%) nephrolithiasis and one nephrocalcinosis. Parathyroidectomy was performed in 57 patients (82.3%). At the initial parathyroid surgery the majority of patients had subtotal parathyroidectomy (61.4%, $n=35$). Long term remission of PHPT was reported in 32 patients (56%), persistence in 7 (12.2%), and recurrent disease in 18 patients (31.5%) at a median follow-up of 4 years (1 to 21 years). Reoperation for recurrent disease was performed in 11 of the 18 patients (61%), and permanent hypoparathyroidism occurred in 11 patients (19.2%%). A total of 23 patients (33.8%) were treated with a calcimimetic agent with favorable results on serum calcium levels, including both first-line and second-line treatment in unoperated patients and persistent or recurrent disease, respectively. Gene analysis was performed in 44 patients (63%) and a variant known to cause MEN1 was identified in 34 patients (77.2%) while 5 (11.3%) had a variant of uncertain significance. No genotype – phenotype associations were reported, albeit the number of patients was small ($n=34$).
Conclsions
PHPT in the context of MEN1 involves a multiglandular disease and remains a therapeutic challenge over long term for treating physicians, as recurrent disease can develop even after 20 years of follow up. Collection of clinical, biochemical, and genetic characteristics of MEN1 in referral centers at a national level is critical for the optimal management of these patients.

Thyroid cancer and thalassemia major: new hypotheses from an old clinical scenario

Maurizio Poggi[1], Irene Samperi[2], Salvatore Monti[1], cecilia motta[1] & Giuseppe Pugliese[1]
[1]Sant'Andrea University Hospital, Endocrinology Unit, ROMA, Italy; [2]Azienda Sanitaria Locale ASL NO, Diabetological Unit, Novara, Italy

Thyroid cancer (TC) is one of the most frequent neoplasia diagnosed in general population with an estimated incidence of 6.6 cases per 100.000 and mortality of 0.43 cases per 100.000. Differentiated thyroid cancer (DTC), which includes papillary (PTC) and follicular cancer (FTC), comprises the large majority (up to 90%) of all thyroid cancer cases. At the moment etiology of TC is not completely understood, with multiple genetic and epigenetic factor that are thought to be important. We report our recent experience, as a dedicated tertiary care unit in the cure of thalassemia major (TM), that could be useful in the knowledge about induction and progression of carcinogenetic process. TM is a clinical disorder characterized by abnormalities in hemoglobin's synthesis with main treatment that is characterized by regularly blood transfusion. This therapy usually esitate in iron overload and tissue damage and could be cause of serological viruses transmission (like hepatitis B and C virus or human immunodeficiency virus). In a group of 126 patients affected by TM and studied by neck ultrasound we found thyroid nodules in 36 out of 126 with a prevalence of about 28.5%. Regarding patients affected by thyroid nodules we found 10 cases of TC with a prevalence of nearly 27% of neoplastic lesion that is higher than one reported in general population. Most of TC patients were female, with a median age at diagnosis of 37 years and with an histological picture of papillary in 9 out of 10. Interestingly most of all were affected by relevant endocrine tissue damage (more than 3 endocrinopathy in nearly 80% of cases) giving us the chanche to consider iron overload as a main actor in pathogenesis. Moreover 80% of patients affected by TC showed Hepatitis C virus (HCV) positivity raising the suspicion that HCV infection could perform a relevant role in induction and progression of disease, as previously reported. In conclusion our work would give a key to consider newer pathogenetic aspects in TC induction and progression. These considerations could be relevant especially in some clinical scenario and could be useful in innovative strategy in prevention, diagnosis and treatment.

Introduction
Primary Aldosteronism is the most common cause of secondary hypertension. First-line treatment; adrenalectomy resects adrenal nodules and adjacent normal tissue, limiting suitability to those who present with unilateral disease. Use of thermal ablation represents an emerging approach as a possible minimally invasive therapy for unilateral and bilateral disease, to target and disrupt hypersecreting aldosterone producing adenomas, while preserving adjacent normal adrenal cortex. Ablation involves heating tissue >50°C to induce cellular necrosis. Outside the core ablation zone, the transitional zone is an area exposed to variable temperatures between 37°C – 50°C. To understand the feasibility of precision ablation in the adrenal gland, we examined the effect of applying these temperatures to adrenocortical cells to identify i) the required temperature to effectively ablate adrenal cells ii) the extent of damage that may occur to surrounding healthy adrenal cells with exposure to transitional zone temperatures.
Methods
Steroidogenic adrenocortical cell lines, H295R and HAC15, were treated with hyperthermia (high precision water bath) at temperatures of 37, 42, 45, 48 and 50°C. Steroidogenesis was subsequently stimulated using forskolin (10μM) and angiotensin II (10 nM), or cells were treated with Thapsigargin (10uM). Cell death (Propidium iodide staining by flow cytometry), proliferation (xCELLigence real-time cell analysis), protein expression (Western blot/qRT-PCR), steroid secretion (HPLC-Mass spectrometry) and intracellular calcium release (Fluo-4 AM flow cytometry/confocal live imaging) were analysed immediately and 7-days post-treatment.
Results
Cell death occurred at 48°C and 50°C ($P<0.05$ vs 37°C control), but not 45°C, or 42°C. Sublethal hyperthermia (45°C for 30 minutes) induced a heat shock response (upregulated HSP70 and HSP90), alongside a decrease in aldosterone and cortisol secretion ($P<0.05$), reduced expression of steroidogenic enzymes (CYP11B1, CYP11A1)($P<0.05$), and decreased intracellular calcium release 18-h post treatment. At 7-days post sublethal hyperthermia, steroid secretion and steroidogenic enzymatic expression returned to baseline levels.
Conclusion
Hyperthermia at 48°C and 50°C for 15 minutes is required for sustained cell death at 7-days post treatment. Sublethal hyperthermia, equivalent to that produced in the transitional zone during thermal ablation, produces a short-lived unsustained inhibition of steroidogenesis that recovers 7-days post treatment. Therefore, segmental adrenal sparing ablation is possible with recovery of transitional zone following ablation. This underlines the potential for precision technology development for bilateral adrenal ablation as definitive measure to treat PA caused by APA or Micronodular disease.

Methodology of the SORENTO clinical trial: assessing the efficacy and safety of high exposure octreotide subcutaneous depot in patients with GEP-NETs

Diego Ferone[1], Jaume Capdevilla[2], Jennifer Ang Chan[3], Wouter W de Herder[4], Daniel Halperin[5], Josh Mailman[6], Simron Singh[7], Mozhgan Dorkhan[8], Lisa Hellström[8], Agneta Svedberg[8] & Fredrik Tiberg[8]

[1]IRCCS Ospedale Policlinico San Martino, Endocrinology, Department of Internal Medicine & Medical Specialties, University of Genova, Genova, Italy; [2]Hospital Universitari Vall d'Hebron, Barcelona, Spain; [3]Dana-Farber Cancer Institute, Boston, United States; [4]Erasmus MC, Rotterdam, Netherlands; [5]The University of Texas MD Anderson Cancer Center, Houston, United States; [6]NorCal CarciNet Community, United States; [7]Sunnybrook Health Sciences Centre, Toronto, Canada; [8]Camurus AB, Sweden

Background
Somatostatin receptor ligands (SRLs) are first-line standard-of-care therapies for gastroenteropancreatic neuroendocrine tumours (GEP-NETs), showing efficacy in tumour and symptom control with an established safety profile. However, disease progression may occur despite standard-dose SRL treatment, requiring more aggressive and toxic treatments. Retrospective/non-randomized data suggest higher-dose SRLs may benefit patients with GEP-NETs who do not respond to standard-dose treatment and provide improved disease control. Octreotide depot (CAM2029) is a novel high-exposure, subcutaneous (SC) formulation. Clinical trials showed ~500% higher CAM2029 bioavailability vs octreotide long-acting release (LAR) (Tiberg *et al*. 2015), and maintenance/reduction of NET symptoms (Pavel *et al*. 2019). Prospective, randomised trial data are needed to confirm the efficacy/safety of higher-dose SRLs such as CAM2029, vs standard-dose SRLs (including octreotide LAR and lanreotide Autogel [ATG]).
Methods
SORENTO is a randomised, multi-centre, open-label, active-controlled Phase 3 trial, aiming to enrol 302 adults with GEP-NETs. Key eligibility criteria: advanced, well-differentiated NET of GEP/presumed GEP origin; ≥ 1 measurable and somatostatin receptor-positive (by nuclear imaging) lesion according to RECIST 1.1; no or <6 months consecutive treatment with long-acting SRLs. Notably, patients with well-differentiated Grade 3 GEP-NETs (excluded by CLARINET and PROMID trials) are eligible. Patients will be randomised 1:1 to CAM2029 20 mg every two weeks (Q2W), or active comparator (octreotide LAR 30 mg intramuscular or lanreotide ATG 120 mg SC, every four weeks). CAM2029 self-/carer-administration is permitted after ≥ 3 supervised/successful administrations. Randomisation stratified by: histological grade, tumour origin and intended comparator. Primary outcome: progression-free survival (PFS; time from date of randomisation to date of first documented disease progression [RECIST 1.1] or death), assessed by a Blinded Independent Review Committee. The study is powered to detect a hazard ratio of 0.65. Key secondary outcomes: overall survival; RECIST 1.1-defined response rate; rescue medication use; patient satisfaction; adverse events. After primary PFS analysis, patients will be followed for up to 2 years for overall survival (if CAM2029 displays superiority in the primary analysis, the comparator group may switch to CAM2029 20 mg Q2W). Patients (in either treatment group) who experience progressive disease in the randomised part of the study may proceed to an open-label extension with intensified CAM2029 treatment, to investigate effects of higher frequency dosing. First patient randomised in Nov-2021; read-out (achieved after 194 events) expected by end of 2024. This novel head-to-head superiority trial is anticipated to demonstrate the potential benefits of CAM2029 as first-line therapy in patients with well-differentiated GEP-NETs. ClinicalTrials.gov identifier: NCT05050942.

Ectopic cushing's syndrome due to thymic neuroendocrine tumour - a case report

Lukasz Dzialach[1], Agnieszka Wojciechowska-Luzniak[1], Anna Migda[1], Maria Maksymowicz[2] & Przemysław Witek[1]

[1]Medical University of Warsaw, Department of Internal Medicine, Endocrinology and Diabetes, Warsaw, Poland; [2]Maria Sklodowska-Curie National Research Institute of Oncology, Department of Pathology and Laboratory Diagnostics, Poland

Introduction
Ectopic Cushing's syndrome (ECS) is a rare endocrine condition caused by corticotrophin (ACTH) hypersecretion of nonpituitary neoplasms. Thymic neuroendocrine tumours (NETs) account for about 5-10% of ECS cases, typically with aggressive clinical course.
Case Report
A 31-year-old previously healthy female presented to the emergency department with a 3-week history of fatigue, muscle weakness, headaches and generalized swelling. Physical examination revealed peripheral oedema, high blood pressure (170/100 mmHg) and tachycardia (170 beats/min). Laboratory tests showed

leukocytosis (13.95 x10^9/l), hyperglycemia (478 mg/dl) and metabolic alkalosis with profound hypokalaemia (2.5 mmol/l). She was started on insulin therapy along with aggressive hypokalemia repletion and antihypertensive treatment. Given the overall clinical presentation and resistance to initiated treatment, aggressive CS was suspected. Hormonal tests were as follows: midnight serum cortisol 69.17 mg/dl, urinary free cortisol 11587.5 µg/24h, ACTH 963.7 pg/ml. Chromogranin A (CgA) level was notably elevated (1385.0 ng/ml). Negative HDDDST and CRH tests, negative pituitary imaging with short duration and rapid progression of symptoms were highly suggestive of ECS. To control hypercortisolemia, continuous etomidate infusion was started with significant improvement in the patient's general condition, oedema reduction and normalization of blood pressure, glycemia and potassium level. Computed tomography (CT) revealed a left adrenal mass measuring 80x56x39 mm infiltrating the diaphragm. Whole-body 18F-FDG-PET/CT showed a metabolically active lesion of the left adrenal gland and multiple active bone lesions suggestive of metastatic malignancy. The patient underwent laparoscopic left adrenalectomy with a postoperative significant decline in cortisol level (4.08 mg/dl) and required hydrocortisone replacement. However, histopathology showed adrenal adenoma with extensive necrosis. A follow-up (8 weeks) whole-body PET/CT finally revealed 18F-FDG-avid (SUVmax 9.3) 42x33 mm lesion in the anterior mediastinum. Due to the local invasion, only a partial resection was performed. Histopathology revealed a thymic large cell neuroendocrine carcinoma with atypical thymic carcinoid component [ACTH(+), CgA(+), synaptophysin(+), CD56(+), MGMT:70%, Ki-67:30%, p53: <1%]. Thymectomy was followed by mediastinal radiotherapy and chemotherapy with the ADOC regimen. The patient has been under endocrine and oncological follow-up for almost 3 years, however, due to the progression of the disease, the prognosis is poor.

Conclusions

The diagnosis and management of ECS remain challenging. ACTH-secreting thymic NETs often behave aggressively and lead to the rapid development of severe hypercortisolism causing uncontrolled hypertension and hyperglycemia with hypokalaemic alkalosis requiring prompt intervention. Due to the rarity and complexity of the disease, management of ECS caused by malignant thymic NETs needs a personalized and multidisciplinary approach.

Spliceosomic landscape across the histological subtypes of lung neuroendocrine neoplasms: a new layer to disentangle tumor Heterogeneity

Ricardo Blázquez-Encinas[1,2,3], Víctor García Vioque[1,2,3], Alexandra Sexton-Oates[4], María Trinidad Moreno Montilla[1,2,3], Emilia Alors-Pérez[1,2,3], Federica Mangili[1,2,3,5], Nicolas Alcala[4], Matthieu Foll[4], Alejandro Ibañez Costa[1,2,3], Lynnette Fernández Cuesta[4] & Justo P. Castaño[1,2,3,6]

Lung neuroendocrine neoplasms (LungNENs) are highly heterogeneous tumors, which are classified by the WHO according to their histological grade into low grade: Typical Carcinoids (TC) and intermediate grade Atypical Carcinoids (AC), and high-grade: Large Cell Neuroendocrine Carcinoma (LCNEC) and Small Cell Lung Cancer (SCLC). Recently, a number of studies have tried to untangle the molecular features that define each subtype by applying different approaches, including genomic, transcriptomic and epigenomic analyses, which have provided useful information to better classify and understand LungNENs. However, an emerging layer of complexity tightly linked to every hallmark of cancer remains to be explored in detail in LungNENs: the spliceosomic landscape. Indeed, the status of the alternative splicing pattern and its underlying machinery (spliceosome components and splicing factors) is heavily altered in many tumors, where it relates to cancer development and progression. Thus, here we aimed to analyze the expression of the splicing machinery and the alternative splicing patterns in LungNENs, compare them among the different subtypes, and explore their relationship with their pathophysiological phenotype. To achieve this aim, RNA-seq data of 284 LungNENs samples were analyzed, comprising: 164 TC and AC, 69 LCNEC and 51 SCLC. Specifically, gene expression was calculated with DESeq-2 and alternative splicing events and isoforms were quantified using SUPPA2. We used Principal Component Analysis and Uniform Manifold Approximation and Projection to cluster the samples according to their spliceosomic landscape. Geneset Enrichment Analysis was used to study molecular pathways involved in groups of genes. Results revealed the splicing machinery has clearly distinct expression patterns among the four subgroups of LungNENs, which enable to precisely discriminate them. Moreover, each subgroup displayed a specific profile of alternative splicing events, where certain genes were enriched in relevant biological pathways. Our analyses represent the first comparative study of the spliceosomic landscape of the different histological subgroups of LungNENs and provide new tools and original information to gain further insight to understand LungNEN heterogeneity.

Autoimmune polyglandular syndromes in childhood: casuistic of a pediatric unit

Bruno Bouça[1], Andreia Nogueira[2], Joana Caetano[3], Rita Cardoso[3], Isabel Dinis[3] & Alice Mirante[3]

[1]Centro Hospitalar Universitário de Lisboa Central, Department of Endocrinology, Diabetes and Metabolism, Lisbon, Portugal; [2]Centro Hospitalar Universitário de Coimbra, Pediatric Department, Coimbra, Portugal; [3]Centro Hospitalar Universitário de Coimbra, Department of Pediatric Endocrinology, Diabetes and Growth, Coimbra, Portugal

Introduction

Polyglandular Autoimmune Syndromes (PAS) are a group of diseases characterized by the association of different endocrine and non-endocrine autoimmune pathologies. Although the diagnosis of PAS is more frequent in adulthood, it can occur in pediatric age, with PAS type 3 being the most frequent.

Objective

To study the prevalence and characteristics of PAS in the pediatric population of a tertiary center.

Methods

Retrospective analysis of the clinical files of patients with type 1 diabetes mellitus, autoimmune thyroid disease (ATD), Celiac Disease (CD) and Addison's disease (AD) followed in a Pediatric Endocrinology consultation from 1 January 2010 to 31st December 2020.

Results and Conclusions

Of the 879 cases consulted, 35 patients with PAS were identified, 27 female, with a mean age at diagnosis of 7.8 ± 4.9 years, mean time elapsed between the 1st and 2 nd manifestation of 50.2 ± 44.3 months and 37.1% had a family history of autoimmune disease. Regarding classification, 3 patients had PAS type 2, 9 patients PAD type 3A, 14 patients PAS type 3C and 9 patients PAS type 4. In the group of PAS type 2 patients (2 males), all had ATD (2 Hashimoto's thyroiditis and 1 Graves' disease). Among patients with PAS type 3 (22 females), 24 had ATD, 9 DM1, 9 CD, 3 Vitiligo, 1 Autoimmune Hepatitis and 1 Systemic Lupus Erythematosus. CD was the first manifestation in 9 patients, DM1 in 6, DAT in 5, Vitiligo in 2 and Autoimmune Hepatitis in 1.Regarding PAS type 4 (5 females), all patients had DM1 and CD, the former representing the first diagnosis in 88.9% of cases.

Conclusion

PAS are rare among the pediatric population. In this sample, all patients were diagnosed with PAS type 2, type 3 or type 4, with the majority being female. The variable clinical presentation is consistent with what is described in the literature, as well as the high prevalence of a family history of autoimmune diseases. Frequently, the time interval until the diagnosis of a second endocrinopathy can be long (decades), which demonstrates the importance of active surveillance of patients with autoimmune diseases.

Effects of decamethylcyclopentasiloxane by maternal exposure on the offspring mice behaviors

Eui-Bae Jeung, Donglin Yi, KangMin Kim, Minsu Lee, Jimin Lee & YongIn Kim

Laboratory of Veterinary Biochemistry and Molecular Biology, College of Veterinary Medicine, Chungbuk National University, Cheongju-si, Chungcheongbuk-do, Rep. of South Korea

Decamethylcyclopentasiloxane (D5) is one of the most common chemical ingredients for daily necessities that can be absorbed through the skin, aerosol, or even orally. People are exposed to D5 daily, but the risk of prenatal exposure to D5 is not completely understood. In this study, the effects of prenatal exposure to D5 on neural development were assessed through behavioral tests on offspring mice. First, the developmental neurotoxicity test (DNT) was performed to determine if D5 is a neurotoxicant. From the DNT, D5 was classified as a developmental neurotoxicant because their score of the discriminant function (SDF) was -1.55603, which is less than the standard score 0 of DNT. The estimated daily exposure of D5 to humans has been reported to be around 0.6 mg/kg. In this study, the pregnant mice were treated with 3, 6, and 12 mg/kg of D5 with corn oil per day from embryonic day 10 (E10) through postnatal day 7 through oral administration. All behavior tests were performed after the pups reached six weeks of age. As a result, the administration of 12 mg/kg of D5 (high dose group) increased the repetitive activity in both the grooming and marble burying tests and even a depression in tail suspension and forced swimming test compared to the vehicle group. In addition, high dose group showed a decrease in social behavior and cognitive ability in the three-chamber test. In the novel object recognition test, impairment of memory and exploring ability was found on the high dose group. The expression level of the four genes, brain-derived neurotrophic factor (BDNF), tyrosine hydroxylase (TH), acetylcholinesterase (AChE), and GABA type A receptor associated protein like 1 (GABARAPL1) related to neural development, were measured in the whole brain. The administration of high dose of D5 decreased the transcription level of BDNF and increased AChE and TH compared to the vehicle. On the other hand, there is no meaningful difference in GABARAPL1. These results show that the maternal exposure to D5 impairs the social and memory ability of mouse offspring and alters gene expression in the brain. In conclusion, maternal exposure to D5 can cause behavioral disorders in their offspring. Therefore, it is necessary to discuss the excessive usage of D5.

Orbital inflammatory disease following mrna sars-cov-2 vaccine: a case report

Grunenwald Solange[1], Gabriel Lethellier[2], Philippe Imbert[1], Céline Dekeister[3] & Philippe Caron[4]
[1]CHU Larrey, Service d'Endocrinologie, Toulouse, France; [2]CH Intercommunal Castres-Mazamet, Service d'Ophtalmologie, Castres, France; [3]Hôpital Pierre-Paul Riquet, Chirurgie Maxillo-Faciale, Toulouse, France; [1] CHU Larrey, Service d'Endocrinologie, Toulouse, France

SARS-CoV-2 vaccination campaigns document a satisfactory high profile of protection against Covid-19 infection, but auto-immune/inflammatory diseases have been reported following Covid-19 vaccines. A 65-year-old woman reported two days following her first dose of the BNT162b2 mRNA vaccine tearing, eye irritation, conjunctival redness, peri-orbital swelling, spontaneous hematoma of the right lower eyelid, right greater than left proptosis, with a spontaneous improvement of symptoms during the following two weeks. She received the second dose of BNT162b2 vaccine after 6 weeks and noted an aggravation of the right proptosis. An ophthalmic examination noted high intraocular pressure on the right eye (30 mmHg) and brinzolamide, timolol and latanoprost eye drops were progressively introduced. After 3 months, Hertel values were 25 and 19 mm and palpebral fissures 12 and 11 mm for right and left eyes, respectively. The clinical activity score (CAS) was 4/7, but visual acuity, ocular motility and color vision test were normal. TSH concentration was 0.83 mU/l, and anti-thyroid antibodies were negative. CT and MRI scans confirm an asymmetric proptosis with a diffuse infiltration of the orbital fat and hypertrophy of extra-ocular muscles in the right orbit. At 4th month, she reported a visual acuity loss of the right eye (20/30) but fundus examination and optical coherence tomography were normal. She had intravenous 500 mg methylprednisolone infusion every two days and she reported transitory improvement of symptoms. Then she received iv 500 mg methylprednisolone once weekly for 4 weeks. She noted a transient improvement of pain and eyelid edema after each infusion, without reduction of proptosis and CAS after the first 6 intravenous infusions. Then the patient had intravenous 250 mg methylprednisolone infusion once weekly for 4 weeks until an orbital bone-wall decompression of the right orbit was performed. One month after surgery, ophthalmic evaluation reported Hertel value (23 mm), intraocular pressure (17 mmHg) and CAS (2/7) for right eye. To our best knowledge, there is the first report of an orbital inflammatory disease following mRNA SARS-CoV-2 vaccination. The temporal relationship between Covid-19 vaccination and onset of orbital symptoms suggest that SARS-CoV-2 mRNA vaccine can probably be associated with this orbital inflammatory disease. The mechanisms of occurrence of this orbital inflammatory side effect are a manner of debate (molecular mimicry, bystander activation, autoimmune/inflammatory syndrome induced by adjuvants). There is no treatment consensus when patients do not respond to first-line glucocorticoids (immunomodulatory therapy, orbital radiation, decompressive surgery).

Di-butyl phthalate exposure in a human adrenocortical cell line impairs steroid hormone synthesis

Liselott Källsten, Paula Pierozan, Jonathan W Martin & Oskar Karlsson
Stockholm University, Science for Life Laboratory, Department of Environmental Science, Stockholm, Sweden

Phthalates are man-made chemicals that are used in many different types of products. The main use is as plasticizers, but they can also be added to, for example, cosmetics, drug coatings, and perfumes. One of the most commonly used phthalates is di-butyl phthalate (DBP), which has been detected in both food and drinking water globally. Once ingested, DBP is rapidly metabolized to its main metabolite, mono-butyl phthalate (MBP), which is frequently detected in human plasma and urine. Studies suggest that DBP has anti-androgenic potential and that it can induce reproductive and developmental effects. However, the molecular mechanisms behind these effects are unknown. We used the human adrenocortical cell line H295R to investigate how DBP and MBP may affect steroid hormone synthesis. After 48-h exposure, samples were collected and the supernatant analyzed by mass spectrometry and cell pellet by western blot to measure the levels of several steroid hormones and key steroidogenic enzymes, respectively. The results demonstrated that DBP induced a dose-dependent decrease in testosterone levels, and a similar decrease was detected for the precursor androstenedione. The corticosterone level also decreased after DBP-exposure, while cortisol increased. MBP induced similar effects as DBP, but with a lower effect size. However, MBP-exposure caused a decrease in cortisol, thereby indicating that there are differences in the mechanism of action between the two compounds. In addition, it was discovered that the decreases in steroid hormone levels are potentiated when the cells are co-treated with dibuturyl-cyclicAMP, which mimics endogenous stimulation of adrenal cells by adrenocorticotropic hormone to increase production of steroid hormones. The results also revealed that the levels of several steroidogenic enzymes were altered, with similar differences between MBP and DBP exposure as for the hormone concentrations. To conclude, these findings suggest that MBP is less potent than its parent compound, that the effects of phthalate exposure on the steroidogenesis are more profound during stimulation, and that both compounds affect steroid hormone production by alterations to the steroidogenic enzymes.

A cell-based platform to screen chemical mixtures for endocrine disruptive effects

Denise Strand[1], Erik Nylander[1], Bo Lundgren[2], Jonathan W Martin[1] & Oskar Karlsson[1]
[1]Stockholm University, Department of Environmental Science, Stockholm, Sweden; [2]Stockholm University, Department of Biochemistry and Biophysics, Stockholm, Sweden

Chemical contaminants from human activity are omnipresent in the environment. A great number of common industrial compounds are detected in human blood and urine. Common chemicals such as bisphenols, phthalates and parabens that can interfere with endocrine signaling are classified as endocrine disruptive compounds (EDCs). The sex steroid hormonal signaling pathway is complex and sensitive to interference, as circulating concentrations of these hormones are low. Even miniscule amounts of an active chemical could therefore result in endocrine

disruption and cause adverse effects on development, brain function, and the reproductive- and immune systems. Industrial chemical production require risk assessments that balance societal benefits to potential negative effects on human- and environmental health. These risk assessments are based on observations in short term single-chemical exposure studies, which is not reflective of real-life scenarios where exposure to different chemicals and classes from many sources occurs simultaneously. Additive or synergistic effects are a concern, since the toxicity of different compounds in the biological system could interact and produce an unexpected and exaggerated toxicological response. The single compound approach therefore run the risk to potentially underestimate the biological impact of mixture effects. We have set up a small chemical library of environmental contaminants and employ liquid handling dispensing to reproduce real-world mixtures for screening of toxic effects. The endocrine disruptive potential of these mixtures is investigated by using OECD-validated *in vitro* cell-based methods that assess effects on steroidogenesis and androgen- and estrogen receptor interactions. Our aim is to establish medium or high throughput (MTS/HTS) micro plate-based screening methods for toxicological investigation of the complex chemical mixtures. This set-up will later be applied to investigate the effects of reconstructed individual exposomes based on chemical profiles detected by advanced mass spectrometry analysis of serum collected from a Swedish cohort. This will aid in the development of highly relevant risk assessments for chemical mixtures, in order to protect the general population from endocrine disruptive mixture toxicity.

Dioxin-like polychlorinated biphenyl (pcbs) congeners induce inflammatory responses and reduce thyroid-specific genes expression in human thyrocytes via ahr pathways

Rosaria Ruggeri[1,2], Aurelio Minuti[2,3], Federica Aliquò[2,3], Fiorenza Gianì[4], Roberta Masto[4], Davide Romano[3], Angela Avenoso[3], Maria Teresa Cristani[5], Francesco Trimarchi[1], Alfredo Campennì[3], Angela D'Ascola[1] & Salvatore Cannavò[2,6]

Martino, Messina, Italy; [3]Dept Biomedical and Dental Sciences, and Morpho-Functional Images, University of Messina, Messina, Italy; [4]University of Catania, Dept Clinical and Experimental Medicine, Catania, Italy; [5]University of Messina, Chemical, Biological, Pharmaceutical and Environmental Sciences, Messina, Italy; [6]University of Messina, Department of Human Pathology of Adulthood and Childhood DETEV, Messina, Italy

Background
PCBs are persistent organic pollutants, able to affect thyroid function (endocrine disruptors) and promote inflammation through multiple mechanisms. The aryl hydrocarbon receptor (AhR), a ligand-activated transcription factor able to bind dioxins and dioxin-like pollutants including PCBs, play a key role in xenobiotic response, by up-regulating specific responsive genes, the so-called "AhR gene battery", including cytochrome P450 1A1 (CYP1A1) and Nuclear factor-2 erythroid related factor-2 (Nrf2), a master regulator of the redox homeostasis with simultaneous anti-inflammatory activity. Aim of the present study was to investigate the influences of the AhR agonist PCBs congeners on thyrocytes *in vitro*.
Methods
Cultured primary thyrocytes were exposed for 24 h to increasing concentrations (5 and 10 μM) of 2.3',4.4',5-pentachlorobiphenyl (PCB 118) and 3.3',4',4',5 Pentachlorobiphenyl (PCB 126). mRNA and proteins expression for IL-1β IL-6, NIS, TG, AHR, CYP1A1 and Nrf2 were evaluated by real-time PCR and Western Blot and ELISA, respectively. Protein quantification was assessed by densitometry analysis
Results
In cultured thyrocytes, exposure to PCB 126 and PCB 118 at 5 and 10 μM concentrations significantly induced the increase of both mRNA and protein levels of the inflammatory cytokines IL-1beta and IL-6 ($P<0.01$ and $P<0.001$, at 5 and 10 μM respectively for mRNA expression; $P<0.05$ and $P<0.01$ at 5 and 10 μM for protein levels). Additionally, both mRNA and protein levels of the AhR and the downstream molecules CYP1A1 and NRF2 were increased in PCBs-treated thyrocytes (for AhR and Nrf2 $P<0.05$ at highest concentration; for CYP1A1 $P<0.05$ and $P<0.01$ at 5 and 10 μM respectively), suggesting activation of AhR pathways and oxidative stress sensitive markers (CYP1A1and NRF2) induction in response to PCBs exposure. On the contrary, the levels of Tg and NIS mRNA and related protein decreased after PCBs treatments at 5 and 10 μM concentrations ($P<0.05$ and $P<0.01$, for mRNA expression at 5 and 10 μM respectively; $P<0.05$ at 10 μM for protein levels), indicating down-regulation of these thyroid-specific genes in PCBs-induced inflammation.
Conclsion
PCB 118 and PCB 126 may promote inflammatory responses, leading to alteration in Tg and NIS genes expression in thyrocytes. Such effects can be partially attributed to the activation of the AhR that, in turn, induces CYP1A1 and NRF2, causing changes in the cellular redox status. These data may contribute to explain the mechanisms underlying thyroid toxicity of dioxin-like PCBs and highlight the potential role of these environmental pollutants in contributing to autoimmune thyroid inflammation and damage.

Synergism between bisphenol a exposure and overweight/obesity in increasing the malignancy risk in a cohort of patients with thyroid nodules

Vincenzo Marotta[1], Lucia Grumetto[2], Ilaria Neri[2], Giacomo Russo[3], Anna Tortora[1], Giulia Izzo[4], Domenico Rocco[4] & Mario Vitale[4]
[1]UOC Clinica Endocrinologica e Diabetologica, AOU San Giovanni e Ruggi d'Aragona, Salerno, Italy; [2]Pharm-Analysis & Bio-Pharm Laboratory, Department of Pharmacy, School of Medicine and Surgery, University of Naples Federico II, Napoli, Italy; [3]School of Applied Sciences, Sighthill Campus, Edinburgh Napier University, Edinburgh, United Kingdom; [4]Dipartimento di Medicina, Chirurgia e Odontoiatria, Università di Salerno, Salerno, Italy

Introduction
The plasticizer Bisphenol A (BPA) is an endocrine disruptor with thyroid interfering activity. Obesity is a recognized risk factor for thyroid cancer. A recent study showed that subjects with BMI $\geq$ 25 are more prone to BPA-related thyroid disruption. To date, few and controversial experimental and epidemiological data provide weak evidence about a correlation between BPA exposure and thyroid cancer development. Aim of the present study was to assess a possible link between BPA, body fat excess, and thyroid cancer risk.
Patients and Methods
Multicentre, cross-sectional study including consecutive patients subjected to cytology for diagnostic definition of thyroid nodules. Blood samples were obtained for all enrolled patients. Serum BPA determination was performed by means of high performance liquid chromatography coupled in tandem with fluorescence and ultraviolet detection. Inclusion criteria: a) age $\geq$ 18 years; b) clinical management performed in one of the involved centres. Exclusion criteria: a) inconclusive cytology (TIR -3A, -3B, -1 categories); b) clinical and/or cytological and/or histological features of autoimmune thyroiditis; c) clinical and/or cytological and/or histological features of medullary thyroid cancer; d) modifications in lifestyle and anthropometric variables occurred within the previous 5 years. BPA exposure was assessed by means of a qualitative approach, categorizing the subjects in exposed (detectable serum BPA levels) and not-exposed (undetectable BPA levels).
Results
Statistical analysis included 94 patients: 30 males and 64 females (median age 52 years); 54 benign nodules, 40 thyroid cancers; 28 normal weight patients (BMI $<$ 25), 66 overweight/obese patients (BMI $\geq$ 25 $<$ 30 in 30 cases; BMI $\geq$ 30 in 36 cases). Detectable BPA was found in 78 cases. In the overall study group and in the BMI$<$25 group exposure to BPA was not significantly related to the risk of malignancy ($P=0.119$; OR 1.84 with 95% CI 0.76-4.45 and$P=0.755$; OR 0.83 with 95% CI 0.28-2.47, respectively). By contrast, in the BMI$\geq$25 group, BPA-exposed subjects showed significantly higher risk of malignancy ($P=0.046$; OR 2.88 with 95% CI 0.79-10.54).
Conclusions
In our series, BPA exposure conferred higher risk of thyroid cancer only in case of concomitant overweight/obesity, therefore suggesting a synergistic action between BPA and the excess of adipose tissue in promoting thyroid carcinogenesis.

Gemelli Rome, Precision Medicine in Breast Cancer Unit, Rome, Italy; [6]Tor Vergata University Rome, Dept of Clinical Sciences and Translational Medicine, Rome, Italy; [7]University of Verona, Section of Oncology, Verona, Italy

The highly toxic heavy metal Cadmium (Cd) is widely spread in the environment and could exert estrogen-like activity in tissues including breast. Previous studies demonstrated that Cd binds to estrogen receptor α positive (ERα+) breast cancer (BC) cells. In this new study, we evaluated effects of Cd on both ERα+ and ERα negative (ERα-) BC models with the aim to further characterize the mechanisms involved in Cd-related BC carcinogenesis. Specifically, the effect of Cd exposure was evaluated on BC cell lines MCF7 (ERα+, PR+, HER-), T47D (ERα+, PR+, HER+), and MDA-MB-231(ERα-, PR-, HER-). First of all, the effects of Cd on cell proliferation and death were evaluated. Cells treated with increasing concentrations (0.5-10 μM) of Cd showed a significant decrease in cell viability from the dosage of 5 μM after 24h in MCF7, after 48h in MDA-MB-231 and after 72h in T47D cells. The levels of steroid receptors expressed by the cells before and after Cd were also evaluated. In detail, ERα, estrogen receptor α (ERα), androgen receptor (AR), and progesterone receptor (PR) were evaluated after Cd exposure. ERα decreased in ERα+ cells while ERα expression increased in all cells. PR levels were reduced or not modulated in all cells. AR levels were increased in both ERα+ and ERα- cell models. We evaluated the ratio of AR/ERα and AR/ERα and we found that Cd induced a significant increase in the two ratios in both ERα+ and ERα- cell models. Furthermore, activation of cellular signaling pathways were evaluated. Cd induced activation of p38 MAPK in all cell lines, activation of PhAKTser473 in T47D and activation of ERK1/2 in MDA-MB-231 cells. Finally, Cd exposure induced a significant increase in the pro-inflammatory cytokines IL-6 and IL-8. In conclusion, our study demonstrates that Cd has a role in regulating cell viability, steroid receptors phenotype, cellular signaling pathways and pro-inflammatory cytokines in both ERα+ and ERα- cell models.

Neonatal thyroid stimulating hormone as indicator of Iodine status in Lithuania

Lina Zabuliene[1], Marius Miglinas[1,2], Deimante Brazdziunaite[2,3], Marija Smirnova[2,4], Jurgita Songailiene[2,3], Nomeda Bratcikoviene[3,4], Valdas Banys[3], Ernesta Macioniene[1,2] & Algirdas Utkus[2,3]
[1]Faculty of Medicine, Vilnius University, Institute of Clinical Medicine, Vilnius, Lithuania; [2]Vilnius University Hospital "Santaros Klinikos", Vilnius, Lithuania; [3]Faculty of Medicine, Vilnius University, Institute of Biomedical Sciences, Vilnius, Lithuania; [4]Vilnius Tech, Faculty of Fundamental Sciences, Vilnius, Lithuania

Background
World Health Organization (WHO), United Nations International Children's Emergency Fund (UNICEF), and the International Council for Control of Iodine Deficiency Disorders included neonatal thyroid stimulating hormone (nTSH) as one of the indicators for assessing iodine deficiency at a population level and as a monitoring tool in programs of iodine supplementation. A prevalence of nTSH concentrations in dry blood spots (DBS) above 5 mIU/l below 3% has been proposed as the threshold indicating iodine sufficiency. Since 1994 WHO and UNICEF reached an agreement to recommend Universal Salt Iodization as a key strategy for prevention and elimination of Iodine Deficiency Disorders worldwide. In Lithuania mandatory universal salt iodization program was implemented in 2005. The aim of this study was to evaluate nTSH data to assess the current status of iodine nutrition in Lithuania.
Methods
The study was conducted as a part of nationwide program NATRIJOD aimed to evaluate sodium and iodine status in Lithuania (the country with 2 784 279 inhabitants in 2021). We retrospectively analyzed the results of nTSH tests from the National Newborn Screening Program for congenital hypothyroidism database between 2002 and 2018. According to screening methodology, heel-prick blood samples of newborns were collected on filter paper cards. Results of samples collected >48 h after birth were analyzed. The nTSH concentration was measured in DBS using fluorometric enzyme immunoassay (Labsystems). Anonymized results of nTSH tests from 492143 cards were retrieved, congenital hypothyroidism cases and inadequately sampled DBS were excluded, frequency of results at the cut-off of nTSH above 5 mIU/l was calculated.
Results
The prevalence of nTSH above 5 mU/l varied between 1.21 % (in 2013) and 5.43 % (in 2004). Since 2011 overall prevalence of nTSH above 5 mU/l was less than 3% and only one region has had frequency above 3% for several years. In 2018 increase in the prevalence of nTSH above 5 mU/l was noted in three regions of the country, indicating possible mild iodine deficiency in these regions.
Conclusions
Despite that children, pregnant women and adult in Lithuania are mildly iodine deficient, based on median urinary iodine concentrations data, the prevalence of nTSH above 5 mU/l was low, suggesting a need to re-evaluate universal cut-off of nTSH and investigate other potential factors impacting nTSH results in order to detect early mild iodine deficiency in population and achieve sustainable elimination of iodine deficiency.

Potential synergic and antagonistic effects of EDC mixtures on human prostate cells

Aldo Mileo[1], Lorenzo Riccio[1], Michele Francesco Di Tolla[2], Vittoria D'Esposito[2], Teresa Chianese[1], Vincenza Laforgia[1], Pietro Formisano[2] & Maria De Falco[1]
[1]Department of Biology, Naples, Italy; [2]Department of Medical and Translational Scieces, Naples, Italy

Endocrine Disrupting Chemicals (EDCs) are a heterogeneous class of compounds so called for their ability to interfere with the endocrine system. These environmental pollutants are detected in different environmental matrices; they can bioaccumulate in adipose tissue and biomagnificate in food chain due to their high hydrophobicity and low water solubility[1]. Two EDCs usually used in the manufacture of domestic, industrial, and agricultural products are Dibutylphtalate (DBP) and Nonylphenol (NP). They are found in personal-care products, children's toys, and food products, so human population appears to be predominantly exposed to them, through ingestion or skin contact. It has been demonstrated that both are able to damage male reproductive system[2-4]. Due to the important role of prostate gland in male reproduction and fertility, in the present work, we evaluated the effects of DBP and NP, used alone or in different mixtures with or without endogenous sexual hormones as 17-α-estradiol and testosterone on human prostate cell line PNT1A. The first data showed that all EDCs, alone or in mixtures affected cell proliferation. Specifically, we observed a hyperproliferative estrogen-like behaviour of NP that in mixtures seemed to hide the antiandrogenic effect of DBP. We have also shown that DBP and NP activated estrogen receptor pathways, mainly interacting with ERα. Moreover, we investigated EDC ability to induce inflammation that is a first step to prostate gland hyperplasia. We observed that cytokines and chemokines levels, such as IL-9 PDGF, TNFα, MIP-1α, MIP-1α, IL-1α were altered after all the treatments, suggesting NP and DBP involvement in the onset of inflammation processes. In conclusion, we have pointed attention on dangerousness of the mixtures able to induce a strong imbalance of prostate cell physiology.

Di-(2-ethylhexyl) phthalate decreases forskolin-stimulated progesterone synthesis in human granulosa cells

Dragana Samardzija Nenadov, Biljana Tesic, Nebojsa Andric & Kristina Pogrmic-Majkic
University of Novi Sad, Faculty of Sciences, Department of Biology and Ecology, Novi Sad, Serbia

Di-(2-ethylhexyl) phthalate (DEHP) is an endocrine disruptor that belongs to the group of phthalates. Human exposure to DEHP is ubiquitous, considering its use in plastics and other common consumer products. *In vivo* and *in vitro* studies demonstrate its harmful effects on female reproductive system. The aim of this study was to investigate the effects of short term exposure to DEHP on progesterone synthesis in human granulosa cells. The human nonluteinized granulosa cells (HGrC1) were exposed for 48 h to 25 μM DEHP alone or in the presence of 25 μM forskolin (FOR), stimulator of progesterone synthesis. The results showed that exposure to DEHP did not affect the viability of HGrC1 cells. DEHP did not affect basal but decreased FOR-stimulated progesterone production in HGrC1 after 48 h. To clarify the potential mechanism of DEHP-induced decrease in progesterone production in FOR-stimulated HGrC1, we have analyzed the expression of key genes involved in progesterone synthesis. The results showed that DEHP decreased FOR-stimulated mRNA and protein expression of steroidogenic acute regulatory protein, which regulates rate limiting step in progesterone synthesis. Furthermore, the mRNA expression of 3-beta-hydroxysteroid dehydrogenase, an enzyme that converts pregnenolone to progesterone, was downregulated in FOR-stimulated cells after DEHP exposure. These results indicate that short-term exposure to DEHP decreases progesterone production in human granulosa cells, which could have negative impact on ovarian function and fertility. Funding: Science Fund of the Republic of Serbia, program PROMIS, project DETOX, grant number 6062573.

Takayasu's artheritis presenting as a large sellar mass with neurological and hypopituitarism manifestations

Elena Galazzi[1], Noemi Giancola[1], Valeria Citterio[1], Mirella Moro[1], Laura Addobbati[2], Sabrina Avignone[3,4], Franco Capsoni[5,6] & Luca Persani[1,7]
[1]Istituto Auxologico Italiano, Endocrine and Metabolic Diseases Unit, Milano, Italy; [2]Istituto Auxologico Italiano, Division of Neurology and Stroke Unit, Milano, Italy; [3]University of Milan, Italy; [4]Fondazione IRCCS Ca' Granda OspedaleMaggiore Policlinico, Neuroradiology Unit, Milano, Italy; [5]Department of Biomedical Sciences for Health (BIOMETRA), Milano, Italy; [6]istituto auxologico Italiano, Allergology, Clinical Immunology & Rheumatology Unit, Milano, Italy; [7]University of Milan, Department of Medical Biotechnology and Traslational Medicine (BIOMETRA), Italy

Introduction
Only one case of hypophysitis secondary to Takayasu's artheritis (TKA) has been described so far. We report the second case of a TKA presenting with a massive sellar and cerebrovascular infiltration.
Clinical case
A 52 years-old female was referred to endocrine outpatient clinics after a brain MRI performed for a 2-year history of headaches, dizziness and general discomfort. Past medical history included hypertension and aspecific sympthoms (fatigue, nausea, loss of libido). Pituitary MRI found a 13 mm sellar tumor-like lesion extending to the optic chiasm with homogenous gadolinium uptake, pituitary stalk thickening and ectopic neurohypophysis; parasellar T2 dark sign was suggestive for an infiltrating process of the cavernous sinus. Brain angio-RMN revealed sub-occlusion of the intracranial and extracranial trait of the left carotid artery with compensation circles and a stenotic intracranial trait of the right carotid artery. Visual field examination resulted in bitemporal hemianopsias. Endocrine work-up revealed panhypopituitarism with mild hyperpolactinemia, probably secondary to deafferentation. Diabetes insipidus was inferred by low urine osmolarity (290 Osm/kg), but requiring revaluation after glucocorticoids replacement. Adrenal and thyroid function were promptly replaced with sudden recovery of fatigue and nausea. Even in the absence of systemic inflammatory symptoms nor increased inflammatory reactants, screening for possible causes of secondary hypophysitis was undertaken. Serum IgG4 levels, serum and liquor angiotensing converting enzyme levels, serum quantiferon testing and liquor culture, ANCA antibodies were all negative. Doppler ultrasound of carotid arteries revealed possible signs of left carotid dissection but no signs of temporal arteries involvement. Hence, evidence of mild stenosis of coeliac and upper mesenteric artery and left common femoral artery on angio-CT together with a mild uptake in the thoracic and abdominal aorta on 18-FDG PET led to the diagnosis of TKA. Immunosuppressive therapy with high doses of methylprednisolone (1 g bolus e.v. for 3 consecutive days) followed by a down-tapering scheme from 50 mg/day prednisone p.o. was undertaken, then shifted to cortone acetate at replacement doses over one year. Follow-up radiological investigations at 6-12 months showed a marked reduction of pituitary infiltrate and up-take of thoracic/abdominal aorta but an unchanged intracranial artery stenosis. Concomitantly, endocrine follow-up revealed a normalization of prolactin levels and gonadotrope/thyrotrope axis, which allowed the discontinuation of levothyroxine replacement therapy.
Conclusion
Pituitary gland and hypothalamus are very unusual yet possible sites of TKA infiltration. Massive sellar infiltration allowed diagnosis of systemic vasculitis even without inflammatory manifestations, reasonably reducing diagnostic delay and fatal consequences.

Pituitary apoplexy in the aftermath of a SARS-CoV-2 infection: a case series from Amiens University Hospital

Joe Balmain[1], Abdallah Al-Salameh[1,2] & Rachel Desailloud[1,2]
[1]Amiens University Hospital, Department of Endocrinology, Diabetes Mellitus and Nutrition, Amiens, France; [2]University of Picardie Jules Verne, PeriTox=UMR_I 01, Amiens, France

Introduction
Since the outbreak of the COVID-19 pandemic, several cases of pituitary apoplexy following a SARS-CoV-2 infection have been described in several countries. Here, we describe a case series of pituitary apoplexy occurring in the aftermath of a SARS-CoV-2 infection to alert physicians about possible neuroendocrinological damage caused by the virus that can lead to visual sequelae and hypopituitarism.
Methods
We retrospectively identified all the adult patients treated at Amiens University Hospital between March 2020 and May 2021 for pituitary apoplexy confirmed by cerebral imaging and following an RT-PCR-confirmed SARS-CoV-2 infection.
Results
Eight cases (6 women, 2 men) occurred between March 2020 and May 2021 and were reviewed in this study. The mean age at diagnosis was 67.5 ± 9.8 years. Only one patient had a 'known' non-functional pituitary macroadenoma. Pituitary apoplexy occurred within 0-16 weeks after COVID-19. The most common symptom of pituitary apoplexy was a sudden headache. Visual disturbances and/or ocular palsies occurred in six patients while seven patients presented with corticotropic and thyrotropic insufficiencies. There was no diabetes insipidus. Brain imaging was typical in all cases. Only two patients required decompression surgery, whereas the others were managed conservatively. The clinical outcome was favorable for all patients but without recovery of their pituitary deficiencies. No death occurred in our series.
Conclusion
Being the largest case series in the literature, our study provides support for the hypothesis that SARS-CoV-2 may be a new precipitating factor for pituitary apoplexy. The ruling out of various known precipitating factors of pituitary apoplexy reinforces the plausibility, strength, consistency, and coherence of the causal association between SARS-CoV-2 infection and pituitary apoplexy. The main hypothesis to explain the neurotropism of SARS-CoV-2 involves direct infection by the virus, with the olfactory bulb constituting a gateway in the early phase of infection via neuronal pathways, notably via nasal cells during aerosolization. Although angiotensin converting enzyme 2 (ACE2), the cellular receptor for SARS-CoV-2, is not expressed in olfactory neurons, it is expressed in sustentacular and perivascular cells which have structural and protective roles on olfactory neurons. The other putative gateway is via hypothalamic tanycytes glial cells which have been shown to express ACE2 and type 2 transmembrane protease serine (TMPRSS2), both of them are implicated in virus entry. It is essential that practitioners be alerted about possible pituitary disease due to the virus so that such patients are recognized and appropriately managed, hence improving their prognosis.

Introduction
Few studies to date have attempted to evaluate the early efficacy of first-generation somatostatin analogs in somatotroph macroadenomas.
Objective
To investigate the short-term efficacy of primary therapy with lanreotide 120 mg on tumor shrinkage and ophthalmologic symptoms in newly diagnosed patients with acromegaly.
Design and patients
This single-center retrospective study included 21 patients who were newly diagnosed with acromegaly resulting from pituitary macroadenoma and were receiving a primary monthly treatment with lanreotide 120 mg. Clinical, hormonal, ophthalmologic and MRI scan evaluations were conducted after the first and the third months of treatment.
Results
Tumor volume reduction was more pronounced at one month [mean volume change -31.4 $\pm$ 19.5%, $P<0.0001$] than between the first and third month of treatment [mean volume reduction -20.6 $\pm$ 13.4%, $P=0.0009$]. The mean volume change between baseline and the third month was -46.4 $\pm$ 21.6, ($P<0.0001$). A significant volume reduction ($\geq$ 25%) was observed in 61.9% of individuals (13/21) at the first month and in 82.3% (14/17) after three months of treatment. Among 14 individuals with optic chiasm compression and visual field defects, visual field normalization was observed in 3 cases (21.4%) and improvement in 7 cases (50%) at one month. The decrease in GH and IGF-1 serum values was significant at one month.
Conclusions
Primary treatment with lanreotide 120 mg in patients with somatotroph macroadenomas provides early significant tumor shrinkage with rapid improvement of visual symptoms at the end of the first month.

Popa" University of Medicine and Pharmacy, Iasi, Romania; [4]"Cuza Vodă" Clinical Obstetrics and Gynecology Hospital, Maternal-Fetal Medicine, Iasi, Romania

Introduction
Bartter syndrome (BS) is a rare autosomal recessive disorder, with an estimated prevalence of 1 in 1.000.000. It is characterized by a primary defect in sodium chloride reabsorption in the medullary thick ascending limb of Henle's loop. Severe hypokalemia, metabolic alkalosis, hyponatremia, hypochloremia, hyperaldosteronism, and increased urinary loss of sodium, potassium, and chloride can raise the suspicion of BS, but genetic testing is required for a definitive diagnosis. Correct diagnosis and early treatment prevent the impairment of renal function, the development of complications and improve the prognosis.
Case report
We present the case of a 3 years and 7 months-old boy, admitted to our Pediatric Endocrinology Department for short stature (H = 87 cm, -3.32 SD), underweight (W = 9.5 kg) and massive polyuria-polydipsia syndrome (ingestion volume = 5000-7000 ml/day and urine volume = 4000-5000 ml/day) with normal blood pressure. He is the first child of non-consanguineous parents, born prematurely by cesarian section at 32 weeks gestation, appropriate for gestational age, with perinatal asphyxia requiring intensive care. Severe unexplained polyhydramnios was diagnosed in the second trimester and required 3 amnioreductions. During his first 3 years of life, he had multiple hospitalizations in the Pediatric Gastroenterology department where celiac disease, mucoviscidosis and intestinal parasitosis were excluded. In our department, the laboratory tests revealed metabolic alkalosis, hypokalemia, hyponatremia, a high urinary calcium/creatinine ratio and a high urinary potassium/creatinine ratio. Hormonal evaluation identified normal for age thyroid, adrenal and gonadal function, with a possible growth hormone (GH) deficiency (low baseline GH and IGF-1), as well as an elevated copeptin value. The abdominal ultrasound showed bilateral medullary nephrocalcinosis and the brain MRI was normal. As the clinical diagnosis of BS was established, he was started on potassium chloride supplementation and was referred to the Pediatric Nephrology Department where indomethacin was added. The genetic testing detected 3 pathogenic variants in the SLC12A1 gene, confirming BS type I. At the six months follow-up, we noted a reduction of polyuria (=3500 ml/day) and polydipsia (=4000 ml/day), with improved weight gain, while plasma potassium and bicarbonate levels normalized.
Conclusions
Despite being rare in clinical practice, the diagnosis of BS should be considered in any premature neonate with unexplained polyhydramnios and in any child with growth failure, hypokalemia, polydipsia and polyuria. Correct diagnosis and early treatment improve the quality of life of these children, allowing them to reach their full growth potential. Genetic testing helps to establish a specific diagnosis and provides the basis of genetic counseling for family members.

Chondrosarcoma of the cavernous sinus treated with postoperative proton radiation therapy: case report and endocrinological follow up after 36 months

Davide Masi[1], renata risi[1], angela balena[1], alessandra caputi[1], maria elena spoltore[1], rebecca rossetti[1], mikiko watanabe[1], Rossella Tozzi[2], Elena Gangitano[1], stefania mariani[1], Andrea Lenzi[1], lucio gnessi[1] & carla lubrano[1]

[1]Sapienza University of Rome, Department of Experimental Medicine, Section of Medical Pathophysiology, Food Science and Endocrinology, Roma, Italy; [2]Sapienza University of Rome, Department of Molecular Medicine, Roma, Italy

Case Summary
In May 2018, a 22-year-old man was admitted to the Emergency Room of Polyclinic Umberto I Hospital of Rome, because of progressive headaches and binocular diplopia. Brain MRI revealed a heterogeneous T1WI-hypointense and T2WI-hyperintense mass of 40x28x25 mm (CC, LL, AP) including calcification areas in the left paramedian region of the clivus invading the homolateral cavernous sinus. The patient underwent partial tumour resection via infratemporal approach and a diagnosis of intermediate grade myxoid chondrosarcoma was confirmed on histopathology. The patient was discharged with no neurological deficit. Two months later, the patient presented with newly onset of hypoesthesia of the face, ophthalmoplegia, and dizziness. A new MRI showed a heterogeneous calcified mass of 36x25x25 mm (CC, LL, AP) arising from the left cavernous sinus, expanding into the left sphenoid wing and impinging the pituitary gland, which was attributable to relapse of chondrosarcoma. Therefore, a second surgical resection was performed and after three months the patient was treated with high-dose (70 Gy/35 fractions) intensity-modulated proton therapy (IMPT). The patient was discharged without replacement therapy. The treatment resulted in a marked volumetric reduction of the pathological tissue which was stably maintained in the following three years of follow-up. Pituitary function evaluation tested normal except for mild hyperprolactinemia likely due to deviation of the pituitary stalk (Table 1).
Conclusion
The treatment of intracranial chondrosarcomas still remains a major challenge, as brain surgery and IMPT can have a detrimental effect on healthy cerebral areas located proximally to the lesion. This case confirms that IMPT can prevent tumour enlargement while preserving normal pituitary function.

Table 1

Patient's characteristics		36-months follow-up	
Age (years)	22	ACTH	17.60 pg/ml [5.00 - 60.00]
Gender	Male	Cortisol	10.90 mg/dl [3.70 - 19.40]
Symptoms	headache, diplopia, cranial nerve injury	PRL	**34.03 ng/ml** [3.46 - 19.4]
Tumor site	Skull base	TSH	2.00 μUI/ml [0.35 - 4.94]
Histology	Myxoid Chondrosarcoma	FT4	0.99 ng/dl [0.70 - 1.48]
Differentiation	G2	FT3	2.89 pg/ml [1.71 - 3.71]
KPS scores	100	FSH	5.53 mUI/ml [0.95 - 11.95]
Brainstem compression	No	LH	2.16 mIU/ml [0.57 - 12.07]
Optic apparatus compression	No	Estradiol	28.00 pg/ml [11-44]
Recurrent disease	Yes	Total Testosterone	389.04 ng/dl [240.24 -870.68]
Radiotherapy (IMPT)	70Gy/35 fractions	GH	0.31 ng/ml
Metastases	No	IGF1	124.00 ng/ml [98.70 - 289.00]
Any compression	Cavernous sinus, pituitary gland, temporo-mesial parenchyma	Serum sodium	136 mEq/l [136 - 145]
		Serum potassium	4.10 mEq/l [3.50 - 5.10]

Efficacy and safety of long-term high doses of cabergoline in prolactin secreting tumor

Chiara Bona[1], Nunzia Prencipe[2], Enrico Mazza[3], Alessandro Maria Berton[1], Fabio Bioletto[1], Emanuele Varaldo[1], Daniela Cuboni[1], Cristina Gottero[3], Valentina Gasco[2], Ezio Ghigo[1] & Silvia Grottoli[1]

[1]University of Turin, Department of medical sciences, Division of Endocrinology, Diabetology and Metabolism, Turin, Italy; [2]A.O.U. Città della Salute e della Scienza, Department of medical sciences, Division of Endocrinology, Diabetology and Metabolism, Turin, Italy; [3]ASL Città di Torino, Maria Vittoria Hospital, Division of Endocrinology and Metabolic Diseases, Turin, Italy

Purpose
The aim of this study was to identify any predictive factors for need of high doses of cabergoline (CAB) in prolactinomas and to study any relationship between adverse events onset and CAB cumulative dose.
Methods
Forty-two patients harboring resistant prolactinomas (High Dose group-HD; cabergoline dose $\geq$ 3.5 mg/week) were matched by gender, age and pituitary tumor diameter at diagnosis with subjects under standard doses (Standard Dose group - SD). All 84 patients were evaluated in terms of response to treatment and for adverse events onset.
Results
Except for higher PRL levels at diagnosis, no significant differences were documented between HD and SD, nor at diagnosis neither at last follow-up. In HD overall treatment duration was significantly longer (P 0.041) and CAB cumulative dose significantly higher (P 0.0001), with lower response rate, both in biochemical (P 0.0007) and morphological (P 0.03) terms. In particular, PRL levels were significantly lower in SD both at diagnosis and after 3, 6, 12 month of CAB and at nadir (respectively p 0.016, P0.0009, $P<$ 0.0001, P0.0001 and P0.003), this last occurring with a CAB dose lower in SD ($P<0.0001$). Adenoma diameter was smaller in SD (P 0.021) after 12 months of CAB. ROC curves highlighted a threshold PRL value of 1081 ng/ml al diagnosis (sensitivity 62% and specificity 71%, AUC 0.67; P0.007) as predictive for high doses necessity, of 75 ng/ml after 3 months of therapy (sensitivity 81% and specificity 60%, AUC 0.74; P0.0001), of 58 ng/ml after 6 months (sensitivity 76% and specificity 81%; AUC 0.80; $P<$ 0.0001) and of 10 ng/ml after 12 months (sensitivity 97% and specificity 48%; AUC 0.77; $P<0.0001$). All ten patients (over 45 studied, 22.2%) who developed valvular fibrosis were in HD (P 0.019) and underwent a higher cumulative dose of CAB (P 0.003). Five patients (5.9%) developed impulse control disorder, equally distributed among two groups (P 0.67), without significant difference (P 0.40) in CAB cumulative dose.
Conclusion
A PRL value higher than 58 ng/ml after 6 months resulted as the best predictive factor for high doses necessity. No additional risk of impulse control disease was detected in HD, but a higher prevalence of heart valvular fibrosis was recorded. Even though this finding may be partly due to echocardiographic test mainly being performed in such patients, this data should not be underestimated.

Gene expression profiling of subcutaneous adipose tissue reveals new biomarkers in active acromegaly

Camilla Maria Falch[1,2,3], Mai C. Arlien-Søborg[4,5], Jakob Dal[4,5], Arvind Sundaram[6], Annika E. Michelsen[3], Thor Ueland[3], Linn G. Olsen[1,3], Ansgar Heck[1,2], Jens Bollerslev[1,2], Jens Otto Jorgensen[4,5] & Cristina Olarescu[1,2,3]

[1]Oslo University Hospital, Section of Specialized Endocrinology, Department of Endocrinology, Oslo, Norway; [2]University of Oslo, Institute for Clinical Medicine, Faculty of Medicine, Oslo, Norway; [3]Oslo University Hospital, Research Institute for Internal Medicine, Oslo, Norway; [4]Aarhus University Hospital, Department of Endocrinology and Internal Medicine, Aarhus, Denmark; [5]Aarhus University Hospital, Medical Research Laboratory, Department of Clinical Medicine, Aarhus, Denmark; [6]Oslo University Hospital, Department of Medical Genetics, University of Oslo., Oslo, Norway

Objective
Patients with acromegaly present increased insulin resistance despite reduced adipose tissue (AT) mass. Growth hormone (GH) stimulates lipolysis, but the role of AT as a metabolic factor in patients with acromegaly is still uncertain. Moreover, there is a need for better biomarkers of disease activity in acromegaly.
Methods
RNA-sequencing was performed on paired subcutaneous AT (SAT) biopsies from patients ($n=6$) with active acromegaly and after disease control obtained by surgery. Clustering and pathway analyses were investigated. HTRA1, METRNL, S100A8, S100A9, PDGFD, PTX3, MMP9, TEK, ANGPT1, GRN and FLT1 and corresponding proteins were selected for further analyses. In a lager patient cohort ($n=23$), serum proteins were measured by immunoassay. Correlations between GH, insulin like growth factor-I (IGF-I), and visceral AT (VAT), SAT, total AT and serum proteins were analyzed. The *in vitro* effects of GH and IGF-I stimulation on the gene expression of HTRA1, METRNL, S100A8, S100A9 and PDGFD in human subcutaneous adipocytes, endothelial cells (HUVEC) and monocytes (THP-1) were investigated.
Results
743 genes were significantly differentially expressed (470 genes downregulated, 273 upregulated after disease control, p-adjusted <0.05). The patients clustered according to disease activity. Pathways related to growth hormone activity, extracellular matrix deposition/adhesion/collagen, and inflammation/vascularization were among the differentially expressed signaling pathways. Of notice, several collagen genes were upregulated in active disease. Serum levels of HTRA1, METRNL, S100A8, S100A9, and PDGFD significantly decreased after disease control ($P<0.05$). HTRA1, S100A8 and S100A9 correlated with VAT ($0.725<R<0.551$, $P<0.05$). *In vitro* GH and IGF-I stimulation of subcutaneous adipocytes and HUVEC did not change gene expression of HTRA1, METRNL, S100A8, S100A9 and PDGFD. METRNL was increased by IGF-I in THP-1 monocytes.
Conclusion
Disease activity has a stronger impact on the mRNA signature of SAT that overplays the inter-individual differences. Novel candidate genes upregulated in SAT of active acromegaly were identified. Among them, HTRA1, METRNL, S100A8, S100A9 and PDGFD can represent potential biomarkers for disease activity and metabolic risk factors in acromegaly.

The role of advanced glycation end products on vertebral fractures in patients with acromegaly

Meliha Melin Uygur, Dilek Dereli Yazıcı & Dilek Gogas Yavuz
Marmara University, School of Medicine, Division of Endocrinology and Metabolism, Istanbul, Turkey

Introduction
Acromegalic osteopathy is an emerging complication characterized by high risk for vertebral fractures (VFS), whereas bone mineral density (BMD) may not be useful to predict the risk. Recent studies have reported that increased advenced glycation end products (AGEs) are associated with bone fragility. We aimed to evaluate the relationship between AGEs and VFs in patients with acromegaly.
Study design
Cross-sectional
Patients & Methods
We enrolled 70 subjects from the Department of Endocrinology and Metabolism Disease, Marmara University Medical School in acromegaly group (AG) and compared with 70 healthy controls (HC) without any risk factors for secondary osteoporosis and pituitary disorder. We performed vertebral morphometric evaluation of the lateral thoracic and lumbar spine X-ray images, and collected demographic, biochemical, clinical data. AGEs were measured by the auto-fluorescence (AF) reader.
Results
The prevalence of VFs was significantly higher despite elevated BMD in AG than HC (32.9% vs. 8.6%; $P<0.001$). Controlled/cured acromegaly had higher VFs prevalence than active acromegaly (12.5% vs. 38.9%, $P=0.06$). AG had significantly higher levels of AGEs, HbA1c and CTx than HC ($P=0.04$, $P=0.01$, $P=0.001$; respectively). There was a negative correlation between AGEs and CTx in AG ($r=$-0.371, $P=0.001$). In multivariate logistic regression analysis (Table-1), disease duration, IGF-1 levels were negatively correlated with VFs, whereas AF was positively related to the VFs ($R^2=19.23$, $P=0.02$) in the AG.
Conclusion
VFs might occur independently from the disease activity and duration and be an early complication of the acromegaly. AGEs may be useful for assessing the risk of prevalent VFs in this clinical setting.

Introduction
Central diabetes insipidus (CDI) occurs due to deficient secretion of arginine vasopressin (AVP) or antidiuretic hormone (ADH) by the posterior pituitary. It is a rare disease with an estimated prevalence of 1:25000. CDI can be acquired or congenital, secondary to malformation or genetics. Familial CDI (genetic inheritance) is mainly autosomal dominant. More than 80 mutations in the AVP gene have been described. In hereditary CDI, the age of onset is variable. Symptoms arise mostly in childhood but, very often, later. Clinical features include polyuria and polydipsia of variable severity, dehydration, in the absence of volume replacement, and hypernatremia. Partial deficit of oxytocin and carrier protein, estrogen-stimulated neurophysin (ESN), and anterior pituitary hormone deficiency may coexist. The aim of this study is to describe the clinical cases and genetic study of a father and his male firstborn with familial CDI diagnosed with a rare variant c.329G>A;p.p.(Cys110Tyr), in heterozygosity in the AVP gene.
Case Reports
Patient 1 presented polydipsia and low body weight at two years of age. Diagnosis of CDI was confirmed with a water deprivation test. Magnetic resonance imaging (MRI) of skull and sella showed only absence of the neuropituitary signal. Treatment was instituted with intramuscular synthetic vasopressin, and posteriorly modified to nasal desmopressin acetate (DDAVP) spray. He remains without signs and symptoms to date, at 41 years of age, on regular use of DDAVP. Patient 2 is the firstborn of patient 1 and first presented polydipsia and nocturia at age of four. Diagnosis was established at 11 years of age with a water deprivation test. MRI of skull and sella showed only absence of the neuropituitary signal. Treatment was instituted with DDAVP nasal spray and maintained until the present time; at 17 years of age, he remains asymptomatic. Genetic study was performed by exome sequencing, which described the c.329G>A;p.(Cys110Tyr) variant, identified in heterozygosity in the *AVP* gene. This very rare variant results in the substitution of amino acid in the protein encoded and is classified as likely pathogenic. The absence of any other manifestation, unlike other genetic causes of CDI, is highlighted.
Conclusion
We emphasize the possibility that rare diseases, such as CDI, may be familial, and the need for a clinical investigation of family members with similar manifestations and molecular testing and genetic counseling if possible.

Are pre-operative intratumoral haemorrhages and post-operative bleeds sentinel indicators of ''silent'' corticotroph adenomas?

Mohummad Shaan Goonoo[1], Andreea Bojoga[2], Saurabh Sinha[3] & Miguel Debono[4]
[1]Sheffield Teaching Hospitals NHS Foundation Trust, Endocrinology and Metabolic Medicine, Sheffield, United Kingdom; [2]C.I. Parhon National Institute of Endocrinology, Endocrinology and Metabolic Medicine, Bucure||ti, Romania; [3]Sheffield Teaching Hospitals NHS Foundation Trust, Neurosurgery, United Kingdom; [1] Sheffield Teaching Hospitals NHS Foundation Trust, Endocrinology and Metabolic Medicine, Sheffield, United Kingdom

Background
Silent corticotroph adenomas (SCAs) are considered to be clinically silent and non-secreting but exhibit positive adrenocorticotropic hormone (ACTH) immunostaining. Whether, SCAs behave more aggressively than other non-functioning adenomas, remains controversial. We characterized our tertiary centre cohort of SCA patients, compared them to gonadotroph adenomas (GAs) and assessed for features predictive of recurrence.
Objective
To compare characteristics and outcomes of SCAs with GAs at a major tertiary centre.

Methods
We reviewed cases of SCAs operated by one neurosurgeon between January 2010 and January 2019 and matched them by age and sex to the GAs operated on by the same neurosurgeon in a 1:2 ratio.
Results
Our retrospective cohorts included SCAs ($n=13$) followed for median 57 months (range, 13-163 months) and GAs ($n=26$) followed for 72 months (range, 12-132 months). Compared to GAs, SCAs were of similar diameter (2.6 vs 2.0 cm, $P=0.149$) but had an increase in residual tumour size on radiological reporting in 38.5% cases compared to 19.2% among GAs. Intratumoral haemorrhage on *pre-operative* magnetic resonance imaging was reported in 53.8% of the SCAs and 11.5% of GAs ($P=0.008$). Higher mean pre-operative ACTH levels (44.7 vs. 23.0 ng/l, $P=0.024$) and lower mean post-operative prolactin (170.3 vs 305.6 mUI/l, $P=0.032$) were observed in the SCAs group. There was no perioperative mortality in either group. However, in the SCAs group 4/13 patients had significant immediate post-operative haemorrhage (two patients had acute subarachnoid haemorrhage predominantly in the suprasellar region, another had a large acute haematoma around suprasellar cistern requiring craniotomy; the last patient had significant sellar bleeding but good recovery postoperatively) whereas among the GAs, there was no post-operative haemorrhage. At one-year post-operative follow-up, 5/13 patients of SCAs had new onset secondary adrenal insufficiency compared to 1/26 in the GA cohort. During follow-up, all-cause mortality (non-pituitary surgery related) was higher among SCAs compared to GAs (30.8% and 19.2% respectively). Sex, tumour size, Ki67% indices and immediate post-operative cortisol measurement were not statistically found to be influencing the predictability of recurrence.
Conclusion
Our study shows that in the SCAs group, intratumoral haemorrhage was significantly higher and accompanied with greater risk of post-operative complications especially bleeding. A higher rate of deaths was observed in the SCA group but this needs to be confirmed in larger studies.

AZP-3813, a bicyclic 16-amino acid peptide antagonist of the human growth hormone receptor as a potential new treatment for acromegaly

Stéphane Milano[1], Haruaki Kurasaki[2], Tatsuya Tomiyama[2], Patrick Reid[2], Aart Jan Van der Lely[3] & Michael D. Culler[4]
[1]Amolyt Pharma, Ecully, France; [2]PeptiDream, Inc., Kawasaki-Shi, Kanagawa, Japan; [3]Erasmus University Medical Center, Rotterdam, Netherlands; [4]Amolyt Pharma, Cambridge, Massachusetts, United States

Medical treatment of acromegaly is based on either suppressing pituitary GH secretion or inhibiting GH action by preventing interaction with its receptor in order to suppress the elevated levels of IGF1. AZP-3813 is a 16-amino acid, bicyclic peptide antagonist of the GH receptor (GHR) derived from peptide sequences discovered using a unique, cell-free in vitro transcription-translation system screened against the human GHR, and that was optimized by rational design to increase binding affinity, solubility and half-life. The K_D of AZP-3813 for the human GHR is 1.9 nM, and 18.5 nM for the rat GHR. The circulating half-life of AZP-3813 in the rat is 11.2 h. To examine the ability of AZP-3813 to antagonize the interaction between GH and its receptor *in vivo* and thereby reduce IGF1 levels, we injected normal, 5-week old (~150g), male Sprague Dawley rats subcutaneously either with vehicle or with AZP-3813 at doses of 0.3, 1, 3, 10 or 30 mg/kg BID or with 10 or 30 mg/kg QD ($n=8$/group). Blood samples were collected immediately prior to AZP-3813 injection and at 24, 48 and 72 h after injection, and were assayed for total IGF1 content by radioimmunoassay. Twenty-four hours after injection, IGF1 levels were suppressed in a dose-related manner, with maximal and similar degrees of suppression achieved with 30 mg/kg AZP-3813 administered either QD or BID (38.4 + 3.8% and 39.2 + 3.7% decrease from vehicle-treated controls, respectively). By 48 h post-injection, IGF1 levels had returned to the level observed in vehicle-treated control rats. In a follow-up experiment, AZP-3813 was administered subcutaneously daily for 4 days at a dose of 30 mg/kg, either QD or BID. As a comparator, the commercially available GH antagonist, pegvisomant, was also administered subcutaneously for 4 days at a dose of 100 mg/kg QD. Blood samples to be assayed for IGF1 were collected immediately prior to compound injection on all days, and at 24, 48 and 72 h after the last injection. IGF1 was maximally suppressed by AZP-3813 within 24 h after the first injection (47.2 + 2.6% decrease vs vehicle-treated controls), and, with continued treatment, the suppression was maintained through 24 h after the last injection. In contrast, pegvisomant treatment gradually lowered IGF1, reaching a maximal suppression of 32.5 + 3.6% 24 h after the third injection. These results demonstrate that the potent GHR antagonist activity exhibited by AZP-3813 translates to *in vivo* suppression of IGF1 levels, and support its development as a potential therapy for acromegaly.

Clinical aspects of pituitary tumors in patients with Multiple Endocrine Neoplasia Type 1: results from the preliminary study

Stanislaw Zgliczynski[1,2], Magdalena Kochman[3], Wojciech Zgliczynski[3] & Tomasz Bednarczuk[4]
[1]Medical University of Warsaw, Department of Internal Medicine and Endocrinology, Warsaw, Poland; [2]Medical University of Warsaw, Doctoral School of the Medical University of Warsaw, Warsaw, Poland; [3]Centre of Postgraduate Medical Education, Department of Endocrinology, Warsaw, Poland; [1] Medical University of Warsaw, Department of Internal Medicine and Endocrinology, Warsaw, Poland

Introduction
Multiple Endocrine Neoplasia Type 1 (MEN1) is a rare disease inherited in an autosomal dominant pattern, caused by mutations in the MEN1 gene. The cardinal components of this syndrome are: primary hyperparathyroidism (PHPT), gastroenteropancreatic neuroendocrine tumors (NETs) and pituitary tumors.
Aim
The aim of the study was to evaluate clinical features of MEN1 patients under care of two teritiary centers in Warsaw, Poland with special focus on pituitary lesions.
Material and methods
We have used an authorial pre-prepared form in order to gain detailed data on the clinical course of the disease. Until the submission of this abstract (January 2022), study group consisted of 73 participants with diagnosed MEN1 syndrome, aged from 18 to 76 years old (mean 43 $\pm$14 years) and followed-up from 2014 to 2022. As many as 47 of patients were women, 26 were men.
Results
In our group nearly 42% of subjects suffered from all three main components of MEN1 syndrome. Among them: 93% developed PHPT, 78% NETs, 60% pituitary tumors. In 77% of patients we have found other benign neoplasms of which the most common were adrenal adenomas (38%). What is more, 12% of subjects developed other malignant tumors. Out of 44 patients with pituitary tumors, in 26 imaging tests showed pituitary microadenomas, yet macroadenomas were present in next 18 cases. Most common type of tumor was prolactinoma (52%), with a predominance of microadenomas (32% of all pituitary tumors). Moreover, acromegaly was diagnosed in 6 patients what accounted for 14% of pituitary gland lesions cases. At least one pituitary surgery was performed in 11 subjects, 9 of them had hormonally active adenomas (4 prolactinomas, 3 cases of acromegaly, 2 non-functioning pituitary adenomas, 1 thyrotropinoma and 1 corticotropinoma). In two cases more than one operation was required. Dopamine agonists were administered to 18 patients. After PHPT, pituitary tumor was second most frequent first diagnosed component of MEN1 (26% of the group). In nearly 10% of all patients it manifested itself as menstrual disorders or decreased libido. Only in 9% patients NETs were diagnosed as the first component.
Conclusions
Despite the fact that pituitary tumors are the third most frequent tumors in MEN1, they are more likely to cause clinical manifestations than NETs. In our group there was relatively high prevalence of acromegaly. What is more, we observed frequent occurrence of other malignant tumors and noted a large number of adrenal gland adenomas.

Glucagon-stimulated copeptin measurements in the differential diagnosis of diabetes insipidus: a double-blind randomized placebo-controlled study

Cihan Atila[1], Odile Gaisl[1], Deborah Vogt[2], Laura Werlen[2], Gabor Szinnai[3] & Mirjam Christ-Crain[1]
[1]University Hospital Basel, Department of Endocrinology, Diabetology and Metabolism, Basel, Switzerland; [2]University Hospital Basel, Department of Clinical Research, Basel, Switzerland; [3]University Children's Hospital Basel, Department of Paediatric Endocrinology and Diabetology, Basel, Switzerland

Background
The differential diagnosis between central diabetes insipidus and primary polydipsia is challenging. To date, the most reliable approaches are copeptin measurement after hypertonic saline infusion or arginine, which is a known growth hormone secretagogue but has recently been shown also to stimulate the neurohypophysis. Similar to arginine, glucagon is also known to stimulate growth hormone release, but its effect on the neurohypophysis and in the differential diagnosis of diabetes insipidus is unknown.
Methods
In this double-blind, randomized, placebo-controlled trial, we enrolled 22 healthy participants, 10 patients with central diabetes insipidus, and 10 patients with primary polydipsia at the University Hospital Basel. Each participant underwent the glucagon test, i.e., subcutaneous injection of 1 mg glucagon, and placebo test, i.e., subcutaneous injection of 1 ml 0.9% sodium. Plasma copeptin levels were measured at baseline and 30, 60, 90, 120, 150, 180 minutes after injection. The primary objective was to determine whether glucagon stimulates copeptin and to explore whether the copeptin response differentiates between central diabetes insipidus and primary polydipsia.
