Maternal free testosterone (FT) increases during 3rd trimester pregnancy and FT levels are higher in women with polycystic ovary syndrome (PCOS) compared to controls. Fetal exposure to maternal FT during 3rd trimester was associated with lower weight, length and shorter abdominal circumference at birth, in boys. Furthermore, lower birth weight has been related to higher abdominal fat mass in young children.

Aim
To examine associations between maternal 3rd trimester testosterone exposure and body composition in children born of women with and without PCOS using whole body dual X-ray absorptiometry (DXA), and to consider the importance of offspring sex.
Hypothesis
Higher prenatal testosterone exposure associates with more fat mass in young children and boys are more susceptible than girls.
Methods
The study is part of the prospective Odense Child Cohort comprising 1,486 mother-child dyads, with a PCOS diagnosis in 145 (9.8 %) women. *Exposure*: Maternal testosterone at gestational week 28; FT was calculated from total testosterone (TT), analyzed by mass spectrometry. *Outcome*: Body composition of 1,008 children (520 boys) at 7 years-of-age (7.0-7.6 years) measured by DXA (lean body, fat, gynoid- and android fat percentage, fat mass index and fat free mass index) and clinical examination (weight, height, body mass index (BMI), abdominal- and head circumferences). Multiple linear regression models were adjusted for maternal age, parity and birth weight.
Results
Maternal FT and TT were comparable in women carrying a boy or a girl. At age 7 years, boys were significantly higher (126.6 vs 125.5 cm, $P<0.001$) and abdominal circumference was longer (56.5 vs 55.6 cm, $P<0.001$) compared to girls. In boys, a doubling in FT and TT were associated with an increase in weight of 0.53 kg ($P=0.01$) and 0.47 kg ($P=0.05$), respectively and a doubling in FT was associated with an increase in BMI z-scores of 0.16 ($P=0.01$) and a 4.4 % increase in fat mass index ($P=0.03$). A maternal PCOS diagnosis tended to be associated with a lower gynoid fat percentage of 1.8 % ($P=0.07$) in girls.
Conclusion
Prenatal exposure to higher FT was linked to larger weight and fat mass index in boys at 7 years. Our data supported an increased susceptibility to prenatal testosterone exposure in boys compared to girls, which may increase future metabolic risk. Furthermore, gynoid fat percentage tended to be lower in girls of women with PCOS compared to controls.

Mental health and illness uncertainty of individuals with polycystic ovarian syndrome: how is the quality of life affected?

Selda Çelik[1], Merve Murat[1], Gülden Anataca[2] & Hande Peynirci[2]
[1]University of Health Sciences; [2]Kanuni Sultan Süleyman Training and Research Hospital, Turkey

Introduction
Polycystic ovary syndrome (PCOS) stands out as one of the prevalent endocrine disorders affecting women in their reproductive years, impacting 8-13% of females as per World Health Organization (WHO) statistics. This condition has significant repercussions on a woman's sense of self, mental well-being, and overall life quality. While individuals with PCOS often grapple with anxiety and sadness throughout the diagnosis and treatment phases, external factors can influence these emotions. This uncertainty stems from a lack of comprehensive understanding about various aspects of the syndrome, such as its lifelong progression, diverse symptomatology, and overall morbidity. The concept of illness uncertainty, prevalent in both acute and chronic conditions, is characterized in literature as a cognitive stressor, a sense of loss of control, and a state of evolving perceptual doubt. This uncertainty is closely tied to an individual's challenges in adapting to the ongoing process of the disease.
Aim
The objective of this study is to assess the levels of mental health and illness uncertainty in women diagnosed with PCOS and to analyze how these factors influence their quality of life.
Method
This study is a descriptive cross-sectional examination conducted with a pilot sample of 127 women attending a public hospital in Istanbul, Turkey. Information was gathered through a Personal Information Form, along with the Depression Stress and Anxiety Scale, the Mishel Uncertainty in Illness Scale, and the World Health Organization Quality-of-Life Scale (WHOQOL-BREF).
Results
The individuals involved in the study had an average age of 30.9 ± 5.40 years, predominantly single (52.8%), and most had completed high school (62.2%), with incomes generally matching their expenses (44.1%). Regarding PCOS characteristics, the participants were diagnosed with PCOS at a mean age of 18.1 ± 2.17 years. Notably, all participants underwent hormone treatment, with only 29.9% adhering to their medication regimen, and a mere 1.6% receiving PCOS education for self-care. A majority of participants exhibited symptoms such as excess body hair (69.3%), acne (33.9%), irregular menstrual cycles (58.3%), and sexual problems (22.0). The participants recorded elevated scores on the Mishel Uncertainty in Illness Scale, the Depression Stress and Anxiety Scale, and the WHOQOL-BREF.
Conclusion
The findings indicate heightened levels of depression, stress, and anxiety and illness uncertainty among women with PCOS, and implementing targeted interventions has the potential to alleviate these symptoms and raise quality of life.

A multinational study to explore the management of dermatological manifestations associated with polycystic ovary syndrome (PCOS) across europe

Kyranna Lafara[1], Gesthimani Mintziori[1], Dimitrios Goulis[1], Amynta Arshad[2], Sahrish Khan[3], Agatha Chu[4], Angharad James[5], Elmira Abdullayeva[6] & Team Dekode[7]
[1]Unit of Reproductive Endocrinology, 1st Department of Obstetrics and Gynecology, Medical School, Aristotle University of Thessaloniki, Thessaloniki, Greece; [2]Birmingham Medical School, University of Birmingham, Birmingham, United Kingdom; [3]Queen Elizabeth Hospital, Birmingham, United Kingdom; [4]Hull University teaching hospital NHS trust, Hull, United Kingdom; [5]South Tyneside and Sunderland NHS Foundation Trust, South Tyneside, United Kingdom; [6]PCOS and hirsutism clinic, yeditepe University hospital, Instabul, Turkey; [7]Institute of Applied Health Research, University of Birmingham, Bermingham, United Kingdom

Objective
To investigate the management of dermatological manifestations associated with PCOS and its management across Europe.
Methods
This multinational retrospective study was conducted from June 2023 to January 2024. All women over 18 years of age attending a first consultation for PCOS from 1st January 2020 to 30th December 2023 in the UK ($n=359$), Turkey ($n=239$), Greece ($n=92$) and Georgia ($n=10$) were included. Those without PCOS or undergoing follow-up were excluded. Data was collected during the first consultation, including sociodemographic variables, reasons for referral, dermatological manifestations, and treatment before and after consultation. Descriptive statistics were performed with SPSS 28.0.
Results
In total, 700 women were seen for the first PCOS consultation. The most common reasons for referral across all countries were irregular menses (65.7%), hirsutism (61.1%) and acne (38.9%). Irregular menses were the most common reason for referral in the UK (59.6%), Greece (82.6%) and Georgia (100.0%), whereas hirsutism was the most common reason for referral (70.3%) in Turkey. Overall, 74.6% of referrals were made due to women having dermatological concerns (UK: 60.7%, Turkey: 94.1%, Greece: 77.2% and Georgia: 100.0%). In total, 611 (87.3%) women were diagnosed with a form of dermatological manifestation of PCOS after the first consultation. All countries showed a similar trend in dermatological diagnoses made, with hirsutism being most common (UK: 92.5%, Turkey: 71.4%, Greece: 85.5% and Georgia: 100.0%) followed by acne (UK: 34.0%, Turkey: 69.6%, Greece: 78.3% and Georgia: 40.0%) and androgenic alopecia (UK: 16.3%, Turkey: 11.2%, Greece: 10.8% and Georgia: 10.0%). Before the first consultation, laser hair removal was the most popular treatment for hirsutism across all countries (33.4%), followed by the oral contraceptive pill (OCP) (22.4%) and shaving (13.9%). Laser treatment was most popular in Turkey (51.8%), Greece (39.8%) and Georgia (90.0%), whereas shaving was most popular in the UK (26.9%). Following assessment at first consultation, 446 (73.0%) women were commenced on pharmacological treatment for hirsutism. Across all countries, the most common drug prescribed was spironolactone (40.8%), followed by the OCP (35.4%) and metformin (32.1%). In the UK, metformin was the most prescribed drug (54.4%), whereas the OCP was the most prescribed drug in Greece (29.9%) and Georgia (100.0%). Spironolactone was most prescribed in Turkey (68.8%).
Conclusion
Dermatological concerns associated with PCOS comprise a large proportion of referrals to tertiary care. Developing a standardised approach to assess and manage dermatological concerns may minimise variation in care internationally and improve patient outcomes.

The risk of obesity and metabolic complications in hyperandrogenic physically inactive young women with PCOS

Justyna Kuliczkowska-Płaksej[1], Aleksandra Jawiarczyk-Przybylowska[1], Lukasz Gojny[1], Aleksandra Zdrojowy-Wełna[1], Felicja Lwow[2] & Marek Bolanowski[1]
[1]Wrocław Medical University, Department of Endocrinology, Diabetes and Isotope Therapy, Wroclaw, Poland; [2]Wroclaw University of Health and Sport Sciences, Department of Physiotherapy, Wroclaw, Poland

Background
Polycystic ovary syndrome (PCOS) is a condition affecting up to 20% of reproductive-aged women. PCOS is associated with obesity and serious metabolic complications. There is a lack of research evaluating differences in metabolic complications between hyperandrogenic physically active and inactive individuals.
Objective
We used a cross-sectional study to compare the risk of obesity, metabolic syndrome, visceral adipose index, and insulin resistance between normoandrogenic, hyperandrogenic, and healthy women, as well as hyperandrogenic active and inactive women.
Participants and design
A total of 259 women aged 20–35, of which 148 had PCOS and 111 were healthy age-matched controls. Anthropometric parameters were calculated and hormonal and biochemical assays were performed in all patients. Physical activity (PA) level was assessed using the International Physical Activity Questionnaire and each participant was classed as inactive or active.
Results
We found an association between free androgen index and PA in hyperandrogenic PCOS women, but not in normoandrogenic or healthy women. Hyperandrogenic individuals presented higher odds ratios of obesity (7.3 times, $P < 0.001$), metabolic syndrome (9 times, $P < 0.001$), and insulin resistance (3.84 times, $P < 0.001$) than the normoandrogenic women. Furthermore, hyperandrogenic women who performed at least 7.5 MET $\times$ h $\times$ week^{-1} of physical activity had lower odds ratios of obesity (5.67 times; $P < 0.001$), MS (5.69 times; $P < 0.001$), and insulin resistance (2.99 times; $P < 0.005$) than inactive hyperandrogenic individuals.
Conclusion
Physical activity should be recommended as an important element for health improvement supporting pharmacotherapy, especially in hyperandrogenic PCOS women.

Early changes in muscle strength and body composition under gender-affirming hormonal therapy in transgender people assigned female at birth

Seda Hanife Oguz[1], Banu Ertürk[2], Sinem Güneri[3], Alp Çetin[3] & Bulent Yildiz[1]
[1]Hacettepe University School of Medicine, Department of Internal Medicine, Division of Endocrinology and Metabolism, Ankara, Turkey; [2]Hacettepe University School of Medicine, Department of Internal Medicine, Division of Endocrinology and Metabolism, Ankara, Turkey; [3]Hacettepe University School of Medicine, Department of Physical Therapy and Rehabilitation, Ankara, Turkey

Background
The effects of gender-affirming hormonal therapy (GAHT) on body composition in transgender people assigned female at birth (AFAB) have been an area of interest. However, the impact of GAHT on muscle strength remains inadequately studied. We aimed to evaluate early alterations in muscle strength following GAHT in transgender people AFAB by isokinetic dynamometry, the gold standard for assessment of strength.
Subjects and Methods
A total of 20 transgender people AFAB were assessed at baseline, and after 3 months of testosterone injections. Fifteen participants were also assessed after 6 months. Muscle strength parameters including lower limb peak torque (PT), PT to body weight ratio (PT/BW) and average PT (AvPT) were measured using isokinetic dynamometry. Hand-grip strength (HGS) was also assessed by a dynamometer. Bioelectrical impedance analysis was used to assess body composition characteristics. Serum androgens, fasting glucose and insulin were measured at all three time points.
Results
The mean age and BMI ($\pm$SD) were 23.0$\pm$3.5 years and 25.1$\pm$5.7 kg/m^2 at baseline. Free androgen index was correlated with lean body mass ($r = 0.45$, $P = 0.04$), and fasting insulin was with truncal fat mass ($r = 0.65$, $P = 0.002$) before initiation of GAHT. BMI did not show a significant change after 3 and 6 months of GAHT. After three months, significant increases occurred in knee flexors' PT (56.6$\pm$18.7 N-m to 63.7$\pm$20.1 N-m, $P = 0.008$), PT/BW (82.5$\pm$24.2% to 92.8$\pm$27.3%, $P = 0.01$) and AvPT (52.1$\pm$17.0 N-m to 57.9$\pm$18.7 N-m, $P = 0.02$), as well as in lean body mass (49.8$\pm$9.0 kg to 54.6$\pm$8.9 kg, $P = 0.001$). There were no further alterations in these composition and strength parameters after 6 months. However, an increase in HGS was only significant after 6 months. Serum creatinine increased significantly with GAHT but remained within the normal range. Lean body mass and knee flexors' AvPT were positively correlated at all timepoints. Muscle strength did not show any correlation with biochemical parameters including serum androgens and insulin.
Conclusion
Our results suggest an early increase in lower limb muscle strength and lean body mass within the first three months of GAHT in transgender individuals AFAB which are preserved and accompanied by a significant increase in upper limb strength at 6 months. Muscle strength appears to be associated with lean body mass. Given these outcomes, early initiation of an exercise plan to further enhance muscle mass and mechanical function may be considered for individuals undergoing GAHT.

"Brief intelligence test" questionnaire in klinefelter syndrome: may words improve diagnosis?

Davide Vimercati[1], Lorenzo Marinelli[2], Serena Cagnina[2], Tommaso Daffara[1], Andrea Bichiri[2], Cataldo Di Bisceglie[2], Giovanna Motta[2], Fabio Lanfranco[3] & Marco Zavattaro[1]
[1]Ospedale Maggiore di Novara, Novara, Italy; [2]Azienda Ospedaliero-Universitaria Città della Salute e della Scienza di Torino, Torino, Italy; [3]Humanitas Gradenigo, Torino, Italy

Background
The clinical burden of Klinefelter Syndrome (KS) is not limited to the impairment of gonadal function and an increased prevalence of cardio-metabolic, endocrinological and oncological diseases, but also involve several cognitional, behavioural and psychological issues. Because of the wide heterogeneity in clinical phenotype, the diagnosis of KS is still challenging, resulting in a significant number of patients to remain undiagnosed or to have a late diagnosis. Verbal deficits in reading/-spelling, delayed language development, impaired syntax, word retrieval and language production/perception are among the most characteristic functional features of KS (up to 70-80% of patients) determining a slight reduction in verbal Intelligence Quotient (IQ). The primary endpoint of our study was to focus on language skills in the area of reading, thus further evaluating whether specific questionnaires might represent a reliable tool for early diagnosis of KS.
Methods
An observational, cross-sectional, multicenter study was performed, consecutively enrolling adult KS patients and a control group of unaffected males, matched for age and years of study, referring to the outpatient clinics of the "S.C.U. Endocrinology, Diabetology and Metabolism - University of Turin" from 1st November 2018 until 1st September 2021 All patients performed the "Brief Intelligence Test" (TIB) test for assessing the overall, verbal and performance IQ. This validated questionnaire relies on the correlation between global intelligence and reading skills, leading to explore the areas of language and learning through the evaluation of errors in pronunciation and accentuation of 54 commonly used words read aloud.
Data on andrological anamnesis, physical examination and hormonal profile were also recorded.
Results
34 unaffected males and 34 KS patients, aged [median (IQR)] 46.5 (45.75 - 54.75) years and with an average length of studies of 15.0 (8.0 - 15.0) years, were enrolled. KS patients were more prone to make mistakes in accentuation ($p < 0.001$) but not in pronunciation ($p = 0.119$) than controls, leading to lower scores (but still within normal range) in overall, verbal end performance IQ ($p < 0.001$). None of the clinical and hormonal variables was found to correlate with the TIB and IQ scores.
Conclusions
TIB questionnaire proved to be a reliable tool in highlighting verbal deficits in KS patients (especially in reading) when compared to unaffected males. Thus, the use of TIB might represent a very useful, quick and effective tool for screening verbal disabilities in a wide number of people, potentially improving the possibility of early diagnosis of KS.

Comprehensive WES reanalysis of rare endocrine patients for the identification of novel disease-causing genes

Muhammad Yousaf[1], Mariateresa Zanobio[2], Francesca Allosso[1], Vincenzo Nigro[2] & Daniela Pasquali[1]
[1]University of Campania Luigi Vanvitelli, Department of Advanced Medical and Surgical Sciences, Naples, Italy; [2]University of Campania Luigi Vanvitelli, Department of Precision Medicine, Naples, Italy

Rare diseases affect more than 300 million people worldwide, often lead to chronic illness, disability, and premature death. The recent advancements in genetics through Next Generation Sequencing (NGS) have revolutionized research and diagnostics. NGS technologies allowed the identification of novel candidate disease-causing genes, significantly also in-depth modification of our understanding of genetic architecture of various rare endocrine diseases. However, despite these recent advancements, over 50% of cases typically remain unsolved. In these unsolved cases, periodical reanalysis has been proposed as a solution to enhance the diagnostic yield. Here, we report results from WES reanalysis of patients with endocrine pathological phenotype from Telethon Undiagnosed Disease Program (TUDP). Our study aimed to identify potential novel disease-causing genes by focusing on unsolved patients, whereas reanalysis of solved patients could reveal potential link of already known disease-causing genes in the endocrine disorders. TUDP cohort comprised of 4809 solved and 6278 unsolved patients. Initially, we selected 359 patients among the solved and 227 patients from unsolved ones, based on human phenotype ontology (HPO). Successively, we considered 39 solved and 26 unsolved patients which had the strongest endocrine phenotype for this pilot study. WES data reanalysis was performed employing bioinformatics in-house pipelines, whereas human genome version 19 (hg19) was used as the reference genome in all cases. For variant interpretation, established guidelines were used as VarSome germline classification. Moreover, we also interrogated variants and genetic disorders databases to validate the association of genes with the patient's phenotype. Furthermore, results from each analysis were compared with the most recent literature studies. Preliminary results obtained from solved patients led us to detect a *de novo AFF2* mutation (NM_002025:c.1444G>A; p.Gly482Arg in exon 10) in a patient diagnosed with cryptorchidism. Among the unsolved patients, a heterozygous compound *PKD1* variant (NM_001009944.3 :c.12436G>A; p.Val4146Ile and c.3496G>A; p.Gly1166Ser, respectively in exon 45 and 15) was observed in a patient with clinical presentation of Hypophosphatemic Rickets. To better understand the putative involvement of *PKD1* gene in endocrine disorders, we are searching for other patients carrying variants in the same gene interrogating MatchMaker Exchange platforms, which facilitates the matching of phenotype-genotype for candidate disease-causing genes connecting researchers and clinicians worldwide. Based on these results, we provide practical evidence to increase novel genetic diagnosis through WES reanalysis. Finally, this study emphasizes the power of reanalysis of WES data, particularly in a clinical context given the implications.

Endocrine responses to kisspeptin in an unusual case of kallmann syndrome with unilateral anosmia

Jovanna Tsoutsouki[1], Alexander N Comninos[1,2], Maria Phylactou[1,2], Bijal Patel[1], Edouard Mills[1,2], Megan Young[1], Arthur Yeung[1], Kanyada Koysombat[1], Manish Modi[1], Deborah Papadopoulou[1,2], Sasha Howard[3], Waljit S Dhillo[1,2] & Ali Abbara[1,2]
[1]Section of Investigative Medicine, Department of Metabolism, Digestion and Reproduction, Imperial College School of Medicine, Imperial College London, London, United Kingdom; [2]Department of Diabetes and Endocrinology, Imperial College Healthcare NHS trust, London, United Kingdom; [3]Department of Paediatric Endocrinology, Queen Mary University of London, London, United Kingdom

Introduction
Kallmann syndrome (KS) is a rare condition characterised by congenital hypogonadotropic hypogonadism (CHH), usually due to defective migration of olfactory axons and GnRH-neurons. KS is typically associated with absent (anosmia) or reduced (microsmia) sense of smell. Unilaterally hypoplastic or absent olfactory bulbs on MRI are reported, although disturbance in smell is usually bilateral. Kisspeptin is a potent stimulator of hypothalamic GnRH-neurons, and endocrine responses to kisspeptin boluses are usually minimal in CHH. We present an unusual case of KS with unilateral anosmia and her responses to kisspeptin.
Case Presentation
An 18yr old woman presented to the endocrine clinic for management of KS. Her mother and sister were known to have KS (heterozygous for FGFR1-mutation) having previously presented with primary amenorrhea and anosmia. Her mother required ovulation induction to conceive. She had spontaneous albeit borderline late menarche aged 16yrs, but only five menstrual periods over the subsequent two years, followed by secondary amenorrhea. She didn't have any other medical history, psychological stress, undertake excessive exercise and took no regular medications. At presentation, her BMI was 22 kg/m^2 and she had normal secondary sexual characteristics. Unusually, she reported a normal sense of smell via the right nostril, but anosmia via the left nostril. Unilateral anosmia was confirmed with an UPSIT smell test (right nostril 32/40 (normosmia); left nostril 12/40 (anosmia)). MRI-brain revealed unilaterally absent left olfactory nerve, bulb, and sulcus. She had undetectable serum estradiol (<100 pmol/l), low LH (0.2 IU/l) and low FSH (0.4IU/L). Pelvic ultrasound demonstrated a thin endometrium (3mm), consistent with hypoestrogenism. Whole-exome sequencing confirmed a heterozygous FGFR1 variant. An intravenous GnRH-test (100 mg) induced an LH rise of 24.8IU/L indicating a functional pituitary gland. An intravenous bolus of kisspeptin-54 (9.8 nmol/kg) induced a subnormal early rise in LH (3.4IU/L), which is greater than typically seen in CHH. On separate occasions, intranasal (12.8nmol/kg) KP54 delivered only to the right nostril, led to a small rise in LH of 0.5IU/L, whereas KP54 delivered only to the left nostril did not induce any LH rise.
Discussion
This lady had spontaneous puberty and menarche indicating some residual GnRH-neuronal function, despite inheriting an FGFR1 variant. Further, she had a small early subnormal gonadotropin response to kisspeptin, rather than the absent response typically observed in complete KS. This, and in view of her unilateral anosmia, unilateral olfactory bulb on MRI, a unilateral albeit small response to intranasal kisspeptin-54, suggest that she has an unusual partial/unilateral form of KS.

Hypoechoic testicular lesions in klinefelter syndrome show volumetric reduction in response to testosterone therapy

Davide Ferrari[1], Franz Sesti[1], Marta Tenuta[1], Francesco Carlomagno[1], Daniele Gianfrilli[1], Carlotta Pozza[1] & Andrea Isidori[1]
[1]Sapienza University of Rome, Department of Experimental Medicine, Rome, Italy

Introduction
Patients with Klinefelter Syndrome (KS) often display small, multiple, non-palpable, and typically benign testicular micro-nodules at ultrasonographic examination, representing Leydig cell hyperplasia or Leydig tumors. Increased LH levels raising from testicular damage might play a pivotal role by acting as growth factor for Leydig cells. To date, evidence on the efficacy of testosterone replacement therapy (TRT) on decreasing the micro-nodules volume are lacking.
Materials and Methods
We prospectively evaluated KS patients with classic karyotype (47, XXY) aged 15 to 50 years and naive to TRT. This evaluation included testicular ultrasound and hormone assessment. Mosaic karyotypes, previous pituitary surgery or radiotherapy or medications affecting the hypothalamus-pituitary-gonadal axis were excluded. Hypogonadal patients who received TRT were assessed after at least 6 months to evaluate the estimated volumetric change in the micro-nodules. The volume of hypoechoic lesions was calculated with the sphere formula ($1/6 * \pi * D^3$). For multiple lesions, the sum of the volumes of the two dominants lesions for each testicle was considered.
Results
Seventy patients (mean age 26.4±8.7 years) were included in the study, 35 of which (Group A) displayed at least one testicular micro-nodule, while the other 35 (Group B) did not show clear lesions. Group A patients were significantly older than those in Group B (P=.010) and showed higher LH levels (P=.001) and lower Testosterone/LH ratio (P=.005), though total Testosterone (tT) levels did not differ significantly (P=.328). Testicular microlithiasis was present in 18 patients, 12 (34%) from Group A and 6 (17%) from Group B (P=.086). The tT/LH ratio effectively predicted the presence of micro-nodules (B= -1.074, OR= 0.342, 95CI= 0.123 - 0.947, P=.039) whereas the increase in age (P=.265) and concomitant microlithiasis (P=.482) did not reflect in increased lesion risk. An interim longitudinal analysis was performed on 20 of the patients who started TRT(44% gel, 56% injective). After 16.7 (11.9-31.2) months, the micro-nodules displayed significant volumetric reduction (62.9 to 22.9 mm^3, P<.001) and were no longer detectable in 4 patients (20%). No difference was observed in volumetric change between TRT formulations (P=.897). Treatment duration did not correlate with the micro-nodules volumetric reduction (P=.512).
Conclusion
Our data demonstrate for the first time the efficacy of TRT in reducing the volume of testicular, non-palpable hypoechoic micro-nodules in patients with KS. These changes are likely secondary to the restoration of more physiological LH and tT/LH.

Patient and public involvement in simulation via instant messaging – birmingham advance (SIMBA) training improves clinicians' confidence in managing reproductive endocrinology cases

Sangamithra Ravi[1], Tamzin Ogiliev[2], Maiar Elhariry[1], Pavithra Sakthivel[1], Abby Radcliffe[1], Rahul Sagu[1], Harshin Balakrishnan[3], Dengyi Zhou[4], Punith Kempegowda[5,6] & Simba and Comics team[5]
[1]College of Medical and Dental Sciences, University of Birmingham, Birmingham, United Kingdom; [2]Lancaster University Medical School, Lancaster, United Kingdom; [3]School of Medicine, Far Eastern Federal University, Vladivostok, Russian Federation; [4]London North West University Healthcare NHS Trust, Harrow, United Kingdom; [5]Institute of Metabolism and Systems Research, College of Medical and Dental Sciences, University of Birmingham, Birmingham, United Kingdom; [6]University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom

Introduction
Simulation via Instant Messaging – Birmingham Advance (SIMBA) is a virtual simulation-based medical training model that improves clinicians' confidence. However, it has lacked input from patients living with these conditions. Engaging patients and members of the public in the formulation and discussion of cases could guide clinicians to tailor management to meet the concerns and expectations of patients better.
Method
A two-day conference took place on 27 and 28 September 2023. Nine reproductive endocrinology cases, focussing on PCOS (two cases), Thyroid disease, Premature Ovarian Insufficiency, Menopause, Azoospermia, Opiate induced hypogonadism, Idiopathic hypogonadism and Kallman syndrome, were simulated over the two days via Whatsapp in real-time. Real patient cases, anonymised to maintain confidentiality, were used to formulate these scenarios. Members of the general public living with these conditions were recruited from several support groups to partake in a workshop-style discussion to provide their opinions on how representative the cases were and how the management of the condition could be improved. Following the simulated cases, the content was discussed by expert speakers, each a specialist in various aspects of reproductive endocrinology. This discussion was interactive so that participants could ask questions and clarify doubts. Pre- and post-SIMBA surveys were sent to participants to evaluate self-perceived improvement in confidence and ACGME Core Competencies, as well as perceptions surrounding SIMBA. Quantitative and qualitative analysis of these responses was undertaken using the Wilcoxon Signed Rank test and thematic analysis of the open-ended questions respectively.
Results
In total, 29 participants completed both the pre- and post-session surveys. Overall, participants' self-reported confidence of simulated cases significantly increased from 36.54% to 88.62% on Day 1 ($n=16$) and from 36.54% to 84.62% on Day 2 ($n=13$) post-session ($P<0.0001$). Self-reported improvements in ACGME Core Competencies were seen in most participants, with 100% ($n=29$) in knowledge of patient management, system-based practice and practice-based learning, and 96.55% ($n=28/29$) in patient care and professionalism. 100% ($n=29$) of participants rated the session as excellent or good and 93% ($n=27/29$) would attend future sessions. Thematic analysis of open-ended questions revealed clinicians' improvements in clinical knowledge and communication skills.
Conclusion
Patient involvement in SIMBA effectively improved clinicians' confidence in reproductive endocrinological scenarios. Implementing SIMBA in larger-scale studies will determine the long-term effectiveness of simulation-based learning in reproductive endocrinology.

Revitalizing kidney health in polycystic ovary syndrome: a novel approach— targeting STAT3 signaling for restored mitochondrial function and reduced kidney injury

Samar Rezq[1], Jelina Basnet[1], Alexandra M Huffman[1], Joseph Flaherty[1], Ngoc H Hoang[1], Kristin Edwards[1], Licy L Yanes Cardozo[1] & Damian G Romero[1]
[1]University of Mississippi Medical center, Pharmacology and Toxicology, Jackson, United States

Background
Polycystic ovary syndrome (PCOS) is characterized by hyperandrogenism and polycystic ovaries. Renal injury is prevalent in PCOS, yet the molecular mechanisms are poorly understood. The JAK/STAT3 signaling pathway, activated by the inflammatory cytokine interleukin-6 (IL-6), negatively impacts renal mitochondrial function to induce oxidative stress and renal injury. Despite its chronic activation by excess androgen in extra-renal tissues in PCOS, its role in PCOS associated renal injury is unknown. We aimed to test the hypothesis that excess androgen activates the JAK/STAT3 pathway, leading to renal injury by inducing mitochondrial dysfunction in PCOS.
Methods
PCOS was induced in 3-week-old female mice by dihydrotestosterone Silastic tubes implantation (DHT, 8 mg, 12 weeks). Eight weeks later, the mice were given the JAK/STAT3 inhibitor Stattic (10 mg/kg, SC, 3x/week) or vehicle for 4 weeks. Kidney weight, serum IL-6 (Bioplex), glomerular filtration rate (GFR, transcutaneous fluorescence), and urinary albumin to creatinine ratio (UACR, clinical chemistry analyzer) were assessed. Renal JAK1, JAK2, active STAT3 [phosphorylated-STAT3 (Tyr705)], total STAT3, and mitochondrial markers (cytochrome C, succinate dehydrogenase A, and stress protein HSP60) were assessed by Western blot. IL-6 mRNA was quantified by RT-qPCR. Histopathological analysis was done in H&E-stained renal sections. Mitochondrial reactive oxygen species (mtROS, Amplex Red assay), complexes I and II-driven respiration, and complex IV activity (Oroboros Fluorespirometer) were measured in freshly-isolated kidney mitochondria. Oxidative stress measurement (DCF fluorescence) was performed in DHT (10nM)/Stattic (100nM) or vehicle-co-treated mouse proximal tubule (MCT) cells.
Results
DHT significantly increased kidney weight, UACR, and both systemic and renal IL-6 levels (1.4-3.2-fold) while decreasing GFR (1067.2 $\pm$ 59.9 vs 1335.6 $\pm$ 60.3 uL/min/100g body weight). PCOS mice have more active STAT3 signaling (higher JAK1, JAK2, and active STAT3). Renal mtROS was higher (2-fold) and complexes I, II, III, and IV respiration was lower (43-71%) in PCOS mice, along with lower cytochrome c (32%), and higher HSP60 (4-fold) levels. These changes were associated with worsen renal histological structure with congested glomeruli and luminal epithelial lining exfoliation. Stattic didn't affect kidney weight but normalized UACR and GFR while decreasing both glomerular and tubular injury. Stattic decreased renal HSP60 and mtROS generation while increasing complexes I, II, and IV derived respiration. Stattic co-treatment abolished DHT-mediated oxidative stress in MCT cells.
Conclusion and significance
Our findings suggest that STAT3 activation plays a significant role in renal outcomes in PCOS, and its targeting could be a novel therapeutic approach to ameliorate renal injury in PCOS.

Klinefelter syndrome is associated with early-onset metabolic defects that are not reversed by testosterone therapy

Karim Chouchane[1], Susanna Hofbauer[1], Ilaria Giordani[1], vionnet nathalie[1], Mohammed Barigou[1], Nelly Pitteloud[1], Michael Hauschild[2] & Georgios Papadakis[1]
[1]Lausanne University Hospital, Service of Endocrinology, Diabetes and Metabolism, Lausanne; [2]Children Hospital, Unit of pediatric endocrinology-diabetology, Lausanne, Switzerland

Background
Klinefelter syndrome (KFS) is the most common chromosomal aberration in men, characterized by an extra-X chromosome (47, XXY). Besides the well-known reproductive defects, KFS is characterized by a 4-fold increase in metabolic syndrome, cardiovascular morbidity and mortality. The exact cause of this constellation remains unclear.
Methods
Data from non-mosaic KFS adults and adolescents, evaluated in the endocrine unit of Lausanne University Hospital between 2015 et 2022, were analyzed. Only men without testosterone replacement therapy (TRT) at the moment of evaluation were included. Metabolic phenotyping consisted of a fasting blood test, an oral glucose tolerance test and body composition assessment using Dual X-ray absorptiometry. A longitudinal analysis was conducted in men with available metabolic data after at least 1 year of TRT intake.
Results
seventy-five men were included of whom 57 at diagnosis (TRT-naïve) and 18 after TRT wash-out. The cohort spanned across a large age range (31.4 $\pm$ 11.9 years). As expected, the majority of patients were hypogonadal, defined as clinical and biochemical [morning serum total testosterone (T) $<$ 10.4 nmol/l] signs of testosterone deficiency. Mean TT levels were moderately decreased (9.4 $\pm$ 6.1 nmol/l) as opposed to normal estradiol (E) levels (0.09 $\pm$ 0.03 nmol/l). Consequently, most participants had relative hyperestrogenism defined as a T/E

ratio < 100. Roughly half of participants were overweight (BMI > 25 kg/m^2), whereas two third of them were insulin resistant (HOMA-IR > 2.6) and had fat excess defined as a fat mass index (FMI) > 6 kg/m^2. Hypogonadal men had higher incidence of metabolic syndrome (26% vs 11%), glucose intolerance (33% vs 10%) and hypertension (11% vs 5%) as compared to those with normal TT levels. Linear regression revealed an inverse association of T with several metabolic traits including FMI (r=-0.48, P=0.002) and HOMA-IR (r=-0.33, P=0.03). Interestingly, T/E ratio exhibited even stronger associations (r=-0.66, P<0.0001 and r=-0.46, P=0.002 for FMI and HOMA-IR, respectively). Sustained TRT intake in 20 patients for a mean follow-up of 5 years led to a slight but significant increase in BMI (mean delta + 1.2 kg/m^2, P=0.02). FMI and HOMA-IR did not significantly improve during TRT.

Conclusions

KFS is characterized by high metabolic risk that is only partially reflected in BMI. Besides hypogonadism, other imbalances such as relative hyperestrogenism may contribute to the metabolic deterioration. The absence of improvement in surrogate metabolic markers by long-term TRT implies the need to evaluate additional therapies for KFS-associated metabolic risk.

4 Cases of postmenopausal hyperandrogenism in glasgow

Ashley Leong[1], Mohammed Azharuddin[2], Chris Jones[2] & Hiba Abdelrahman[2]
[1]University of Glasgow, United Kingdom; [2]Inverclyde Royal Hospital, United Kingdom

Background

New onset postmenopausal hyperandrogenism (PMH) is rare and is a diagnostic and therapeutic challenge.

Clinical Case

AB, a 69-year woman, had 14-years of hirsutism and 1-year of male-pattern balding. Androgen profile was high: testosterone (T) 4.9nmol/L, androstenedione (A) 3.7nmol/L, 17OHP 2.3nmol/L. DHEAS and pre- and post-1 mg ONDST cortisol was normal. Adrenals and ovaries on CT were unremarkable, hence benign ovarian source assumed. She declined surgery, leuprolin and finasteride. Spironolactone was trialled but discontinued due to nephrotoxicity. Symptoms are currently controlled by topical minoxidil. CD, a 46-year woman, had 1-year of hirsutism, clitoromegaly, mood changes and bilateral labial hypertrophy. Androgen profile was high (T 2.0nmol/L; A 4.8nmol/L; 17OHP 6.9nmol/L); a normal SST excluded NCCAH. DHEAS was normal. TVUS showed normal ovaries; MRI showed unremarkable ovaries and adrenals. Benign ovarian source was assumed. Leuprolin caused T suppression (1.1nmol/L after 5 months), hence laparoscopic BSO was done; ovarian histology was normal with few cystic follicles. 2 months later, A reduced (3.2nmol/L) and symptoms improved. WX, a 58-year woman, had 4-years of hirsutism and male-pattern balding. Pre- and post-ONDST androgen profile was high (T 12.4nmol/L, A 5.4nmol/L, 17OHP 2.8nmol/L) with no suppression (T 11.3nmol/L, A 4.4nmol/L, 17OHP 2.7nmol/L). ACTH, pre- and post-ONDST cortisol, DHEAS, 24h-urinary steroids and CA125 were normal. CT showed unremarkable adrenals and ovaries. Benign ovarian source was assumed. Leuprolin improved biochemistry (T <0.5nmol/L, A 1.4nmol/L after 3 months) and symptoms. WX awaits bilateral oophorectomy. YZ, a 56-year woman, had 9-months of hirsutism, hair loss and mild clitoromegaly. Pre- and post-ONDST androgen profile was high (T 4.9nmol/L, A 3.7nmol/L, 17OHP 2.3nmol/L) with no suppression (T 4.0nmol/L, A 2.0nmol/L, 17OHP 2.1nmol/L). Prolactin, DHEAS and 24h urinary steroids were normal. No adrenal/ovarian tumour was found on CT; pelvic USS showed normal postmenopausal ovaries (volume right 4.6ml, left 2.7ml, n<6ml) and some small fibroids. Benign ovarian source was assumed. Leuprolin improved biochemistry and symptoms (T <0.5nmol/L after 3 months). Laparoscopic BSO was done; histology showed ovarian hyperthecosis. Androgens normalised after 8 months with symptom improvements (T 0.6nmol/L, A 2.7nmol/L).

Conclusion

We propose an algorithm to standardise initial workup of PMH and highlight that: 1) PMH has significant phenotypic variability; 2) DHEAS and pre- and post-1 mg ONDST androgen profile may differentiate ovarian/adrenal sources; 3) consider combined ovarian and adrenal imaging regardless of malignancy risk; and 4) localising source and excluding malignancy can inform management.

MiRNAs specific for PCOS phenotypes

Olivia Trummer[1], Jonas Hoeller[1], Sharmaine Reintar[1], Veronika Tandl[1], Ines Föbl[1], Valentin Borzan[1], Verena Theiler-Schwetz[1], Christian Trummer[1], Elisabeth Lerchbaum[1] & Barbara Obermayer-Pietsch[1]
[1]Medical University of Graz, Department of Internal Medicine, Graz, Austria

Background

Polycystic ovary syndrome (PCOS) is a common endocrine condition of unclear origin, characterized by hyperandrogenism (HA), oligo-/amenorrhoea (OM), and polycystic ovarian morphology (PCOM). According to the Rotterdam criteria, PCOS phenotypes A-D range from mild to severe and are defined as phenotype A (HA, OM and PCOM), phenotype B (HA, OM), phenotype C (HA, PCOM) and phenotype D (OM, PCOM). Recent discoveries indicate that microRNAs (miRNAs) play a role in the development of PCOS and may be potential biomarkers. Our main aim was to characterize miRNAs previously reported to be altered in PCOS, in women with different PCOS phenotypes.

Methods

We conducted a pilot study (n=51) with 11 women in each phenotype group and 8 control women. Candidate miRNAs were selected based on previously reported associations with PCOS. MiRNA isolation, complementary DNA (cDNA) synthesis and quantitative real-time PCR (qRT-PCR) were performed with assays from Qiagen. UniSp 2/4/5/6 were used as exogenous controls, and qRT-PCR data were normalized to the mean of miR-484 and snu6 as reference genes. After verifying the normal distribution and homogeneity of variances, a one-way-ANOVA or a non-parametric Kruskal-Wallis test was conducted, followed by Dunnet and Tukey's post-hoc tests. The diagnostic value for discriminating a PCOS phenotype from the other phenotypes was calculated by area under the curve (AUC) and by a receiver-operating-characteristic (ROC) analysis. TargetScanHuman8.0 was used to identify potential target genes of differentially expressed miRNAs.

Results

Systemic expression of miR-23a-3p was upregulated in phenotype B and discriminated PCOS phenotype B from the other phenotypes (AUC=0.837; 95% confidence interval (CI), 0.706-0.968; P=0.006). MiR-424-5p was downregulated in phenotype C and discriminated this phenotype from the others (AUC=0.801; 95%CI, 0.591-1.000; P=0.007). A subgroup analysis between hyperandrogenic PCOS phenotypes (phenotypes A, B, C, n=32) and PCOS women without hyperandrogenism (phenotype D, n=8) showed no group specific differences in their miRNA expression profiles. Functional annotation of differentially expressed miRNAs revealed binding sites in genes of pathways related to insulin resistance and carbohydrate metabolism, iron and lipid metabolism, inflammation, steroid and peptide hormones as well as fertility.

Conclusion

Understanding the differential hormonal and miRNA profiles across various PCOS phenotypes is important to improve the pathophysiologic understanding of PCOS. The miRNAs identified, miR-23a-3p and miR-424-5p, hold promise as potential biomarkers for differentiating between specific PCOS phenotypes. These findings contribute to a deeper understanding of PCOS heterogeneity, potentially improving diagnostic and treatment strategies for women with PCOS.

Anti-Müllerian hormone as a predictor of ovarian function in patients undergoing radioiodine treatment for thyroid cancer

Barbora Havlinova[1,1], Ilona Součková[2] & Jiří Doležal[3]
[1]University Hospital Hradec Králové and Charles University, Faculty of Medicine in Hradec Králové, The 4th Department of Internal Medicine – Hematology, Hradec Králové, Czech Republic; [2]University Hospital Hradec Králové and Charles University, Faculty of Medicine in Hradec Králové, Department of Clinical Immunology and Allergology, Hradec Králové, Czech Republic; [3]University Hospital Hradec Králové, Department of Nuclear Medicine, Hradec Králové, Czech Republic

Background

Differentiated thyroid carcinoma is the most common endocrinological malignancy with an increasing incidence over the last 30 years. It is the fifth most common cancer among the young population (15–39 years), with women being more frequently affected. Surgical removal of the tumour is the standard treatment method. In indicated cases, total thyroidectomy with subsequent adjuvant radioiodine administration is performed, despite international trends towards less aggressive treatment. International studies have reported anti-Müllerian hormone

(AMH) as the best endocrine marker to assess physiological age-related oocyte loss for healthy women. The possible adverse effects of radioiodine (RAI) on ovarian function and female fertility for women are currently being investigated.
Methods
The aim of our ongoing prospective study is to determine serum AMH to estimate ovarian reserve for premenopausal women treated with RAI. Over the course of one year, 33 serum samples from women with thyroid cancer and 3 serum samples from healthy women were examined. The mean age of the whole group was 35.5 years. The mean RAI dose was 4 888 MBq. AMH levels were compared before and after radioiodine treatment (4–6 months after RAI, 8–12 months after RAI). The Enzyme-Linked ImmunoSorbent Assay (ELISA) microtiter plates were used to test blood samples.
Results
Mean of the AMH level was 5.4 ng/mL ($n=$ 33) prior to RAI. A significant decrease in AMH levels occurred 4–6 months after therapy (mean 1.8 ng/mL) and 22.2 % of patients experienced a decrease in AMH levels to 0 ng/mL from non-zero levels after treatment. A subsequent slight rise in AMH level was 8–12 months after RAI (mean 2.7 ng/mL). Equivalent radioiodine dose to the ovaries was calculated with a mean of 180 mGy in the treated group. Very low AMH values at the beginning of treatment and after radioiodine administration were significant in women aged around 50 years.
Conclusion
AMH has gained interest as a possible predictor of ovarian reserve in recent years. The effects of RAI on the change in AMH levels were more significantly observed in patients older than 35 years. Although findings from retrospective studies suggest a slight decrease in AMH levels after radioiodine treatment of DTC, a long-term decrease in pregnancy rates has not been demonstrated. However, more data from prospective studies are needed.

Assesing the proficiency and alignment of ChatGPT 3.5 responses with guidelines in addressing frequently asked questions by transgender individuals

Selin Tekin[1], Banu Ertürk[1], Seda Hanife Oguz[1] & Bulent Yildiz[1]
[1]Hacettepe University School Of Medicine, Division of Endocrinology and Metabolism, Ankara, Turkey

Background
ChatGPT, an advanced language model, employs sophisticated deep learning techniques to generate human-like responses. It stands as one of the most extensive publicly accessible language models. Despite the longstanding application of Artificial Intelligence (AI) in diverse domains, its application in healthcare raises concerns about the reliability of information. It is equally important to assess whether the provided information is supported by dependable references and remains up-to-date.
Methods
A cross-sectional non-human subject study was conducted, posing 20 commonly asked questions to ChatGPT 3.5 related to gender dysphoria and transitioning. The questions were formulated in accordance with the recommendations provided in current guidelines and frequently asked questions posed by patients. Questions were categorized into five subgroups; (a) terms and definitions ($n=3$), (b) gender affirming hormonal therapy ($n=4$), (c) adverse outcomes and long-term care ($n=4$), (d) surgical procedures ($n=2$), and (e) other frequently asked questions ($n=7$). The responses from ChatGPT 3.5 were categorized into four groups based on adherence to the Endocrine Society Guideline for endocrine treatment of gender-dysphoric/gender incongruent persons and World Professional Association Standards of Care-8: 1-compatible, 2-compatible but insufficient, 3-partially incompatible, and 4- incompatible.
Results
Eleven of the responses from ChatGPT 3.5 were in accordance with current guidelines (%55), while the answers to the remaining nine questions were aligned but deemed insufficient (%45). The majority of questions with insufficient answers were associated with the treatment and side effects (75% of questions in subgroup-b and 75% of questions in subgroup-c). However, the responses provided by ChatGPT 3.5 to 3 questions (1/3 in subgroup-d, 2/3 in subgroup-e) contained more information than the guidelines, addressing queries on the specialized centers for surgery as well as questions about insurance coverage. Additionally, there were more detailed responses to questions related to increased facial hair density, a common inquiry among transgender men.
Conclusion
The first study in the literature evaluating the responses to the most frequently asked questions about gender dysphoria and transgender individuals using ChatGPT 3.5 suggests that the model can provide accurate information regarding the path and treatment process for individuals undergoing gender transition; even though some responses lack the necessary detail. Some responses to questions are more detailed than those provided in guidelines. Nevertheless, the source and accuracy of this information cannot be definitively confirmed. To enhance accessibility to accurate and comprehensive information, there is a call for scientific studies and guidelines tailored to the unique needs of individuals experiencing gender dysphoria.

Dampened HPG axis activity and improved reproductive lifespan in dummerstorf superfertile mouse lines

Joachim Weitzel[1], Ludwig Carolin[1] & Michaelis Marten[1]
[1]Forschungsinstitut für Nutztierbiologie, Dummerstorf, Germany

Research in the field of reproductive biology is largely based on informative mouse models. Almost all of these mouse models (~99%) exhibit an unfavourable reproductive phenotype - these mouse models are subfertile or infertile in one or possibly both sexes. In contrast, the number of animal models that show an enhanced reproductive phenotype is extremely rare. Nevertheless, these mouse models could be very informative in identifying mechanisms and pathways associated with enhanced fertility. We analyse two Dummerstorf outbred mouse lines that have been selected for high fertility for 200 generations (fertility lines 1 and 2; FL1, FL2). In both mouse lines, the number of offspring per litter almost doubled (from 11.5 (ctrl) to 20.6 (FL1) and 21.4 (FL2)), without the offspring showing any signs of growth retardation compared to animals from a non-selected control line. We analysed the lifetime fecundity of all three lines and found significant differences. Control and FL1 females gave birth to up to 10 litters, whereas FL2 only gave birth to a maximum of six litters per female per lifetime. In a first set of experiments, we analysed the ovarian phenotype of FL1 females. We noticed a reduced concentration of FSH, both on serum hormone levels (-60%) as well as in pituitary gene transcription (-90%). In line with this decreased FSH levels also hypothalamic GnRH transcription was decreased by 70% compared to ctrl. Gene expression analysis in ovaries revealed that multiple genes associated with follicular development, such as Lhcgr, Esr1, Kit or Foxl2 are differentially expressed in FL1 mice. Holistic gene expression analysis in ovarian granulosa cells further identified a differential regulation of multiple genes involved in follicular atresia. These data suggest that the phenotype of FL1 is at least partly due to attenuated follicular atresia leading to increased follicular survival. More successful folliculogenesis is in turn associated with higher ovulation rates (from 13 (ctrl) to 24 (FL1) oocytes per cycle). There is evidence that the complex interplay of endocrine and molecular changes leading to enhanced follicular development in FL1 females is associated with good reproductive longevity and health. Several genes associated with reproductive lifespan, such as Per2, Kl, Tex14 and Rora, are differentially expressed in the ovaries and granulosa cells of FL1 mice. These data suggest that the unique ovarian phenotype of FL1 females selected for high fertility provides valuable approaches for the search for molecular mechanisms predisposing to increased fertility.

In vitro analysis of FSHR internalization and signalling mediated by two different FSH preparations

Lara Baschieri[1,2], Clara Lazzaretti[1], Elisa Mascolo[1], Carmela Perri[1,2], Samantha Sperduti[1,3], Claudia Fusco[1], Manuela Simoni[1,3,4] & Livio Casarini[1,3]
[1]Unit of Endocrinology - University of Modena and Reggio Emilia, Department of Biomedical, Metabolic and Neural Sciences, Modena, Italy; [2]University of Modena and Reggio Emilia, International Ph.D. School in Clinical and Experimental Medicine (CEM), Modena, Italy; [3]University of Modena and Reggio Emilia, Center for Genomic Research, Modena, Italy; [4]Azienda Ospedaliero-Universitaria di Modena, Department of Medical Specialties, Modena, Italy

Follicle stimulating hormone (FSH) is produced by the anterior pituitary gland and is a key hormone in the reproductive system. FSH is a heterodimeric glycoprotein composed with two extensively glycosylated protein subunits (α and β) N-glycosylated in two positions (Asn^{52} and Asn^{78}in the FSHα subunit and Asn^{7} and Asn^{24} in the FSHβ subunit). Due to different glycosylation pattern, several FSH isoforms may differently act on the receptor (FSHR). We compared *in vitro* the trafficking mediated by two FSH commercial preparations, characterized by different glycosylation pattern, Gonal-f® (Merck KGaA) and Rekovelle® (Ferring Pharmaceuticals). HEK293 cells transiently overexpressing FSHR were treated by

increasing doses of FSH (nM-μM range) and with/without Dynamin inhibition (Dynasore). We evaluated cAMP production, interaction between FSHR and endosomal specific markers, and CRE-controlled reporter gene activation using luciferase and energy transfer-based methods. Statistics: Mann Whitney's U-test ($P<0.05$; $n=4$-5). We found no different interaction between FSHR and the marker of early endosome Rab5, in cells treated with Gonal-f® or Rekovelle®, regardless the presence of Dynasore ($P>0.05$; $n=5$). Dynamin inhibition was linked to increased Gonal-f®-, but not Rekovelle®-induced FSHR-Rab7 interaction, indicating preparation-specific routing to the degradation pathway ($P<0.05$; $n=5$). Gonal-F® induced more pronounced cAMP production at 1 μM concentration, while at 10 nM Rekovelle® induced a significantly higher cAMP production, regardless of Dynasore treatment ($P<0.05$; $n=4$). Finally, CRE reporter gene activation in absence of Dynasore is higher at 60 nM concentration of Gonal-F®, compared to Rekovelle® ($P<0.05$; $n=4$). To conclude, Gonal-f® and Rekovelle® mediate different FSHR internalization and signaling.

Assessment of muscle mass and strength in women with PCOS following oral contraceptive therapy

Seren Aksun[1], Levend Karaçoban[2], Ilkay Idilman[3] & Bulent Yildiz[4]
[1]Hacettepe University, Internal Medicine, Ankara, Turkey; [2]Hacettepe University, Sports Medicine, Ankara, Turkey; [3]Hacettepe University, Radiology, Ankara, Turkey; [4]Hacettepe University, Internal Medicine, Division of Endocrinology, Ankara, Turkey

Background and Aim
Polycystic ovary syndrome (PCOS) is characterized by androgen excess and ovulatory dysfunction and appears to be associated with alterations in muscle mass and function. Combined oral contraceptives are commonly used for the long-term management of PCOS and their potential impact on muscle mass and strength remains unknown. This study aimed to assess whether oral contraceptive (OC) use along with general lifestyle advice would alter muscle mass and strength in women with PCOS.
Methods
Twenty women with PCOS (median age and BMI: 20.5 years and 26.1 kg/m^{2}respectively) and 20 age- and BMI-matched healthy controls were included. Following clinical, hormonal and biochemical assessments, body composition analyses were performed by magnetic resonance imaging (MRI) proton density fat fraction (PDFF%). Muscular strength parameters including lower limb extensor/-flexor torque, total work and average power (AvP) were obtained by isokinetic dynamometry, gold standard for assessment of muscle strength. Measurements were made for all participants at baseline and repeated after OC use in women with PCOS.
Results
Women with PCOS at baseline had higher levels oftotal testosterone, free androgen index (FAI), and homeostasis model assessment of insulin resistance (HOMA-IR) levels compared to healthy women ($P<0.001$, $P=0.001$, $P=0.004$ respectively). The PCOS group showed significantly higher average power (AvP) of knee extensors at 60°/sec compared to controls before initiation of OC therapy ($P=0.002$), with positive correlations noted between AvP and total testosterone and FAI levels in the whole study group ($r=0.45$, $P=0.004$, $r=0.318$, $P=0.045$ respectively). The median duration of OC therapy in the PCOS group was 121 days (IQR: 85-149). Testosterone levels and FAI showed significant decline following OC use ($P=0.02$, $P<0.001$ respectively). However, these alterations were not associated with any significant change in thigh muscle mass or lower limb strength.
Conclusion
The results of this study suggest that short-term OC use ameliorates androgen excess but does not alter muscle composition or strength in women with PCOS. Further research is needed in PCOS to understand potential effects of long-term management strategies on muscle mass and function.

Investigation of circulating androgens' circadian variations: expanding the knowledge by monitoring phase II metabolites

Federico Ponzetto[1], Mirko Parasiliti Caprino[1], Lorenzo Campioni[1], Lorenzo Marinelli[1], Fabio Settanni[2], Antonello Nonnato[2], Giulio Mengozzi[1], Roberta Giordano[1] & Ezio Ghigo[1]
[1]University of Turin, Department of Medical Sciences, Turin; [2]City of Health and Science University Hospital, Clinical Biochemistry, Turin

Background
Many endogenous steroid hormones are reported to be subjected to distinct circadian rhythms, which are driven by central regulators, hormonal bioavailability and half-life. Recently, the measurement of androgens phase II metabolites has gained interest in the diagnosis and management of different endocrinological pathologies, such as polycystic ovarian syndrome (PCOS), female adrenal hyperandrogenism and hirsutism, prostate cancer, but their circadian patterns have not yet been characterized.
Methods
Serum samples were collected at six different time points across 24 hours (8:00, 10:00, 12:00; 16:00, 20:00, 8:00) from 19 healthy volunteer males. In-house UHPLC-MS/MS method was used for measuring in a single analysis circulating concentrations of 13 steroid hormones together with 13 androgens phase II metabolites (7 glucuronides and 6 sulphates). Cosinor analysis was performed to obtain diurnal models including mesor (rhythm adjusted median), zenith, and nadir concentrations, to measure rhythm's acrophase and amplitude as well as to test variations' statistical significance.
Results
The monitoring of target steroids' circadian rhythmicity highlighted that among endogenous hormones, all ACTH-related steroids showed significant fluctuations throughout the 24-hours period, with the highest concentrations measured in early morning samples then decreasing until afternoon collection. Concerning androgens, for testosterone a less pronounced but significant circadian rhythm was observed, while DHT did not show any variation during the day. A similar pattern was obtained by investigating phase II metabolites: the absence of diurnal fluctuations was noticed for both sulpho- and glucuro-conjugated androgens, with the latter owning a shifted zenith at 10 a.m.
Conclusions
The outcomes of this study highlighted that, in contrast with the majority of circulating steroid hormones, androgens phase II metabolites have satisfactory performance in terms of intra-day stability of circulating levels. For this reason, their introduction in clinical practice as biomarkers of pathological conditions to be monitored with longitudinal monitoring in the context of individualized precision medicine could be envisaged.

Introduction
In the thyroid gland, humoral immunity manifests with thyroid peroxidase (TPO) antibodies. In our studies, when TPO concentrations increased, thyroid cancers of follicular origin (TCFO) tended to develop less frequently.[1] Other studies, though, reported an opposite trend in less aggressive cancers. The present work was designed to characterize the differential role of TPO antibodies in aggressive forms of TCFO (AGG) as compared to non-aggressive (NAG) ones.
Methods
We performed a retrospective review of data from subjects who had thyroidectomy at 4 centers, in 2 countries [USA: 1 (2007-2013) and Greece: 3 (2021-2023)] on gender, age, surgical pathology and preoperative TPO antibody concentrations. Tumors producing distant metastases, spreading to multiple lymph nodes (LNs) ($\geq$ 10 or $\geq$ 6 with a positive malignant to benign ratio $\geq$75%), those requiring $\geq$ 2 courses of I-131 therapy or large structural local

recurrences were deemed AGG, while those not exhibiting these features were deemed NAG, and a control group was formed from subjects with benign histology (BEN). TPO were divided in very low (VL) (< 1 IU/ml), low (L) (1 - 10 IU/ml), intermediate (IN) (10 - 30 IU/ml), high (HI) (30-300 IU/ml) and very high (VH) (≥300 IU/ml). AGG thyroid cancer ratios were compared between these subgroups.

Results

TPO titers were available for 1,943/11,212 subjects; n = 948 BEN (48.8%). Overall mean age 46.7 ± 14.9 years, lower in TCFO (45.7 ± 14.6) compared to BEN (47.7 ± 15.1), and in AGG (40.2 ± 15.3) compared to non-AGG (46.2 ± 14.5), $P < 0.01$ for all comparisons. Overall n = 1477 (76.0%) were females; 736/1477 (49.8%) with TCFO as compared to 259/466 (55.6%) in males, $P = 0.02$. Out of 995 TCFO, n = 73 (7.3%) were AGG. These were found more frequently in the VL ($P = 0.018$) and less frequently in the H groups ($P = 0.016$).

Conclusion

Patients with very low TPO titers harbor aggressive (AGG) thyroid cancers of follicular origin (TCFO) more commonly, while those with high titers harbor these more rarely. These findings imply that immune response in the form of TPO antibodies modulates the risk to develop aggressive thyroid cancers. A strong autoimmune response appears protective with regard to the development of aggressive tumors even though abnormal.

Thyroid hormone transporter Mct8/Oatp1c1 deficient mice display impaired CNS capillary network formation

Boyka Markova[1], Androniki Alevyzaki[1], Philippa Spangenberg[2], Daniel Robert Engel[2], Steffen Mayerl[1] & Heike Heuer[1]
[1]University Duisburg-Essen, Endocrinology, Diabetes & Metabolism, Essen, Germany; [2]University Duisburg-Essen, Institute f. Experimental Immunology, Essen, Germany

The thyroid hormone (TH) transporters Mct8 (encoded by Slc16a2) and Oatp1c1 (encoded by Slco1c1) are critically involved in mediating TH passage across mouse brain barrier cells. Mct8/Oatp1c1 deficient mice (= DKO mice) exhibit a strongly reduced brain TH content and consequently, an impaired neuronal development and hypomyelination all of which are also seen in patients with MCT8 deficiency (Allan-Herndon-Dudley Syndrome, AHDS). Our recent studies of mouse mutants lacking both TH transporters specifically in blood-brain-barrier (BBB) endothelial cells (= Endo del mice) underscore the physiological relevance of Mct8/Oatp1c1 in facilitating TH access to the CNS. yet, these Endo del mice showed a much milder phenotype compared to DKO animals pointing to additional pathogenic CNS events in global Mct8/Oatp1c1 deficiency that still needs to be unraveled. We considered a hitherto unknown function of both TH transporters in brain angiogenesis and therefore examined brain capillary network formation in wildtype, single and double TH transporter knockout mice. For this, we performed immunoflurescence stainings of brain vibratome sections using the endothelial vascular marker CD31. Quantification of vessel parameters was conducted using the open-source software 'VesselExpress'. While vessel parameters at postnatal day P6 were similar in all experimental groups, quantification of cortical vessel length and branching at P12 revealed an almost 50% reduction in DKO mice. Single TH transporter mutant mice were not affected. Brain vessel rarefaction was also observed at P21 and P120 in DKO mice. Moreover, comparing the total vessel lengths of capillaries with different diameter revealed a significantly reduced total length only of DKO capillaries with a diameter less than 10 µm. Of note, while Oatp1c1 is ubiquitously found in all brain endothelial cells under physiological conditions, Mct8 is preferentially expressed by CNS endothelial cells of small capillaries suggesting that this subgroup of endothelial cells is particularly impacted by combined Mct8/Oatp1c1 deficiency. We further quantified the transcript levels of different capillary proteins in dissected brain areas of four months old animals and confirmed reduced CD31, Vegfa as well as glucose transporter Glut1 mRNA expression in DKO mice. Altogether, our observation of a reduced microcapillay network in DKO mice that potentially compromises local oxygen and/or nutrient supply may thus add novel insights into the pathogenic mechanisms underlying human MCT8 deficiency. (Study is financially supported by DFG and embedded in CRC/TR296-P01, P09, P19)

Plasmablastic lymphoma presenting as a rapidly increasing thyroid mass: a case report

Charikleia Paschalidi[1], Athanasios Fountas[1], Athina Markou[1], Charikleia Vlachou[2], Bazani Efthymia[2], Georgios Gorgolidis[2], Marina Sassi[3], Ioannis Nitsios[3], Ioanna Liokati[4], George Papastergiou[4] & Labrini Papanastasiou[1]
[1]General Hospital of Athens 'G Gennimatas', Department of Endocrinology, Athens, Greece; [2]General Hospital of Athens 'G Gennimatas', Department of Hematology, Athens, Greece; [3]General Hospital of Athens 'G Gennimatas', Department of Pathology, Athens, Greece; [4]General Hospital of Athens 'G Gennimatas', Department of Otolaryngology, Athens, Greece

Introduction

Primary thyroid lymphoma is a rare entity accounting for <5% of thyroid malignancies and <2% of extra-nodal lymphomas with diffuse large B-cell lymphoma (DLBCL) being the most common subtype. Plasmablastic lymphoma (PBL) is an uncommon and aggressive subtype of DLBCL mainly detected in patients with immunosuppression, especially related to HIV infection. Typically, PBL occurs in extra-nodal sites, usually the oral cavity and the gastrointestinal tract while primary thyroid PBL is extremely rare.

Objective

To report an extremely rare case of extra-nodal PBL presented as a rapidly increasing thyroid mass.

Case presentation

A 73-year-old male with a history of multinodular goiter and autoimmune thyroiditis, presented to the emergency department with a rapidly growing, painless, cervical mass and dyspnea. Computed tomography (CT) scan revealed an enlarged heterogenous thyroid gland (12 cm right lobe, 10 cm left lobe), causing trachea compression and displacement to the left side. Fine needle aspiration (FNA) cytology suggested an undifferentiated thyroid cancer and a core biopsy was performed to confirm the diagnosis. However, histological examination revealed the presence of a PBL with expression of Vimentin, LCA, CD79a, slgk, CMyC (in 35% of the tumor cells), while staining for TTF1 and TG was negative; cell proliferation index Ki-67 of 50% was found. Bone marrow biopsy showed no lymphoma cells infiltration, but whole body CT scan showed stage IV disease (multiple subcutaneous nodules, as well as abdominal and inguinal lymphadenopathy). Thyroid function was normal (TSH 1.71 µIU/ml, fT4 15.07 pmol/L, NR 9-19), while anti-TPO and anti-Tg were positive (>2000 IU/ml, NR <5.6 and 143.32 IU/ml, NR <4, respectively). Virology testing for HIV was negative. Treatment with systemic chemotherapy DA-EPOCH (dose adjustment etoposide, prednisolone, vincristine, cyclophosphamide and doxorubicin) was initiated with ≥30% decrease of the longest diameter of the thyroid masses after the completion of 3 cycles of chemotherapy. Compression of the trachea was significantly decreased and the patient does not experience any dyspnea.

Conclusion

To our knowledge, this is the third documented case of primary thyroid PBL. Due to its rarity, primary thyroid lymphoma can be challenging to diagnose and it should always be suspected in patients with a rapidly enlarging cervical mass. FNA is often insufficient for diagnosis and a core biopsy with histological confirmation is necessary to differentiate thyroid lymphoma from anaplastic thyroid cancer. Early and appropriate treatment can lead to significant patient's response and outcome improvement.

Introduction
Several cases of subacute thyroiditis (SAT) have been described in patients with SARS-CoV-2. However, no prospective data about follow-up in SARS-CoV-2-related SAT are known.
Aim
The characterization of clinical peculiarities and response to medical treatment of SAT cases, correlating to virus exposure, ascertained with antibody (Ab) dosage.
Methods
A prospective, 3-years, multicentre study was conducted, enrolling patients with SAT diagnosis based on anamnesis, physical examination, blood tests (TSH, freeT4, freeT3, thyroglobulin (Tg), TgAb, Ab to thyroperoxidase (TPOAb), TSH receptor-Ab, C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), complete blood count and thyroid ultrasound (US). At baseline, a serum sample was taken to assess the presence of IgG against the SARS-CoV-2 spike protein or nucleocapside, distinguishing natural infection and vaccination. Patients were evaluated after 1, 3, 6, 12 months with anamnesis, physical examination, blood tests and US. The study was supported by the 'ESE COVID-19 Research Grant', from the European Society of Endocrinology.
Results
A total of 66 subjects were enrolled. Eight were excluded because of symptoms onset earlier than 60 days before diagnosis. At baseline, 54 subjects presented with pain, 36 (67%) for at least 15 days. Only 4 did not report previous/concomitant neck pain but they all presented with non-homogeneous thyroid echostructure, TgAb and TPOAb negativity, thyrotoxicosis, elevated ESR and/or CRP. In 52 subjects, serum SARS-COV-2 IgG measurement was performed, documenting that the 13.5% had infection before SAT diagnosis (Covid+). At baseline, 17 patients were taking nonsteroidal anti-inflammatory drugs (NSAIDs), 7 β-blockers, 14 steroids, 2 levothyroxine, and 3 methimazole. However, this bias equally affected the Covid+ and Covid- groups. Between them, at diagnosis, there were no statistically significant differences except for respiratory symptoms and fever, more represented in Covid+ ($P=0.039$ and 0.021), despite significantly lower ESR values ($P=0.021$). 41 subjects completed follow-up. Covid+ and Covid- did not differ for therapeutic approach to SAT (NSAIDs, β-blockers, steroid), all having an improvement in pain, inflammation parameters, US features. The 30% of subjects experienced transient hypothyroidism without difference in the percentage that restored thyroid function (100% in Covid+ and 81% in Covid-) or developed permanent hypothyroidism (0% in Covid+ and 8.3% in Covid-) at 12 months.
Conclusions
This is the first prospective study investigating any difference at diagnosis and at follow-up between classical and SARS-CoV-2–related SAT. Our data confirm that the diagnosis of SAT is often delayed and demonstrate that SARS-CoV-2 infection does not modify SAT onset, progression and outcome.

Transcriptomic characterization of single cells derived from immortalized human thyroid follicular epithelial cell lines

Leonie Wittner[1], Marie Schnapp[1], Tobias Busche[1,2] & Joachim Feldkamp[3]
[1]Bielefeld University, Medical School and University Medical Center East Westphalia-Lippe, Bielefeld, Germany; [2]Bielefeld University, Center for Biotechnology (CeBiTec), Bielefeld, Germany; [3]Bielefeld University, Medical School and University Medical Center East Westphalia-Lippe, Klinikum Bielefeld, Academic Department of General Internal Medicine, Endocrinology and Diabetes, Infectiology, Bielefeld, Germany

Immortalized human thyroid follicular epithelial cell lines represent a valuable tool for the investigation of thyroid physiology *in vitro*. While there is an extensive selection of human thyroid carcinoma cell lines, the number of healthy follicular epithelial cell lines is limited. The vast majority of studies on thyroid physiology is based on the human immortalized cell line Nthy-ori 3-1, leading to comprehensive characterization of this cell line. However, in 2021 Hopperstad *et al.* generated four novel immortalized cell line variants derived from normal human thyroid tissue (CI-huThyrEC clone 1-4). In order to verify, if results obtained from the different cell lines are comparable, we decided to characterize and to compare the transcriptomic profile of each cell line. For this, we chose a novel approach that focusses on RNA sequencing of particularly low cell numbers. We prepared RNA sequencing libraries from one cell, four cells and ten cells derived from the different cell lines, which then underwent Illumina Next Sequencing. Overall, we obtained high quality sequencing data with minor variability depending on the method of cell separation. Further, gene detection and mapping statistics are comparable. On average 10k – 12k genes were detected with 80 % – 90 % uniquely mapped reads independent of the input number of cells. Downstream principal component analysis (PCA) revealed that sequencing data generated from samples containing ten Nthy ori 3-1 cells cluster closer than data from lower cell numbers, pointing to a high transcriptional similarity and reproducibility at this cell number. The CI-huThyrEC clones 1-4 show a greater variability in the PCA plot indicating that the four cell line variants differ in their transcriptional profile. Comparing the transcriptomic profile of the cell lines it is noticeable that CI-huThyrEC show a significant upregulation of *NKX2-1* gene expression that encodes the thyroid transcription factor-1 (TTF-1). Having established RNA sequencing of ultra-low cell numbers enables us to transfer this method to further questions. Next, we aim to transcriptionally characterize single neoplastic cells derived from fine needle aspiration biopsies of high-risk thyroid nodules. This might lead to the identification of new potential oncogenes or tumor suppressor genes, which might serve as potential biomarkers in the context of thyroid cancer and tumor stage assessment.

New plasma biomarkers: XIAP and survivin in patients with medullary thyroid cancer (MTC)

Piotr Glinicki[1,2], Alicja Szatko[1,2], Agnieszka Żyłka[3], Joanna Długosińska[3], Magdalena Ostrowska[1], Małgorzata Gietka-Czernel[1], Maciej Ratajczak[1], Wojciech Zgliczyński[1] & Marek Dedecjus[3]
[1]Department of Endocrinology, Centre of Postgraduate Medical Education, Warsaw, Poland; [2]EndoLab Laboratory, Centre of Postgraduate Medical Education, Warsaw, Poland; [3]Department of Oncological Endocrinology and Nuclear Medicine, Maria Skłodowska-Curie National Research Institute of Oncology, Warsaw, Poland

Introduction
Medullary thyroid carcinoma (MTC) constitutes 3.5-5% of all thyroid cancers. Routine biochemical diagnostics include determination of calcitonin (CT), procalcitonin (PCT) and carcinoembryonic antigen (CEA). XIAP (X-linked inhibitor of apoptosis protein) and survivin belong to the family of proteins – inhibitors of apoptosis (IAP). Using tissue microarrays, the expression levels of XIAP and survivin were tested in patients with medullary thyroid cancer. The study showed different expression of these biomarkers in patients with MTC at different stages of the disease. The clinical evaluation of the determination of these two proteins in blood in patients with medullary thyroid cancer has not been evaluated.
Materials and Methods
Thirty-four patients with MTC were included in the study. Patients were divided into two groups. Patients with confirmed active MTC ($n=15$) and patients with confirmed MTC in the stable phase, without recurrence or metastasis ($n=19$). The control group consisted of 40 healthy subjects. Serum CT and PCT levels were determined by the CLIA immunoassay. The concentration of CEA was determined by IRMA immunoassays, and the concentration of XIAP and survivin were determined in plasma by ELISA immunoassay.
Results
Levels of the tested biomarkers were assessed in patients with MTC in the active form of the disease, in patients with stable MTC and in the control group. Statistically significant differences were found between the study groups. The study groups were compared with each other: **XIAP**: MTC (active form) vs. control group: $P=0.797$; **Survivin**: MTC (active form) vs. control group: $P=0.857$, **XIAP**: MTC (stable form) vs. control group: $P=0.793$, and **Survivin**: MTC (stable form) vs. control group: $P=0.844$. ROC curves were used to compare the biomarkers studied in the group of patients with MTC (active form) vs. the group of healthy subjects. AUC (95%CI): **XIAP** 0.477 (0.296;0.657; $P=0.866$), **Survivin** 0.483 (0.302;0.664; $P=0.951$); CT 0.940 (0.857;1.203; $P<0.001$); PCT 1.000 ($P<0.001$); CEA 0.855 (0.704;1.004; $P<0.001$).
Conclusion
Determination of concentrations of new biomarkers: XIAP and survivin in the diagnostics of MTC can complement biochemical diagnosis in this group of patients.

Differentiated thyroid cancer in pregnancy. A retrospective analysis of newly diagnosed patients

Maciej Bulwa[1], Konrad Samborski[1], Magdalena Kolton[1], Malgorzata Haras-Gil[1], Barbara Jarzab[1], Daria Handkiewicz-Junak[1] & Jolanta Krajewska[1]
[1]M. Sklodowska-Curie National Research Institute of Oncology Gliwice Branch, Nuclear Medicine and Endocrine Oncology Department, Gliwice, Poland

Introduction
The question of whether pregnancy has any impact on the prognosis of differentiated thyroid cancer diagnosed in pregnant women was addressed mainly in retrospective analyses, which showed no significant differences in overall and progression-free survival between women diagnosed during pregnancy in comparison to women whose thyroid cancer diagnosis was unrelated to pregnancy. Thus, following the recent guidelines, watchful waiting is the preferred option, and surgical intervention may be postponed to the postpartum period. Surgery may be considered in the second trimester if high-risk features are present or a significant tumor is observed.
Aim
The aim of this study is to analyze the dynamics of malignant thyroid nodules followed in pregnant women.
Methods
A retrospective analysis of a group of 75 women at a mean age of 30.9 ± 4.8 years with suspected thyroid nodules detected during pregnancy. All patients underwent fine-needle aspiration biopsy (FNAB). The FNAB result was classified according to the Bethesda System for Reporting Thyroid Pathology. The diagnosis was confirmed by two independent pathologists. Only patients with the Bethesda V category (suspicious for malignancy) or Bethesda VI category (malignancy) were considered. Patients were followed by neck sonography (US) every 2-3 months until surgery. The median follow-up from the diagnosis to surgery or the last follow-up was 10.0 months (range 1.0-39.0).
Results
Papillary thyroid cancer (Bethesda VI) was diagnosed in 53 patients, whereas in the remaining 22 patients, the FNAB result was suspicious for papillary thyroid carcinoma (Bethesda V). The mean nodule diameter at the first US evaluation was 12 ± 7.7 mm. Thirty-nine nodules were ≤ 10 mm in diameter. In 29 nodules, the tumor diameter ranged between 11 and 20mm. Only 7 nodules (9,3%) were stable during the whole follow-up in 65 (86.6%) patients. The nodule diameter increased in 9 (12%), while in one patient, the nodule dynamics could not be evaluated. Lymph node metastases were diagnosed at initial evaluation in 1 patient. Although in 55 patients (73.3%) thyroid nodules were diagnosed before 24 weeks of gestation, the majority of them chose watchful waiting. Only 2 women were operated on during pregnancy. Sixty-five (86.7%) underwent surgery after delivery. Histopathological data and outcomes will be presented during the congress.
Conclusions
Watchful waiting is a safe option for patients diagnosed with papillary thyroid carcinoma or suspicion of papillary thyroid carcinoma. However, careful monitoring should be considered to choose the most optimal time for surgery.

Falsely elevated thyroid function tests due to laboratory interference

Jan Drugda[1], Filip Gabalec[1] & Radomír Hyšpler[2]
[1]University Hospital Hradec Králové, 4th Department of Internal Medicine, Hradec Králové, Czech Republic; [2]University Hospital Hradec Králové, Department of Clinical Biochemistry and Diagnostics, Hradec Králové, Czech Republic

Introduction
Thyroid function tests (thyroid hormones and thyreotropin) are frequently used by physicians all over the world. The interpretation is usually quite simple and straight-forward, however sometimes there is a strange discrepancy between the laboratory findings and clinical presentation. There are several potential explanations to this discrepancy and interference in laboratory assay may be one of them.
Observation
We present a case of a 73-year-old woman without any significant comorbidities except of atrial fibrilation and arterial hypertension. She was presented to endocrinologist by her general practitioner because of elevated estradiol, free thyroxine and triiodothyronine coupled with elevated thyreotropin but she was lacking any signs or symptoms of thyreotoxicosis. Central hyperthyreoidism was mainly considered so we started thyrostatic treatment with thiamazol. Nevertheless the MRI and PET/CT was negative, other pituitary hormones were normal and thiamazol was totally ineffective. At this point we started to think about possible laboratory interference. We suspected presence of antibodies that block the antibody of the assay we used. That was confirmed by precipitation of the sample with polyethylene glycol after which the estradiol, tyroxine, triiodothyronine and thyreotropin normalized. According to the literature IgM rheumatoid factor is the most common cause of such interference so we evaluated it and it was indeed positive. We then immediately withdrawn thiamazol and after short follow up the patient was handed over back to her general practitioner.
Conclusion
Laboratory interference in thyroid function tests is fortunately very rare. However if there is a discrepancy between the laboratory findings and clinical presentation it is good to have it in mind. It is generally quite easy to exclude and it can help you to avoid misdiagnosis and pottentialy harmful unnecessary treatment.

[1]Endocrine Unit and Diabetes Centre, Department of Clinical Therapeutics, Alexandra Hospital, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece; [2]Multiple Sclerosis & Demyelinating Diseases Unit, 1st Department of Neurology, Eginition Hospital, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece; [3]Second Department of Neurology, School of Medicine, National and Kapodistrian University of Athens, 'Attikon' University Hospital, Athens, Greece; [4]Department of Endocrinology, 'Korgialenio-Benakio', Red Cross General Hospital, Athens, Greece.; [5]Department of Endocrinology, Alexandra Hospital, Athens, Greece

Aim
Autoimmune thyroid disease (AITD) is the most common adverse effect in alemtuzumab (ALZ) treated relapsing–remitting (RR) multiple sclerosis (MS) patients. The objective of this prospective study was to analyze the occurrence, timing of onset, clinical course, and laboratory characteristics of AITD post-ALZ and subsequently the clinical outcome of AITD post-ALZ in patients who received ocrelizumab.
Patients and methods
We evaluated 36 RRMS patients treated with ALZ; of which 3 patients subsequently received ocrelizumab. Clinical and laboratory data were collected before ALZ initiation and thereafter quarterly on follow-up with a median of 55.5 months.
Results
Nineteen out of 32 patients (59.4%) with no prior history of thyroid dysfunction developed AITD with a mean onset of 19.7 ± 11 (SD) months after the first ALZ cycle. The incidence of AITD and during the first year of follow-up was 18.8%, and 50% after the second ALZ course. Ten patients developed Graves' disease (GD), one developed hypothyroidism with positive stimulating thyrotropin receptor antibodies (TRAb) and eight developed Hashimoto thyroiditis (HT), of which one developed hypothyroidism. The mean time to TRAb and anti-thyroglobulin (anti-Tg) and/or anti-thyroperoxidase (anti-TPO) antibody positivity onset from the first ALZ infusion was 24.8 ± 8.1 months and 18.1 ± 12.7 months, respectively. Seven of ten (70%) GD patients showed a fluctuating course of hyperthyroidism-hypothyroirdism. All GD patients commenced antithyroid drugs (ATDs); six continued on 'block and replace' treatment; one required radioactive iodine and one total thyroidectomy. Five patients developed mild Graves' ophthalmopathy. Remission was reported in four out of ten GD patients (40%); one spontaneously and three after ocrelizumab treatment with a mean time of 31.5 ± 11.7 months. No significant relationship of AITD with age at the time of ALZ treatment, sex, smoking status, previous DMTs, positive baseline anti-TPO/anti-Tg antibodies and family history of AITD was found. Only in patients who were treated with fingolimod as last treatment before ALZ a trend for an increased incidence of TRAb positivity was reported ($P = 0.07$). Two successful pregnancies were recorded: one with HT and hypothyroidism and the other with GD.
Conclusions
Our analysis showed earlier onset of ALZ-induced AITD in comparison to most other ALZ cohorts. We observed a higher rate of fluctuating GD, with earlier onset and lower remission rate than previously reported. The majority of patients required prolonged 'block and replace' therapy in the minimum dose of each

therapeutic agent or more definitive interventions. Treatment with ocrelizumab contributed in remission of GD.

High local and systemic expression of pentraxin-3 in anaplastic thyroid cancer

Andreea Bojoga[1,2,3], Pepijn van Houten[2], Martin Jaeger[2], Katrin Rabold[2], Dumitru Ioachim[4], Birgitte Walgreen[5], Liesbeth van Emst[2], Corin Badiu[1,6] & Romana Teodora Netea-Maier[2]

[1]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [2]Radboud University Medical Center, Department of Internal Medicine, Division of Endocrinology, Nijmegen, Netherlands; [3]National Institute of Endocrinology, Bucharest, Romania; [4]National Institute of Endocrinology, Department of Pathology, Bucharest, Romania; [5]Radboud University Medical Center, Laboratorium Rheumatology, Nijmegen, Netherlands; [6]National Institute of Endocrinology, Department of Endocrinology IV, Bucharest, Romania

Introduction

Long pentraxin 3 (PTX3), a protein cells produce in response to several inflammatory stimuli, is essential in innate immunity, controlling inflammation, tissue remodeling, and cancer dynamics. PTX3 promotes the migration and invasion of cells in different tumor models. This study aims to (I) immunohistochemically assess the presence and distribution of PTX3 in tissue samples from non-medullary thyroid cancer (NMTC) and (II) (TC) to determine the differences of circulating PTX3 in patients with NMTC vs patients with benign goiters.

Methods

We prospectively included 55 patients (41 preoperatively, 14 with recurrent active disease) with various subtypes of NMTC: 42 with papillary, 3 with follicular, 4 with oncocytic, 4 with anaplastic (ATC), 2 with poorly differentiated (PDTC). The control group consisted of 32 patients with multinodular goiter. Patients with chronic systemic inflammatory diseases (such as rheumatologic diseases), other active neoplasms, active infections, or pregnancy were excluded. PTX3 plasma levels were analyzed using ELISA. Local PTX3 and CD68 expression were assessed by co-staining on paraffin-embedded tissue in a patient with ATC with a positive somatic v600E BRAF mutation and a patient with goiter.

Results

No significant differences in PTX3 plasma levels between the control group and non-medullary differentiated TC were found. PTX3 plasma level in patients with ATC was significantly higher compared to control, and compared to the rest of the TC subtypes, including the aggressive histological subtypes. The plasma level of PTX3 did not correlate with tumor load (defined as the sum of all tumoral foci). There were no significant differences between patients with recurrence and those included preoperatively. The intensity and quantitative expression of PTX3 were higher in ATC, both interstitial and cellular expression, compared to normal thyroid tissue or goiter where immunostaining for PTX3 was virtually absent, with sparse and faint staining. The IHC expression of CD68 was also diffusely increased in ATC compared to goiter, suggesting infiltration by tumor-associated macrophages (TAMs). Less than 10% of the cells were double-positive for PTX3 and CD68 suggesting another source of PTX3 than TAMs.

Discussions and Conclusions

Our findings highlight significantly elevated PTX3 levels in ATC, both in plasma and in tumor tissue, compared to other TC types and control subjects. The low number of double-positive TAMs suggests that PTX3 might likely be produced by tumoral cells, stromal cells, or other immune cells. Further investigation is needed to consolidate the significance of PTX3 in ATC and its effect on the tumor microenvironment.

Introduction

Medullary thyroid cancer (MTC) is a rare tumour. Mostly sporadic, 25% are associated with multiple endocrine neoplasia (MEN2A/B) or isolated familial MTC. Surgery is the only curative option: its response is defined as complete (no evidence of biochemical or structural disease), incomplete (only structural response) and persistence of structural disease. We aimed to analyse the clinical and pathological factors associated with the prognosis of MTC.

Materials and Methods

Retrospective analysis of clinical and pathology records from MTC cases in a tertiary centre from 2001-2023. Surgical response was assessed through cervical ultrasound and calcitonin 6 months postoperatively. Histopathological reports included tumour size, uni-/multifocality, margin distance, C-cell hyperplasia, coagulative necrosis, and linfovascular invasion. The remaining parenchyma was assessed for nodular hyperplasia or chronic lymphocytic infiltration.

Results

From 42 patients, 64% ($n=27$) were female. Mean age at diagnosis was 46.2 ± 2.8 years. Mean follow-up duration was 12 ± 1.1 years. 35.7% presented symptoms at diagnosis (mostly cervical swelling); two had diarrhoea (both with distant metastases). 19% ($n=8$) had a RET germline mutation, 5 of whom performed a prophylactic thyroidectomy. Surgery resulted in excellent response in 71.4% ($n=30$), biochemical incomplete response in 16.7% ($n=7$) and persistent structural disease in 11.9% ($n=5$). Among patients with excellent response, 16.6% ($n=5$) experienced recurrence, 3 were only biochemical. Male patients were more likely to have persistence of structural disease after surgery (35.7%), $P=0.003$. Multifocal MTC showed less complete response rates (46.2% vs 82.1% in unifocal MTC), $P=0.029$. Only 30% of patients with linfovascular invasion in the histopathology report exhibited a complete response to surgery ($P=0.003$). All patients with nodular hyperplasia showed complete response post-surgery, compared to those with chronic lymphocytic infiltration (75%) or thyroid parenchyma without these alterations (55.6%), $P=0.041$. Coagulative necrosis was present in 2 patients and was associated with persistence of structural disease ($P=0.012$). Tumours that touched the thyroid margin showed a poorer response to surgery ($P=0.021$). Higher recurrence was associated with RET germline mutation ($P=0.04$) and with T staging at diagnosis ($P=0.009$). Thirty-nine patients are alive: 61.5% ($n=24$) cured; 38.5% ($n=15$) with disease persistence. N staging at diagnosis associated strongly with disease persistence ($P<0.001$). 3 patients died, 2 due to MTC.

Conclusion

An incomplete response to surgery, whether biochemical or structural, was associated with male gender, multifocal MCT, linfovascular invasion and coagulative necrosis. Adjacent nodular hyperplasia associated with better response to surgery. Higher recurrence was associated with RET germline mutation and with T staging at diagnosis.

Graves' disease relapse after 30-year remission in a female patient due to SARS-CoV-2 infection- a case report

Dimitrios Askitis[1]

[1]Private Practice for Endocrinology, Alexandroupolis, Greece

Introduction

COVID-19 has been established as a multisystemic disease with the potential of affecting all the organs of the human organism including the thyroid gland which features ACE2 receptors for the cellular entry of SARS-CoV-2. Graves' disease comprises the most common cause of thyrotoxicosis, manifests in genetically predisposed individuals with an autoimmune background and may be triggered by a variety of environmental factors, including viral infections. A few cases of new-onset or relapsed Graves' disease related to SARS-CoV-2 infection have been reported globally. Herein, we present the case of an otherwise healthy patient who developed hyperthyroidism due to Graves' disease reactivation after 3 decades of remission following exposure to SARS-CoV-2.

Case report

A 65-year old female patient with a history of active Graves' disease over a period of 2 years and remission over the past 30 years presented for endocrinological evaluation due to newly detected hyperthyroidism. The patient had been tested positive for COVID-19 10 days ago with persistent fever over a period of 2 days and concomitant heart palpitations. The neck ultrasound revealed a pattern typical of autoimmune thyroiditis with diffuse heteroechogenicity and inhomogeneity accompanied by elevated blood flow bilaterally. The adjunctive laboratory evaluation showed a hyperthyroid state with elevated TRAb-titers and negative anti-Tg and anti-TPO autoantibodies. The patient was started on thyrostatic medication with methimazole 15 mg daily combined with propranolol 10 mg thrice daily. Biochemical and clinical euthyroidism was rapidly restored in 6 weeks and the methimazole dosis was progressively reduced till complete

cessation 8 months after diagnosis. Neck ultrasound at that point showed a remission of the autoimmune process with normalization of the blood flow, whereas the laboratory assessment showed negative TRAb. The patient remained euthyroid without related medication since.

Conclusion

The above case presentation comprises the first official report of Graves' disease relapse following COVID-19 in northern Greece, as well as the case of autoimmune hyperthyroidism with the second longest remission duration before relapse due to SARS-CoV-2 infection in the literature. Clinicians should be aware of thyroid-related complications due to SARS-Cov-2, especially in individuals with a known history of autoimmune thyroid diseases and conduct the appropriate diagnostic and therapeutic procedures in cases of suspected infection-triggered thyroid dysregulation.

Characterizing TSH-receptor antibody (TRAb) seropositive and TRAb seronegative patients with Graves hyperthyroidism - a cross-sectional study

Simon Mifsud[1], Zachary Gauci[1] & Sandro Vella[1]
[1]Mater Dei Hospital, L-Imsida, Malta

Background

The concept of autoantibody-negative Graves' disease (GD) is a subject of debate. Studies have revealed that autoantibody-negative GD does exist, albeit rare.1

Method

Over a 3-year period, a total of 108 hyperthyroid patients who exhibited diffuse or normal thyroid uptake on thyroid scintigraphy, were assessed in a cross-sectional study. The thyroid function tests, TSH-receptor antibody (TRAb) levels, anti-thyroid peroxidase (anti-TPO) antibody levels, and thyroid ultrasound scans of these subjects at initial diagnosis were reviewed. TRAb-seronegative GD was defined as the presence of hyperthyroidism with a negative TRAb and diffuse or normal thyroid uptake on thyroid scintigraphy. Continuous variables were compared using the Mann-Whitney U test, while categorical variables were compared using the Chi-Square test. Statistical significance was defined by a two-tailed p-value <0.05.

Results

The mean (SD) age of the study group was 58.59 (16.782) years with a female dominance of 66.67% ($n=72$). 83.3% ($n=90$) had overt hyperthyroidism whilst the remaining had subclinical hyperthyroidism. In the cohort with overt hyperthyroidism, 52.2% ($n=47$) had a positive TRAb status. In the cohort of patients with overt hyperthyroidism, thyroid-stimulating hormone (TSH) levels were significantly lower in TRAb-seropositive GD when compared to TRAb-seronegative GD (median TSH:0.008mIU/mL [IQR:0.008-0.011] vs median TSH:0.012mIU/mL [IQR:0.008-0.0285], respectively; $P=0.0013$). Furthermore, in the overt hyperthyroid cohort, free thyroxine (fT4) and free triiodothyronine (fT3) levels were significantly higher in TRAb-seropositive GD when compared to TRAb-seronegative GD (median fT4:34.1 pmol/L [IQR:25.1-46.85] vs median fT4:27.1 pmol/L [IQR:22.37-34.5], respectively; $P=0.026$ and median fT3:11.1 pmol/L [IQR:8.5-17.2] vs median fT3:8.1 pmol/L [IQR:6.6-10.8], respectively; $P=0.001$). Only 23.8% ($n=5$) of TRAb-seronegative GD had a positive anti-TPO antibody status when compared to TRAb-seropositive GD ($P=0.0019$). Age ($P=0.242$), gender ($P=0.102$), and presence of thyroid nodule/s ($P=0.152$) did not differ significantly between the overt TRAb-seropositive GD and TRAb-seronegative GD groups.

Conclusion

Our findings suggest that whilst TRAb-seropositive and TRAb-seronegative patients with Graves' overt hyperthyroidism have comparable findings concerning age, gender, and thyroid nodule distribution, TRAb-seronegative GD is associated with a less severe form of biochemical thyrotoxicosis. In addition, our results indicate that TRAb-seronegative GD tends to be associated with negative anti-TPO antibody status.

Thyrotoxicosis and thyrotoxic periodic paralysis in hong kong: a population-based cohort study

Gloria Hoi-yee Li[1], Ching-Man Tang[1], Ray Shing-Hin Li[1], Xiaoyu Wan[1], Kathryn Choon-Beng Tan[2], Elaine Yun-Ning Cheung[3] & Ching-Lung Cheung[4]
[1]The Hong Kong Polytechnic University, Department of Health Technology and Informatics, Hong Kong; [2]The University of Hong Kong, Department of Medicine, Pokfulam, Hong Kong; [3]The Chinese University of Hong Kong, Hong Kong Institute of Diabetes and Obesity, Shatin, Hong Kong; [4]The University of Hong Kong, Department of Pharmacology and Pharmacy, Pokfulam, Hong Kong

Background

Thyrotoxic periodic paralysis (TPP) is a rare complication of thyrotoxicosis, characterized by recurrent hypokalemia, episodic muscle weakness and paralysis. It is potentially fatal in serious attacks with occurrence of life-threatening cardiopulmonary complications. Currently, lack of large cohorts comprising individuals with TPP history restrict the conduct of relevant epidemiology study.

Methods

Clinical data from a population-wide electronic medical database in Hong Kong, namely the Clinical Data Analysis and Reporting System (CDARS), was retrieved for the study. The diagnostic coding and/or potassium test records in blood were used to randomly identify 100 potential cases of thyrotoxicosis [by International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM): 242.××] and TPP (by ICD-9-CM: 242.×× and 359.3, plus low potassium level) for validation, respectively. The positive predictive value (PPV) of the clinical data from CDARS for thyrotoxicosis and TPP were determined by reviewing clinical notes and examining relevant laboratory test records. A population-based registry of thyrotoxicosis and TPP in Hong Kong was subsequently established. With reference to the United Nations population, we computed the standardized incidence rate of both thyrotoxicosis and TPP in Hong Kong, with average annual percentage change (AAPC) for trend analysis.

Findings

The PPV of clinical data in CDARS for thyrotoxicosis and TPP were 86% [95% Confidence Interval (CI): 79.2%-92.8%] and 98% (95% CI: 95.3%-100%), respectively. With this high PPV, we established a populational-based cohort, comprising 83,185 and 971 adults with diagnosis of thyrotoxicosis and TPP respectively from 1 January 2002 to 31 December 2021. The proportion of thyrotoxicosis patients experiencing TPP was 1.17%. The age- and sex-standardized incidence rate of thyrotoxicosis increased from 50.031 to 76.516 per 100,000 person-years from 2002 to 2021, with AAPC of 4.6 (95% CI: 1.11-8.01). Such increasing trend was also observed in male and female. Since more male thyrotoxicosis patients had TPP with reference to female patients, the age-standardized incidence rate of TPP in both sexes were calculated. In 2002 and 2021, the incidence rate in male was 1.405 and 1.226 per 100,000 person-years respectively. Whereas the incidence rate in female was 0.097 and 0.131 per 100,000 person-years. No significant trend was observed in both sexes.

Interpretation

This is the first study validating the clinical data in electronic medical database for TPP. The high PPV of validation enabled us to establish the largest population-based cohort of individuals with TPP history to-date, facilitating future epidemiology studies of this rare complication.

Determination of the relationship between the development of persistent hypothyroidism after subacute thyroiditis and subtypes of human leukocyte antigen

Fatma Nur Korkmaz[1], Mustafa Sahin[1] & Klara Dalva[2]
[1]Ankara University, Faculty of Medicine, Department of Internal Medicine, Endocrinology and Metabolism, Ankara, Turkey; [2]Ankara University, Faculty of Medicine, Department of Internal Medicine, Hematology, Tissue Typing Laboratory, Ankara, Turkey

Introduction

Subacute thyroiditis (SAT) can often resolve completely; however, it has been observed that in 11.6% of patients, permanent hypothyroidism (PHT) may develop the follow-up after diagnosis. Various studies have explored the relationship between thyroid volume at the time of diagnosis, post-treatment changes in thyroid volume, steroid therapy, and the development of PHT following SAT. While some studies suggest associations, there are also data indicating that no single factor can be determinative. The role of Human Leukocyte Antigens (HLA) in controlling the immune response, influencing the development of autoimmune diseases, and contributing to the development of chronic hypothyroidism is well-established.

Objective

In our study, we examined the impact of an individual's HLA characteristics on the development of hypothyroidism following SAT, considering other clinical factors as well.

Method
In this retrospective study, data were obtained from the hospital information management system for 51 patients diagnosed with SAT who were followed in the endocrinology outpatient clinic between June 2019 and October 2021, and whose HLA types were known. Diagnostic and follow-up data of the patients were reviewed, and 48 patients with data available for more than 180 days were included in the study. PHT was defined as the detection of thyroid-stimulating hormone levels above the reference range (4.2 μIU/ml) for six consecutive months. HLA-A, -B, -C, -DQB1, and -DRB1 genotyping was performed using the MiaFora Flex5 typing kit (Immucor, Peachtree Konars, GA) and the Illumina platform (Illumina, San Diego, CA) upon the extraction of DNA from blood sample. The results of the sequencing were analyzed using the MiaFora NGS software.
Results
In the 48 SAT patients, 33 patients without PHT (PHT (—)) and 15 patients with PHT (PHT (+)) were detected. In the PHT (+) group, the frequency of HLA-B*44:02 and –C*15:02 was observed to be higher compared to the PHT (—) group, while the frequency of HLA-B*35:02 and -DQB1*05:02 was found to be lower. Additionally, the SAT area on ultrasonographic examination was lower, and C-reactive protein levels (CRP), as well as the frequency of TPO positivity, were higher at the time of diagnosis in the PHT(+) patients.
Discussion
Patients exhibiting factors such as a reduced SAT area on ultrasonographic examination, elevated CRP levels, and TPO antibody positivity—factors potentially linked to the development of PHT following SAT—require heightened vigilance in monitoring. Further studies are necessary to identify high-risk HLA alleles.

Reference range and determinants of serum thyroglobulin in south-western greece

Georgios Markantes[1], Anastasia Armeni[1], Panagiotis Bountouris[1], Dionysios Chartoumpekis[2], Irene Mamali[1], Ioannis Kioutsioukis[3] & Marina Michalaki[1]
[1]University of Patras, Division of Endocrinology - Department of Internal Medicine, Patras, Greece; [2]University of Lausanne, Service of Endocrinology, Diabetology and Metabolism, Lausanne, Switzerland; [3]University of Patras, Department of Physics, Patras, Greece

Background
Thyroglobulin (Tg) is a protein exclusively synthesized by follicular thyroid cells. Serum Tg levels depend on thyroid volume, serum TSH levels, gender, age, smoking, and iodine intake. Consequently, serum Tg reference range may exhibit variations among different populations. It is crucial to establish population-specific reference ranges, especially when interpreting serum Tg values in the follow-up of patients with differentiated thyroid cancer who have undergone lobectomy or total thyroidectomy without radioiodine ablation.
Objectives
The aim of our study was to assess Tg levels in euthyroid individuals without autoimmunity in an iodine sufficient area, and to identify factors affecting Tg in our population.
Methods
Participants were attendants of our outpatient endocrinology clinic. Screening included a complete medical history and physical examination, thyroid function tests (TSH, T3, T4, Tg, thyroid autoantibodies), urinary iodine excretion assessment, and thyroid ultrasound with estimation of the total thyroid volume.
Results
We selected 115 euthyroid and iodine sufficient individuals (65 women and 50 men), without thyroid autoimmunity, with a mean age of 36.93 (range 17-72) years. None of them had abnormal sonographic findings, and none had known thyroid disease or was on medication interfering with thyroid function. Tg levels were non-normally distributed in our population. The mean Tg level was 14.55 ng/mL (range: 0.39-56.74 ng/mL) and the median value was 12.38 ng/mL (interquartile range: 10.82 ng/mL), with 95% of the data falling in the interval 1.8-31.5 ng/mL. Tg levels were higher in smokers vs non-smokers (Median / IQR: 17.73 / 12.01 ng/mL vs 11.85 / 9.41 ng/mL, $P=0.003$). Tg was positively correlated with T3 ($r=0.250$, $P=0.038$) and T4 ($r=0.235$, $P=0.012$) levels. In multiple linear regression, the best model for Tg prediction had three regressors (smoking, T4, and TSH) and explained 11.7% of Tg variability. Non-linear models were able to explain $>90\%$ of Tg variance, but most of the explained variance was due to random effects.
Conclusion
We propose a reference range of 1.8-31.5 ng/mL for Tg in a euthyroid, iodine sufficient Greek population. Tg is higher in smokers, and is weakly correlated with T3 and T4 levels, but not with thyroid volume. Tg levels in our cohort seem to depend on unknown factors, other than those traditionally described in the literature.

Diagnosis of medullary thyroid microcarcinoma by calcitonin measurement in fine-needle aspiration washout

Bogdan Radu Ditescu[1], Luca Diana-Simina[1], Stan Andrei[1], Caragheorgheopol Andra[2], Terzea Dana[3], Niculescu Dan Alexandru[1,4] & Poiană Cătălina[1,4]
[1]Department of Pituitary and Neuroendocrine Disorders, C. I. Parhon National Institute of Endocrinology, Bucharest, Romania; [2]Research Laboratory, C. I. Parhon National Institute of Endocrinology, Bucharest, Romania; [3]Pathology Department, C. I. Parhon National Institute of Endocrinology, Bucharest, Romania; [4]Department of Endocrinology, Carol Davila University of Medicine and Pharmacy, Bucharest, Romania

Introduction
Medullary thyroid carcinoma (MTC) is an uncommon thyroid malignancy arising from calcitonin-producing parafollicular cells. Micro-MTC is defined traditionally as MTC that measures ≤ 1 cm and represents a very rare entity. Ultrasound-guided fine-needle aspiration biopsy cytology (FNAB-C) sensitivity is about 63% for MTC and can be improved by measurement of calcitonin in the needle washout (FNA-CT). The value of FNA-CT in micro-MTC has not been studied. Our aim was to further investigate the value of FNA-CT as a diagnostic marker for micro-MTC.
Methods
We retrospectively analyzed all patients with thyroid micronodules and elevated serum calcitonin in whom FNAB-C and FNA-CT was performed during 2019-2023. Clinical, imaging, biochemistry and pathology parameters were retrospectively extracted.
Results
A total of 21 patients with elevated serum calcitonin and thyroid micronodules detected on ultrasound, underwent FNAB-C and FNA-CT. Furthermore, 12 patients underwent surgical treament whenever a cytological suspicion for malignancy existed. Validation of the technique for these cases was realized through the correlation between the cytologic diagnosis of thyroid FNAB and the postoperative histopathologic diagnosis. The specificity and sensitivity for MTC was 100% for both FNAB-C and FNA-CT at a cut-off value of 62.7 pg/ml.
Conclusion
Early clinical detection and preoperative confirmation of MTC still represent a diagnostic challenge in clinical practice and through this study we demonstrated that FNA-CT measurement is an effective method for micro-MTC diagnosis. We set our own laboratory cut-off for calcitonin at 62.7 pg/ml. Although FNA-CT is a important complementary diagnostic tool, it should only be integrated but not substitute FNAB-C to detect micro-MTC.

Safety of primary care-led surveillance for low-risk thyroid cancer patients

Gedoni Eni[1] & Mohamed Malik[1]
[1]Scunthorpe General Hospital, Scunthorpe, United Kingdom

Background
Post-treatment monitoring of thyroid cancer depends on risk stratification for future recurrence or possible extra-thyroidal metastasis. Current guidance suggests that patients with favourable prognostic factors and a low likelihood of recurrence can be effectively monitored in community settings. This study explores the safety of community-based surveillance for stable low-risk thyroid cancer patients discharged from specialised thyroid clinic.
Methodology
A retrospective review of 26 thyroid cancer patients discharged from the thyroid clinic, Scunthorpe General Hospital to primary care surveillance in the period from 2021 to 2023 was conducted. The study involved a comprehensive review of diagnosis, histology reports, blood and radiology results, and clinic correspondence extracted from electronic medical records.
Results
During the study period, 26 patients with thyroid cancer were discharged for long-term primary care (community) surveillance. 73% were female and median age was 61 years (IQR 48-70). Among the discharged patients, papillary carcinoma (18) was the predominant histological diagnosis and 34.6% were micro carcinomas. Definitive treatment among the study population comprised of surgery with radio-iodine ablation (61.5%) and surgery alone (38.5%). Median duration of thyroid clinic follow-up prior to discharge was 12 years (IQR 8-17). Written recommendations for post-discharge screening protocol were provided to the general practitioners for all 26 patients. Compliance with the screening

protocol was observed in 21 patients (81%); among these, only 5 patients underwent complete screening in accordance with the prescribed protocol (annual assessment of thyroid-stimulating hormone, thyroglobulin levels, and neck examination), while 16 patients had partial screening (less than annual, average interval of 18-24 months). There was no difference observed in screening uptake or frequency between age groups, gender, micro or macro carcinomas, and mode of primary treatment. Average TSH value was (1.46 mU/L $\pm$ 1.5); none had raised tumour markers (thyroglobulin) or positive finding to suggest recurrence.
Conclusion
Upon reviewing low-risk thyroid cancer patients discharged from Scunthorpe General Hospital's thyroid clinic, it becomes apparent that community-based surveillance, following an initial period of specialist clinic follow-up, is safe and appropriate. To enhance the effectiveness of this approach, we propose improvement of the patient recall system incorporating automated prompts within the shared electronic medical records and utilising posted or emailed letter reminders. Additionally, we recommend sustained support from specialist teams through periodic audits and expert advice.

Thyroid health in inflammatory bowel disease

Suleyman Sami Guzel[1], Ahmet Numan Demir[2], Tugce Eskazan[3], Ali Ibrahim Hatemi[3] & Mustafa Sait Gonen[2]
[1]Istanbul University-Cerrahpasa Cerrahpasa Faculty of Medicine, Department of Internal Medicine, Istanbul, Turkey; [2]Istanbul University-Cerrahpasa Cerrahpasa Faculty of Medicine, Department of Internal Medicine, Division of Endocrinology, Metabolism, and Diabetes, Istanbul, Turkey; [3]Istanbul University-Cerrahpasa Cerrahpasa Faculty of Medicine, Department of Internal Medicine, Division of Gastroenterology, Istanbul, Turkey

Aim
Changes in thyroid functions, parenchymal structure and increased frequency of thyroid diseases in inflammatory bowel diseases(IBD) have been described in various studies. In the literature, studies using the data scanning method, most of which belong to the past period, stand out. In this study, we wanted to investigate the relationship between IBD and thyroid diseases in a non-retrospective study. The aim of this study is to systematically check whether there is a relationship between Hashimoto's thyroiditis and IBD, which is especially common and whether the thyroid parenchymal structure of people with IBD is impaired, using the newly defined/started to be used VESINC scoring system. In this study which was conducted with subgroups receiving classical treatment and biological agent treatment for ulcerative colitis(UC) and Crohn's disease(CD), the thyroid health was examined.
Material and Method
Among the patients diagnosed with CD and UC who were followed up in our hospital's IBD outpatient clinic those who applied to the hospital between January-June 2023, met the study criteria and accepted to attend the study were included. A healthy control group similar to patient group in terms of age and gender was also included in the study. Thyroid stimulating hormone(TSH), free T_3(fT_3), free T_4(fT_4), anti thyroid peroxidase(anti-Tpo), anti thyroglobulin(anti-Tg) was measured and thyroid gland structure was evaluated using the VESINC system by thyroid USG in patients with a known diagnosis of UC/CD and healty control group. At the same time, sociodemographic characteristics, clinical/endoscopic parameters were recorded from the patients' files. Each group was also separated and compared according to the drug groups they used(conventional treatments, biological agents).
Results
A total of 260 individuals, including 203 patients and 57 healthy controls were evaluated cross-sectionally/prospectively. In the IBD arm, it was observed that the thyroid structure was impaired, the number of nodules increased and the gland volume increased compared to the healthy control group. Biological agents used in the treatment of IBD also have different effects on thyroid gland echogenicity;it was concluded that the rate of thyroid isoechogenicity was higher in patients receiving ustekinumab and infiliximab compared to other groups. TSH, fT_3, fT_4levels were similar between CD/UC and control groups regardless of treatments. Autoantibody levels were also found to be similar in all groups regardless of treatment.
Conclusion
Thyroid gland morphology changes in IBD. There are changes in gland volume, nodule number and heterogeneity compared to the healthy population. Since the study was cross-sectional, long-term prospective follow-up of these patients may reveal the high rate of thyroid dysfunction and autoantibody positivity that may be overlooked during the disease process. The positive effect of ustekinumab on thyroid morphology may be worth investigating as a potential therapeutic approach.

Changes of lipid profile in subclinical hyperthyroidism and following restoration of euthyroidism

Grzegorz Kaminski[1], Ewelina Szczepanek - Parulska[2], Michał Olejarz[3], Marek Ruchała[4] & Marek Saracyn[1]
[1]Military Institute of Medicine - National Research Institute, Endocrinology and Radioisotope Therapy, Warsaw, Poland; [2]Poznan University of Medical Sciences, Endocrinology, Metabolism and Internal Medicine, Poznan, Poland; [3]Poznan University of Medical Sciences, Endocrinology, Metabolism and Internal Medicine, Poznan; [4]Poznan University of Medical Sciences, Endocrinology, Metabolism and Internal Medicine, Poznan, Poland

Background
The impact of subclinical hyperthyroidism (sHT) on lipids concentration is still unclear. The aim of the study was to prospectively evaluate the changes in lipid profile in patients with sHT and following restoration of euthyroid state.
Patients and methods
The studied group consisted of 44 patients (37 females, 7 males), diagnosed with endogenous sHT in the course of either toxic multinodular goiter, diffused thyroid autonomy or autonomously functioning thyroid nodule. All patients were treated with radioiodine. We measured TSH, fT3, fT4, total cholesterol (TC), low-density lipoprotein cholesterol (LDL), high-density lipoprotein cholesterol (HDL), triglycerides (TG), and sex hormone binding globulin (SHBG) serum concentrations at admission, and at every check-up visit until the last visit, which was scheduled 6 months after the restoration of euthyroidism.
Results
The restoration of euthyroidism was associated with a statistically significant increase in LDL cholesterol from 114.3 to 121.9 mg/dl ($P=0.018$) and HDL cholesterol from 64.02 to 66.25 mg/dl ($P=0.041$). An increase in serum triglycerides from 95.2 to 102.6 mg/dl was also observed but it was not statistically significant ($P=0.273$). The total cholesterol serum concentration also increased after treatment (from 204.6 to 211.1 mg/dl), however the increase was statistically nonsignificant ($P=0.11$).
Conclusion
Treatment of sHT results in a statistically significant increase in LDL cholesterol and HDL cholesterol serum concentration. The rise in serum triglycerides and in total serum cholesterol did not reach statistical significance. Further studies assessing the impact of sHT treatment on lipid metabolism are still needed. It is still unclear how different treatment modalities and different causes of sHT impact lipid metabolism and whether the observed changes are clinically relevant in terms of cardiovascular risk.

ALK fusion genes in a large cohort of thyroid carcinomas

Barbora Bulanova[1], Vlasta Kuklikova[1], Karolina Mastnikova[1], Eliska Vaclavikova[1], Jitka Carkova[1], Petr Vlcek[2], Petr Lastuvka[2], Rami Katra[2], Petr Bavor[2], Daniela Kodetova[2], Martin Chovanec[3], Jana Drozenova[3], Jaromir Astl[4], Jiri Soukup[4], Josef Vcelak[1] & Bela Bendlova[1]
[1]Institute of Endocrinology, Prague, Czech Republic; [2]Motol University Hospital, Prague, Czech Republic; [3]University Hospital Kralovske Vinohrady, Prague, Czech Republic; [4]Military University Hospital, Prague, Czech Republic

Objectives
ALK fusion genes are a rare genetic alteration and have been described in various t types of thyroid carcinomas, particularly in papillary thyroid carcinomas (PTCs), poorly differentiated thyroid carcinomas (PDTCs) and anaplastic thyroid carcinomas (ATCs). The aim of this study was to identify *ALK* fusion genes in thyroid carcinoma samples, correlate them with clinical and histopathological features, and determine the prognostic significance of *ALK* fusion genes based on long-term follow-up of patients.
Methods
The cohort consisted of 1221 fresh frozen thyroid carcinomas, including 1051 PTCs, 11 PDTCs and 17 ATCs. The samples were sorted based on the mutation detected. Samples positive for *BRAF*, *HRAS*, *KRAS*, *NRAS* or *RET* mutations or *RET/NTRK* fusion genes were excluded from further analysis of the *ALK* fusion gene. Samples were analyzed for the presence of *ALK* fusion genes using the FusionPlex Comprehensive Thyroid and Lung panel (Invitae) by next-generation sequencing (MiSeq, Illumina).
Results
ALK fusion genes were detected in 13/1051 (1.2%) of PTCs. The mean age of patients at diagnosis was 23.7 $\pm$ 14.7 years, and 7/13 patients with *ALK* fusion-

positive PTC were of childhood or adolescent age (2-20 years). Three types of *ALK* fusions were found, including the following partner genes: *STRN, EML4* and *FMNL2*. *STRN/ALK* was identified in ten cases, *EML4/ALK* in two cases and *FMNL2/ALK* in one case. All *ALK* fusion-positive samples had no other mutation, and even none of the samples had a *TERT* or *TP53* mutation. The majority (10/13; 76.9%) of PTCs with a positive *ALK* fusion gene were of the follicular subtype. Lymph node metastases were found in 7/13 (53.8%) patients and distant metastases were found in 1/13 (7.7%) patients. Radioiodine treatment was indicated in 10/13 patients. In the first two years after surgery, 4/11 patients had a structural incomplete response to treatment due to local or distant metastases. In 3/4 patients, radioiodine treatment eliminated the metastases. In 1/4 patients, a reoperation was necessary. Current response to treatment in all 11 evaluable patients is excellent.

Conclusion

In summary, *ALK* fusion genes were identified only in PTCs and occurred in pediatric and adolescent patients rather than in adult patients. The most common type was the *STRN/ALK* fusion gene. The prognosis of patients with *ALK* fusion-positive PTC was favorable. Genetic molecular testing of *ALK* fusions is important for patient's diagnosis, prognosis and also for possible targeted therapy.

Long-term gene expression changes in the rat thyroid by neonatal irradiation - a possible mechanism related to thyroid carcinogenesis by childhood radiation

Nariaki Fujimoto[1], Mutsumi Matsuu-Matsuyama[2] & Masahiro Nakashima[2]

[1]Hiroshima University, Research Institute for Radiation Biology and Medicine, Hiroshima, Japan; [2]Nagasaki University, Atomic Bomb Disease Institute, Nagasaki, Japan

Introduction

Radiation exposure at young ages is a risk of thyroid cancer. Although early studies of the infants treated with X-rays already indicated an association, the risk became well-known by a rapid rise in childhood thyroid cancer cases after the Chernobyl nuclear plant accident. Human cases have been investigated extensively, but the underlying mechanisms have yet to be elucidated. Our previous investigation in rats found that neonatal X-irradiation induced long-term mRNA expression changes in the thyroid cancer-related marker genes, which may be a key to understanding childhood susceptibility to thyroid carcinogenesis. Then, in the present study, we performed a global gene expression analysis to identify the thyroid genes whose expressions were altered by neonatal irradiation in the rat model.

Materials and Methods

Male Wistar rats at 1 week old (neonates) and 8 weeks old (adults) were cervically X-irradiated at 0, 6, or 12 Gy. After 8 weeks, the thyroid was dissected and subjected to the gene expression analysis by the RNA-Seq (20 million reads, 100 bp pair-end analysis) to classify the genes regulated by radiation. The expression changes in the newly identified genes were confirmed by Q-RT-PCR. The expression changes were further examined in the thyroid tumors induced by feeding with an iodine-deficient diet in rats.

Results

1) The RNA-Seq analysis identified 114 up-regulated and 29 down-regulated thyroid genes in 8 weeks after irradiation. 2) A comparison between neonatal and adult irradiation found that 9 up-regulated and 5 down-regulated genes were specific to neonatal radiation exposure. 3) Among them, Cdkn1a and Vnn1 were identified as the up-regulated genes in the thyroid tumors.

Conclusions

We successfully identified a series of thyroid genes whose expression could be changed long-term after a single cervical irradiation during the neonatal period. Some of those genes, such as Cdkn1a and Vnn1, were also up-regulated in the thyroid tumors. These findings suggested that the alteration of gene expressions by neonatal radiation may contribute to the increased risk of thyroid cancer by childhood radiation exposure.

The association of gestational thyroid function and thyroid autoimmunity with offspring neurodevelopment: an individual participant meta-analysis

Joris Osinga[1, 2], Leonie Warringa[1, 2], Consortium on Thyroid and Pregnancy[3], Robin Peeters[1, 2] & Tim Korevaar[1, 2]

[1]Erasmus MC, Internal Medicine, Rotterdam, Netherlands; [2]Erasmus MC, Academic Center for Thyroid Diseases, Rotterdam, Netherlands; [3]Working group on offspring neurodevelopment (see https://www.consortiumthyroidpregnancy.org)

Objective

Adequate thyroid hormone availability is essential for foetal neurodevelopment. While overt maternal hypothyroidism is associated with lower offspring IQ, recent studies suggested an inverse U-shaped association, with suboptimal offspring neurodevelopment for both the lower and higher thyroid function range. Our aim is to investigate the association of gestational thyroid function with offspring IQ scores, assess if this association is different based on the gestational age at blood draw or TPOAb positivity.

Methods

We performed an individual participant data meta-analysis using data from prospective birth cohorts on gestational thyroid function and offspring IQ. Exclusion criteria were pre-existing thyroid disease, thyroid hormone altering medication usage, multiple gestation. IQ measurements <50 or >150 were winsorized. Neurodevelopmental tests were standardized to a mean of 100 and standard deviation of 15 to facilitate comparison among cohorts. We performed hierarchical linear mixed regression models accounting for repeated measurements, adjusting for potential confounders including maternal age, education, ethnicity, body mass index, smoking status, parity, gestational age at blood sampling and fetal sex. We used multilevel multiple imputation for missing covariate data and inverse probability weighting to account for attrition.

Results

The final study population comprised 14, 767 participants from 11 cohorts of whom 6, 064 had repeated IQ measurements (median age of measurement 6.1 years, interquartile range [IQR] 3.1-8.7 years). There was an inverted U-shaped association of FT4 concentrations with child IQ ($P=0.00048$). For both low and high FT4 this corresponded with a mean difference in IQ scores of -5.5 to -6.5 in the full range and -1.0 to -1.5 in the euthyroid range. A leave-one-out analyses to prevent a single cohort from driving the association yielded similar results. After stratification for gestational age at blood sampling (median 13.2 weeks, IQR 11.6-17.5), there was no association between FT4 and child IQ scores after 25 weeks of gestation, although data were limited in this period. There was no statistically significant association of TSH, TPOAb positivity, subclinical hypothyroidism, isolated hypothyroxinaemia, subclinical hyperthyroidism or overt hyperthyroidism with child IQ scores.

Conclusions

Both low and high maternal FT4 concentrations, but not TSH, in pregnancy are associated with lower child IQ scores. This is the first multicentre study to replicate these findings and add important data on time dependency and persistency of the effect until older offspring age. These results emphasize that caution should be exercised when supplementing thyroxine in pregnancy at the risk of overtreatment and possible detrimental effects on offspring neurodevelopment.

Clinical value of reverse triiodothyronine in the identification of euthyroid sick syndrome and prediction of mortality in critically ill patients

Shaoyong Xu[1, 2] & Jingjing Zeng[2]

[1]Xiangyang Central Hospital, Affiliated Hospital of Hubei University of Arts and Science, Department of Endocrinology, Xiangyang, China; [2]Xiangyang Central Hospital, Affiliated Hospital of Hubei University of Arts and Science, Center for Clinical Evidence-Based and Translational Medicine, Xiangyang, China

Background

Elevated reverse triiodothyronine (rT3) is a characteristic feature of euthyroid sick syndrome (ESS), which is associated with mortality in critical patients. However, the lack of reference values limits the use of rT3 for ESS diagnosis and the prognostic value of rT3 is unclear. This study aimed to determine the reference range of rT3 in the ESS identification and mortality prediction in critically ill patients.

Methods

This ongoing prospective cohort study was conducted from April 2022 at eight hospitals in China. Patients who had been hospitalized in intensive care unit for at least 24 hours without thyroid disorders were consecutively enrolled. Demographic characteristics, APACHE II, and thyroid function were evaluated on admission. Patients were followed up at the time of ICU discharge, hospital discharge, and 90 days after discharge. Study outcomes included ESS diagnosis (defined as decreased free triiodothyronine on admission without thyroid itself lesion), in-hospital death, and 90-day death. The 2.5th percentile ($P_{2.5}$) of rT3 in ESS patients

was calculated as early warning. The optimal cut-off points of rT3 for the ESS diagnosis and mortality prediction were determined using receiver operating characteristic (ROC) curve and time-dependent ROC curve, respectively.
Results
This preliminary analysis presented the results of data collected up to January 2024. A total of 959 critical patients were screened, of which 849 (mean age 64.63 years, 3.25% male) were eligible and 34 were lost to follow-up after discharge. Of those, 394 (46.41%) had ESS on admission, 79 (9.31%) died during hospitalization, and 250 (30.67%) experienced 90-days deaths. The $P_{2.5}$ of rT3 levels in ESS patients was 0.57 ng/mL. The optimal cut-off point of rT3 for diagnosing ESS was 1.06 ng/mL, with an area under the curve of 0.745, sensitivity of 73.32%, and specificity of 67.13%. The optimal cut-off points for predicting in-hospital and 90-days mortality were 1.92 and 1.62 ng/mL, respectively. The log-rank test showed that patients with high rT3 level had higher in-hospital and 90-days mortality than those with low rT3 ($P < 0.001$). Sensitivity analysis (excluding patients discharged from ICU to home) did not significantly change the results.
Conclusion
In critically ill patients, rT3 had clinical value in identifying ESS and predicting mortality, which would contribute to risk stratification and care. The different levels of rT3 may have different clinical implications: 0.57 ng/mL for ESS early warning, 1.06 ng/mL as the optimal cut-off point for ESS diagnosis, and 1.62 ng/mL for mortality risk stratification.

Papillary thyroid cancer and body mass index: the role of mitochondrial arginase-2 in tumor microenvironment

Rebecca Sparavelli[1], Francesca Signorini[1], Riccardo Giannini[1], Elio Marchetti[1], Ferruccio Santini[2], Alessio Basolo[2] & Clara Ugolini[1]
[1]University of Pisa, Department of Surgical, Medical and Molecular Pathology and Critical Care Medicine, Unit of Anatomic Pathology; [2]University of Pisa, Obesity and Lipodystrophy Center, Endocrinology Unit

Background
Papillary thyroid cancer (PTC) is a disease with an indolent course, excellent overall prognosis and long-term survival. However, some PTCs are associated with an increased risk of recurrent disease and aggressive behaviour. Many exogenous factors, as obesity, could be implicated in the pathogenesis of thyroid cancer but the biological mechanisms that may explain this connection have been only partially described. Potentially factors that combine overweight with this cancer should be searched for in the immune pathways and chronic inflammation onset. In this study, we evaluated the role of immune system in patients affected by PTC and stratified according to body mass index (BMI).
Methods
Based on BMI, samples were subdivided into four categories: underweight, normal weight, overweight, and obese. The analysis of the expression profiles of >700 immune-related genes was performed in 36 PTCs. Normal weight was considered as reference category. Furthermore, results of gene expression analysis -and thus the existence of an effective concordance between gene expression and protein synthesis- were confirmed by immunohistochemistry (IHC), calculating the H-score, a semiquantitative measure based on the combined assessment of staining intensity and the percentage of positive neoplastic cells.
Results
The immune microenvironment of PTC does not seem strongly influenced by BMI; however, we identify a statistically significant downregulation of *CASP3*, *FCGR2A*, *HMGB1*, *MAPK1*, *SPP1* and an upregulation of *ARG2*, *BCL2*, *NT5E*, *RORA* in the obese category. One of these genes, the mitochondrial arginase-2 (*ARG2*), was significant upregulated after application of Benjamini-yekutieli correction. A directly proportional and statistically significant correlation was observed between H-score and ARG2-mRNA, and between H-score and BMI, therefore the IHC results agree with those of the molecular analysis and show that the expression of ARG2 in the tumor microenvironment of PTC patients increases in relation to the increase in BMI, being significantly more intense in obese patients.
Conclusions
ARG2, which hydrolysed arginine into urea and ornithine, can influence the endogenous level of polyamines, proline, and NO (nitric oxide), key components for collagen system, tissue proliferation, immune system regulation and inflammatory response. In the last years, many studies have focused on the relationship between altered metabolism and the activity of immune system. Although, molecular mechanisms linking excessive adiposity with the development of cancer are complex and still not completely known. The investigation of molecular processes in tumor microenvironment may provide an opportunity to understand the role of immunometabolism in thyroid cancer.

Introduction
Medullary thyroid cancer (MTC) is a rare thyroid neoplasm arising from parafollicular C-cells secreting calcitonin. Although it possesses specific histological and biochemical markers, real-life diagnosis and management remain challenging.
Aim
A retrospective analysis of MTC patients from four Hungarian endocrine university centres over 23 years (2000-2023) was undertaken. Demographic data and biochemical markers, staging, germ-line RET mutation, intervention types, and monitoring through calcitonin-doubling time were analyzed.
Results
Data from 156 patients were collected from patient files. Bilateral disease was demonstrated in 26, 6% of patients, with 37, 5% having lymph node involvement at the time of diagnosis. Preoperative calcitonin was measured in 84, 2% of cases, and FNAB was performed in 72% of patients. Diagnosis of MTC based on preoperative cytology accounted for 67, 4% of cases. The use of preoperative diagnostics increased with time ($P<0$, 05). Nearly one-third of patients were diagnosed with advanced disease (stage IV). Total thyroidectomy and node dissection were performed in 53, 8%; this rate was higher following 2015 vs before ($P<0.05$). Progression of disease was recorded in 47, 8% of patients. Two, three and four neck dissections were performed in 43, 17 and 4 patients, respectively. In the first year after surgery, calcitonin measurements were available in 75% of patients. Forty-four patients (29.53%) were declared cured after the first surgery. Postoperative calcitonin doubling time less than two years was associated with significantly lower progression-free survival than calcitonin doubling time longer than two years ($P<0.05$). RET mutation analysis was performed in 73% of patients, and of these, 34, 2% were confirmed to have RET germ-line mutation, and the most frequent genetic alteration was on codon 634. In advanced disease, tyrosine kinase inhibitors were instituted in 35 cases. Disease progression and drug-induced adverse events were significantly more frequent with multikinase inhibitors as compared to that of selpercatinib ($P<0.05$).
Conclusion
Despite the progress and more widespread use in diagnostic procedures and recent advances in drug treatment options, there are still unmet needs in managing MTC. Preoperative calcitonin measurement is the best marker for diagnosis, although its routine use in screening is debated. FNAB alone is often not sufficient for exact preoperative diagnosis of MTC; completion with immunocytology or calcitonin measurement from the washout fluid could increase the sensitivity of preoperative biopsies. Surgery can be curative, mostly in local diseases. Advanced cases need an individualized approach. Recently, germ-line/somatic RET mutation analysis has become indispensable in choosing appropriate targeted medical treatment for MTC.

Women-specific reference ranges for serum TSH in Liguria: the impact of age and time of collection in a single-centre cross-sectional study

Massimo Giusti[1, 2] & Marilena Sidoti[1, 3]
[1]Endocrine Unit, Centro Clinico Diagnostico Priamar, Savona, Italy; [2]Dipartimento di Medicina Interna, Università di Genova, Genoa, Italy; [3]Endocrine Unit, Azienda Sanitaria Locale 2 Savonese, Savona, Italy

Background
TSH is the first-line test for thyroid function. Since the 1990s, 3rd-generation assays have been available on automated platforms, and the normal ranges

provided by manufacturers are generally used in diagnoses. In the age of gender medicine there is a need to refine normal TSH ranges. The aim of this study was to construct a normal TSH range in women living in our district.
Methods
From 2005 to 2020, 4544 records from women undergoing their first endocrinological examination were anonymously evaluated; 18% of records were excluded owing to lack of data (65%), age (<18 years; 18%), pregnancy (7%), non-Caucasian ethnicity (6%) and other reasons (4%). Age, BMI, TSH, TPOAb, pharmacological treatments and US findings were collected from 3724 records. 1638 were excluded owing to the presence of overt diseases, interfering treatments and TPOAb positivity. Thus, statistical analysis was performed on a sample of 2086 medical records. Data are reported as medians and 2.5-97.5 percentiles.
Results
Median TSH was 1.70 mIU/l (0.20-7.41 mIU/l). The median of TSH values collected from 2005 to 2020 ranged between 1.20 mIU/l (2005) and 1.99 mIU/l (2017), with significant differences between 2017 and 2005 ($P<0.01$), 2010 ($P=0.03$) and 2014 ($P=0.02$). On stratifying the sample into 3 age-groups (18-44 years, N=910; 45-64 years N=780; >65 years, N=393), TSH was 1.75 mIU/l (0.41-6.21 mIU/l), 1.66 mIU/l (0.20-6.93 mIU/l) and 1.52 mIU/l (0.07-7.78 mIU/l), respectively. In the whole sample, no correlation emerged between TSH levels and age or BMI. A significant ($P<0.0001$) decrease in the percentage of women considered to have sub-clinical hypothyroidism was observed when the upper limit of normal TSH was set at the age-related value of 97.5% (3.5%) instead of the TSH range reported in the assays (7.8%). By contrast, no difference in the percentage of women considered to have sub-clinical hyperthyroidism was noted when either the calculated age-related normal lower TSH limit (2.7%) or the manufacturers' normal lower TSH range (2.3%) was applied.
Conclusions
This is the first study in Liguria aimed at establishing new age- and gender-specific reference values for TSH. Based on a large number of women (about 2% of adult women living in the Savona district), this new age-related range could be more extensively employed in order to improve diagnoses and therapies. The main result of implementing age- and gender-related normal TSH levels between the 2.5 and 97.5 percentiles seems to be a reduction in the hasty diagnosis of sub-clinical hypothyroidism.

Adolescent with multiple benign skin lesions, cutaneous angiosarcoma and multiple thyroid nodules. what is the diagnosis?

Eirini Dikaiakou[1], Evgenia Magkou[2], Marina Servitzoglou[2], Marina Vakaki[3], Periklis Makrythanasis[4], Joanne Rachel Synodinou-Traeger[4], Nikolaos Marinakis[4], Myrsini Gkeli[5], John Skondras[6], Margarita Baka[2] & Elpis Vlachopapadopoulou[1]
[1]Children's Hospital 'P. & A. Kyriakou', Endocrinology Growth and Development, Athens, Greece; [2]Children's Hospital 'P. & A. Kyriakou', Oncology Department, Athens, Greece; [3]Children's Hospital 'P. & A. Kyriakou', Radiology Department, Athens, Greece; [4]Medical School, National and Kapodistrian University of Athens, St. Sophia's Children's Hospital, Laboratory of Medical Genetics, Athens, Greece; [5]General Hospital "Agios Savvas", Athens, Greece, Radiology Department, Athens, Greece; [6]Children's Hospital 'P. & A. Kyriakou', Department of B' Pediatric Surgery, Athens, Greece

Objective
To present the rare case of a patient with cutaneous angiosarcoma, multiple benign skin lesions together with multiple thyroid nodules and to discuss his genetic diagnosis.
Case Presentation
A $13^{2/12}$ years-old boy was referred to the Endocrinology department, following chemotherapy and radiotherapy. His medical history was uneventful until the age of 8 years. His mother reported Graves' disease and his maternal grandmother papillary carcinoma. Starting at the age of 8 years, he gradually developed multiple skin lesions: 1. Hemangioma on the right tibia, 2. Skin lesion on the left posterior chest wall characterized as Kaposi-form hemangioendothelioma that recurred after 1 year. 3. Infiltrating vascular skin neoplasm on the left posterior chest wall, with lymph node involvement, characterized as cutaneous angiosarcoma. The patient received chemotherapy together with radiotherapy. 4. New multiple benign skin lesions (skin fibromas, papillomatous lesions, lymphangioma) appeared during follow-up. The initial clinical assessment was remarkable for macrocephaly (head circumference 1 cm, >97th perc.) as long as obesity (BMI 31.8, >95th percentile), while his height (1.71m) was at the 95th percentile. He was pubertal with testicular size 12ml. Thyroid ultrasound revealed multiple nodules, including a prominent one on the right lobe with dmax:12.9mm, solid, strongly hypo-echogenic, with increased vascularization, wider than taller, without calcifications. Fine needle biopsy (FNB) revealed a hyperplastic nodule, BETHESDA II. Thyroid function was normal whereas anti-TPO, anti-TG were negative. From the age of 14 to the age of $16^{10/12}$ years, two additional FNBs were performed, because during regular follow up, the size of the nodule on the right lobe was increased (dmax: 24mm at the age of $16^{10/12}$ years old). They were both characterized as BETHESDA II. Thyroglobulin progressively increased to 143ng/ml. Genetic testing with WES revealed a variant in *PTEN*, NM_000314.8:c.389G>A, p.(Arg130GIn), which is characterized as pathogenic.
Conclusions
Pathogenic variants in *PTEN* are associated with Cowden syndrome (CS), Bannayan-Riley-Ruvalcaba syndrome (BRRS), *PTEN*-related Proteus syndrome (PS), and *PTEN*-related Proteus-like syndrome. They include a wide range of clinical manifestations, as well as increased risk of cancers mainly breast, thyroid, endometrial and renal. However, cutaneous angiosarcoma is not a typical manifestation of these syndromes. To our knowledge, this is the second case to be reported. Given the patient's increased risk of thyroid cancer, close follow-up with thyroid US is recommended. Any changes suggestive of malignancy should be appreciated and if results of FNB are suspicious, a total thyroidectomy should be performed.

Complications associated with the performance of thyroidectomies in a third-level hospital

Mónica Gómez-Gordo Hernanz[1], Gloria Collado González[1], Alberto García Piorno[1], Isabel Losada Gata[1], Marta Pérez Noguero[1], Ignacio Jiménez Hernando[1], Blanca Farache Suberviola[1], Amaya Morales Jaurrieta[1], Aurelio López Guerra[1] & Olga González Albarrán[1]
[1]Hospital General Universitario Gregorio Marañón, Endocrinology, Madrid, Spain

Introduction
major complications of thyroid surgery include; injury to the recurrent laryngeal nerve that can cause dysphonia and acute respiratory distress, postsurgical hematoma, infection and hypoparathyroidism, which can be transient or permanent.
Objective
to analyze the complications observed after performing thyroid surgery with different pre-surgical diagnoses in our center.
Methods
retrospective descriptive study of thyroidectomies performed during the years 2018 to 2021 by the General surgery, Otolaryngology, Thoracic surgery and Pediatric surgery services of the Gregorio Marañón Hospital in Madrid, Spain.
Results
A total of 624 patients were included, 69.6% of whom were women. The presurgical diagnoses were: multinodular goiter (36.1%), hyperparathyroidism (14.6%), nodule suspicious for malignancy (4.5%), thyroid cancer (24.8%), Graves-Basedow disease (7.1%) and others (5%). 47 patients (7.5%) underwent reoperation. Total thyroidectomy was performed in 56.4%, followed by right hemithyroidectomy in 19.2%, left hemithyroidectomy in 11.5%, parathyroidectomy in 2.4% and others in 1.4%. 80.3% of the surgeries were performed by General surgery, 5.6% by Otolaryngology, 2.4% by Thoracic Surgery, 3% by other services. Lymphadenectomy was performed in 18.3%. Of the patients who underwent surgery, 6 of them (1%) presented pre-surgical hypoparathyroidism. After surgery, 21.5% of patients had transient hypoparathyroidism, which was the most frequently observed complication and 5.8% had permanent hypoparathyroidism. In more than 60% of patients both recurrent laryngeal nerves were visualized and intraoperative neuromonitoring was performed. In 61%, intraoperative parathyroid hormone (PTH) drop was calculated in addition to pre- and postoperative PTH. In relation to recurrent paralysis, it was transient in 7% and permanent in 3.4%. 26 cases (4.2%) of postsurgical hematoma and 6 cases (1%) of infection were documented.
Conclusion
the most common postsurgical complication was transient hypoparathyroidism (21.5%) followed by transient recurrent paralysis (7%). Intraoperative determination of PTH is a predictive factor for the development of hypoparathyroidism. Neuromonitoring during surgery helps to preserve recurrent nerves. The development of postsurgical complications is greater in patients undergoing surgery for thyroid cancer, in total thyroidectomy and to a large extent depends on the experience of the center and the surgeons.

Objectives
Phosphatase and tension homolog (PTEN) is a part of signal pathways which are essential for cell proliferation, cell cycle progression, and apoptosis. Variants in the *PTEN* gene occur in different types of thyroid tumors with unclear diagnostic and prognostic impact. Most variants are somatic, but they can also be germline, which are associated with PTEN hamartoma tumor syndrome (PHTS). PHTS includes Cowden syndrome, which is characterized by hamartomas, and an increased risk of developing benign and malignant thyroid and other tumors. The aim of the study was to detect variants in the *PTEN* gene in a large cohort of patients with malignant as well as benign thyroid tumors.
Methods
The study consisted of 665 fresh frozen thyroid tumor samples from patients aged 3-91 years. Extracted DNA was used for next-generation sequencing of the *PTEN* gene (NM000314.8, exons 5-8). Variants in the *PTEN* gene were visualized in Integrative Genomics Viewer (Broad Institute) and evaluated by the VarSome platform (Saphetor SA). MLPA fragmentation analysis was performed to determine the presence of large-scale deletion or duplication in *PTEN*-positive samples. Data were evaluated by Coffalyser (MRC Holland).
Results
Pathogenic or likely pathogenic variants in the *PTEN* gene were detected in 11/411 (2.68 %) carcinomas (seven papillary thyroid carcinomas (PTCs), two anaplastic thyroid carcinomas, one follicular thyroid carcinoma, one oncocytic carcinoma), in 5/56 (8.93 %) low-risk neoplasms, and in 5/198 (2.53 %) benign nodules. The variants in the *PTEN* gene coexisted in three cases with variants in the *RAS* genes, in four cases with variants in the *TP53* and once with the *BRAF* V600E. MLPA revealed structural abnormalities in 5 *PTEN*-positive samples (1 PTC, 3 low-risk neoplasms, 1 benign nodule). Two patients with PTC had germline variant in the *PTEN* gene and had other symptoms of Cowden syndrome. Most patients with *PTEN*- positive carcinoma received one or two doses of radioiodine with different responses to treatment, only one patient with 90mm PTC died after 2× 7.4 GBq of radioiodine treatment with final stimulated thyroglobulin 24, 345 µg/L. In this PTC, *PTEN* c.801+1G>A and *TP53* R306* were identified.
Conclusion
In summary, *PTEN* variants were detected in 21/665 (3.16 %) thyroid tissues, higher appearance was in low-risk neoplasms (8.93 %). Due to the frequent occurrence of structural abnormalities in the *PTEN* gene, screening for copy number variants should be performed in *PTEN*-positive samples. *Supported by AZV NU21-01-00448 and MH CR RVO 00023761.*

Characterization of a series of 661 papillary throid microcarcinoma with excellent response to treatment

Elisabete Rodrigues[1, 2], Paulo Silva[2], Joao Magalhaes[2, 3], Mafalda Pinto[4, 5], Tiago Pimenta[2, 6], Manuel Sobrinho-Simões[2, 4, 5] & Paula Soares[2, 4, 5]

[1]Uls Sao Joao, Endocrinology; [2]Faculty of Medicine of the University of Porto - FMUP; [3]Uls Sao Joao, Pathology; [4]Instituto de Patologia e Imunologia Molecular da Universidade do Porto - Ipatimup; [5]3S -Institute for Research & Innovation in Health; [6]Uls Sao Joao, Endocrine Surgery

Introduction
The management of small size (≤ 1 cm) papillary thyroid carcinoma, also known as papillary thyroid microcarcinoma (PTMC) is a debated topic as it includes tumors with a wide range of biological characteristics and behavior.
Objectives
To describe prevalence, clinical and histological characteristics of PTMC with excellent response to treatment after a median follow up of 9.85±6.21 years.
Methods
We did a retrospective analysis of clinical and histopathological data of all patients operated on for thyroid cancer at our hospital between 1996 and 2013 with diagnosis of PTMC. Statistical analysis was done with SPSS 22.0 for MAC.
Results
During this period 1057 patients were diagnosed with PTMC. Of these 661 (577 females and 84 males with a mean age of 51.2±13.5 and 55.4±12.7 years, respectively) showed an excellent response to treatment. In 472 (72%) the diagnosis of PTMC was incidental and in 182 (27.8%) was non incidental. Incidental PTMC were significantly smaller than nonincidental (3.86±2.82 vs 7.43±2.36mm, $P<.001$). Initial surgery was lobectomy in 142 (21.5%), total thyroidectomy (TT) in 488 (73.8%), subtotal thyroidectomy in 5 (0.8%), totalization of thyroidectomy in 24 (3.6%) and TT+neck dissection in 2 (0.3%). Most cases were classical PTC and follicular variant of PTC (84% and 11%, respectively). In 547 (82.8%) cases no additional treatment was necessary after first surgery (group A), whereas in 114 (group B) another surgery and/or radioiodine was done. When comparing these groups we found significant differences between them in terms of age at diagnosis (71.7% were ≥45 years in group A vs 58.8% in B), incidental finding (77.8% in group A vs 45.6% in group B), multifocality (23.3% in group A vs 54.4% in B), vascular invasion (0.6% in group A vs 21.1% in B), extrathyroidal extension (2.8% in group A vs 26.3% in B), lymph node involvement (0% in group A vs 7.9% in B). During the follow-up tumor relapse occurred in 12 cases (1.8%), all locoregional, 8 initially treated with lobectomy and 4 with total thyroidectomy. The time to relapse was 5.08±5.56 (1-18) years.
Conclusion
PTMC is frequently found and the optimal treatment is still a matter of debate. Most of them had an excellent prognosis and no further treatment was needed after lobectomy or thyroidectomy. However some patients have clinical and histopathological poor prognostic factors as it is demonstrated in this series that justifies a longer follow-up.

Ocular myasthenia gravis and sub clinical hyperthyroidism- a rare occurrence

Umer Qazi[1], Yusuf shaikhali[1] & Melina Kostoula[1]

[1]Watford General hospital, Endocrine and diabetes clinic, Watford, United Kingdom

Introduction
The coexistence of myasthenia gravis (MG) and autoimmune thyroid disease (AITD) is well recognised, with 5-10% of MG patients also having an AITD[1-2]. Among AITD, hyperthyroidism association with MG is the most common[3]. Conversely, MG has a relatively low incidence of around 0.2% in individuals with hyperthyroidism[2, 4]. This implies a potential immunological cross-reactivity between the neuromuscular junction and thyroid components in certain cases of MG and hyperthyroidism[3]. Nevertheless, the precise pathogenic link between these two autoimmune diseases remains uncertain. There are reports of ocular MG in conjunction with hyperthyroidism[5-8]. There are limited reports of ocular MG in association with sub-clinical hyperthyroidism[10].
Case summary
A 60-year-old man with a history of prostate cancer underwent various treatments. In April 2023, he presented with right ptosis for three months with no associated symptoms. Initial thyroid tests in June revealed sub-clinical hyperthyroidism, suggesting thyroid-associated orbitopathy. Despite starting carbimazole, his ocular motility worsened, and he developed double vision when looking to each side. Positive acetylcholine receptor antibodies led to an ocular myasthenia gravis diagnosis in August 2023. A pyridostigmine trial showed inconsistent improvement, so prednisolone was initiated in September. A CT thorax and neck ruled out significant abnormalities, and thyroid function tests returned to normal. Ongoing carbimazole treatment was recommended after an October endocrinology review.
Discussion
The exact cause of this is unclear; immunological cross-reactivity and a genetic link have been postulated. For instance, an increase in thyroid antibodies has been found in patients with ocular MG[5-6]. Human leukocyte antigen (HLA) specificity (B8, DR3 and BW46) has also been reported between MG and thyroid disease[6, 11]. More recently, the TNF- α-863 polymorphism and HLA DQ-3 have both been

linked with MG and Graves' disease[12]. However, our understanding of the underlying mechanism behind MG and hyperthyroidism's association remains limited. Both hyperthyroidism and MG can present with ocular manifestations[9]. Thus, the initial presentation in this case was thought to be thyroid-associated orbitopathy. The patient's symptoms initially worsened until ocular MG was diagnosed; this highlights the importance of early diagnosis as about half of patients who present with ocular myasthenia develop generalised weakness within 6 months[13]. Previous case reports have also demonstrated thyrotoxicosis delaying the diagnosis of MG[14]. The patient in this case initially presented with unilateral ptosis. Ptosis is uncommon in thyroid-associated orbitopathy and suggests coexistence of MG[9-10, 15]. He then developed orbicularis oculi weakness and a positive Cogan lid twitch sign which strongly indicated MG[10, 15].

Autoimmune endocrinopathies in patients with relapsing and remitting multiple sclerosis

Sofia Chatzi[1], Vasiliki Georgakopoulou[1], Stavroula Paschou[2] & Georgios Boutzios[1]
[1]National and Kapodistrian University of Athens, Department of Pathophysiology, Medical School, Athens, Greece; [2]National and Kapodistrian University of Athens, Endocrine Unit and Diabetes Center, Department of Clinical Therapeutics, Alexandra Hospital, School of Medicine, Athens, Greece

Introduction
Patients with multiple sclerosis (MS) demonstrate, in a number of studies, increased risk of acquiring another autoimmune disease compared to general population. Autoimmune thyroid diseases, type 1 diabetes, psoriasis and inflammatory bowel disease are the most common reported. The aim of our study is to determine potential factors that affect the presence of autoimmune endocrinopathies in patient with relapsing and remitting MS.
Methods
We conducted a retrospective study in the outpatient clinic of autoimmune endocrinopathies of the Department of Pathophysiology at Laikon University Hospital. All patients were diagnosed with MS. We collected data from the medical record of patients with MS and autoimmune endocrinopathies. We compared the study group with control group consisting of patients with MS without endocrine autoimmunity. Patients with MS who have been treated with alemtuzumab were excluded from the study due to the association with hyperthyroidism.
Results
A total of 55 patients [29 MS patients with autoimmune endocrinopathy and 26 MS patients without, 46 (83.6%) females] were enrolled in the study. Hashimoto thyroiditis (HT) was the most common comorbidity, observed in 20 patients (68, 9%). Moreover, seven patients (24, 1%) had Graves' disease (GD) and two patients (6, 8%) diabetes mellitus type 1(DM1). Comparing the MS patients with autoimmune endocrinopathies and MS patients without, we observed a statistically significant difference in the mean value of age (50.62 ± 10.95 years vs 42, 88 ± 13.12 years, $P=0.021$) and the median value of years of disease duration [15 years (range 1-51) vs 9 years (range 1-23). $P=0.044$]. Performing binary logistic regression analysis neither age nor duration of the disease exhibited independent association with autoimmune endocrinopathy in MS patients. In addition, we did not detect any statistically significant difference between the MS patients with autoimmune endocrinopathy and MS patients without regarding gender, smoking, presence of cancer, presence of other autoimmunities and family history of autoimmunity.
Conclusion
In our study we showed a statistically significant difference in age and MS duration between patients with and without concomitant autoimmune endocrinopathies and HT was the most common disease presented.

Interrelationships between thyroid function, autoimmunity, low-grade inflammation, lipid profile and insulin resistance in graves' disease

Celestino Neves[1], João Sérgio Neves[1], Luis Miguel Pereira[1], Oksana Sokhatska[2, 3], Joana Queirós[1] & José Luís Delgado[2, 3]
[1]São João University Hospital, Faculty of Medicine of University of Porto, Department of Endocrinology, Diabetes and Metabolism, Porto, Portugal; [2]Faculty of Medicine, University of Porto, Basic and Clinical Immunology Unit, Department of Pathology, Porto, Portugal; [3]Faculty of Medicine, University of Porto, Center for Health Technology and Services Research (CINTESIS), Porto, Portugal

Aim
The aim of this study was to evaluate the association between thyroid function in Graves' disease (GD) with high-sensitivity C-reactive protein (hs-CRP), lipid profile, homocysteine, folate, vitamin B12 and insulin resistance.
Methods
We performed a cross-sectional of 104 patients with recently diagnosed GD. All participants were in the first cycle of treatment with methimazole. We collected demographic information, body mass indexes (BMI), laboratory data including thyroid function tests (TSH, FT3 and FT4), antithyroid antibodies levels (TRAb, anti-TPO and anti-thyroglobulin), lipid profile, hs-CRP, homocysteine, folate, vitamin B12 and insulin sensitivity indexes obtained from a 75 g OGTT. Statistical analysis was performed using the Mann-Whitney test, Spearman's correlation coefficients and logistic regression models adjusted for age and BMI. A two-tailed $P<0.05$ was considered statistically significant.
Results
Of the 104 subjects with GD, 94% were female. Forty-nine subjects were included in the hyperthyroid group and 55 in the euthyroid group. No differences were observed between groups regarding age and BMI. Patients with higher levels of TRAb (OR = 1.166; $P=0.004$), hs-CRP (OR = 3.064; $P=0.042$), Homeostatic Model Assessment for Insulin Resistance (HOMA-IR) (OR = 1.613; $P=0.025$) or insulinogenic index (IGI) (OR = 2.933; $P=0.046$) had a higher risk of being hyperthyroid. In the overall population, TSH levels were positively correlated with folate ($r=0.240$; $P=0.021$), hepatic insulin sensitivity index (HISI) ($r=0.217$, $P=0.046$) and whole-body insulin sensitivity index (WBISI) ($r=0.356$, $P=0.001$). TSH levels were negatively correlated with TRAb ($r=-0.461$, $P<0.001$), HOMA-IR ($r=-0.218$, $P=0.045$) and IGI ($r=-0.313$, $P=0.004$). FT3 and FT4 levels were positively correlated with HOMA-IR ($r=0.284$, $P=0.008$ and $r=0.261$, $P=0.016$ respectively) and negatively correlated with HISI ($r=-0.283$; $P=0.009$ and $r=-0.261$, $P=0.016$ respectively) and WBISI ($r=-0.233$, $P=0.032$ and $r=-0.260$, $P=0.016$ respectively). Negative correlations were also found between FT3 levels and quantitative insulin sensitivity check index (QUICKI) ($r=-0.281$, $P=0.009$) and between FT4 levels and HDL-C ($r=-0.198$, $P=0.046$). In the hyperthyroid group, FT3 levels were positively correlated with levels of Lp(a) ($r=0.367$; $P=0.020$) and with HOMA-IR ($r=0.384$; $P=0.017$), and negatively correlated with QUICKI ($r=-0.379$; $P=0.019$) and HISI ($r=-0.384$; $P=0.017$). In the euthyroid group, TSH levels were positively correlated with WBISI values ($r=0.291$; $P=0.047$) and the levels of FT3 and vitamin B12 were negatively correlated ($r=-0.358$; $P=0.01$).
Conclusion
Our study shows a significant interrelationship between thyroid function, autoimmunity, insulin resistance, lipid profile, folate, vitamin B12 and low-grade inflammation in patients with GD.

Serum CD5L as potential biomarker of thyroid hormone status during pregnancy

Sabrina Asaad[1], Thilo Chillon[1], Dorota Filipowicz[2], Britta Wilms[3], Frank Strenge[4, 5], Ewelina Szczepanek-Parulska[2], Minich Waldemar[1], Sebastian Meyhöfer[6, 7], Jens Marquardt[5], Jens Mittag[3], Henrik Oster[4], Marek Ruchala[2] & Lutz Schomburg[1]
[1]The Institute for Experimental Endocrinology, Charité-Universitätsmedizin; [2]Department of Endocrinology, Metabolism and Internal Medicine, Poznan University of Medical Sciences; [3]Institute for Endocrinology and Diabetes, Center of Brain Behavior & Metabolism, University of Lübeck; [4]Institute of Neurobiology, Center of Brain, Behavior and Metabolism, University of Lübeck; [5]Department of Medicine I, University of Lübeck; [6]Institute for Endocrinology & Diabetes, University of Lübeck; [7]German Center for Diabetes Research (DZD)

Introduction
The thyroid hormone (TH) status is routinely assessed by thyrotropin (TSH) and thyroxine (T4). Both biomarkers are mainly regulated by thyroid hormone receptor beta, whereas many peripheral organs employ the alpha receptor. Serum CD5L is a liver-derived protein under control of both TH receptor isoforms, but the data base is small [1]. An additional biomarker of TH status is needed in particular during pregnancy, where the routine biomarkers become dynamically disturbed [2]. Ideally, such a diagnostic parameter should display little circadian variation in order to be suitable for routine measurements [3].

Objective
This study aimed to determine possible covariates regulating serum CD5L and to test its potential suitability as additional TH biomarker during pregnancy.
Subjects and Methods
A sandwich ELISA for serum CD5L was established using newly raised antibodies. Circadian effects and the impact of liver disease on serum CD5L concentrations were assessed. Serum samples from pregnant women with well-characterized TH and trace element status were analyzed, and CD5L concentrations were correlated with other indicators of TH status including TSH, fT4, fT3, copper and selenium concentrations.
Results
The new quantitative assay for CD5L showed high accuracy. Serum CD5L was stable in dilution and refreezing experiments and did not show strong circadian variance or dependency on liver disease. In serum of pregnant women, CD5L correlated positively to fT3, but not to fT4 or TSH. Significant positive correlations of CD5L were observed with serum levels of the TH-responsive trace elements selenium and copper.
Conclusion
The data support the potential suitability of serum CD5L as an additional marker of TH status, with potential value for pregnancy and thyroid disease. This notion needs to be tested in sufficiently large clinical studies.

Antithrombotic/anticoagulant drugs did not increased the riscк of bleeding during thyroid fna (nor its whithdrawal up to one month reduced iťs risk)

Catarina Roque[1], Cláudia Correia[1], Sandra Silva[1], Andreia Caldeira, Nurse[1], Ricardo Valadares, Nurse[1], Ana Paula Fernandes, Nurse[1], Filipa Barreiros, Nurse[1], Ana Osório[1], Sofia Oliveira[1] & Ricardo Fonseca[1]
[1]Hospital Prof Dr Fernando Fonseca

Introduction
Thyroid fine-needle aspiration cytology (TFNA) is a widely used diagnostic method that is generally safe. Aiming to reduce haemorrhage doctors frequently advise patients to withdrawal antithrombotic/anticoagulant (AT/AC) drugs before TFNA. There are no guidelines recommending so and the so called 'novel anticoagulants' have been poorly studied in this context. Some patients are likely being exposed to increased thrombotic risk unnecessarily. Evidence is little but increasing indicating no extra risk of haemorrhagic complications and possibly no need of antithrombotic/anticoagulant (AT/AC) drug withdrawal.
Objective
To compare the incidence of haemorrhage in patients with and without AT/AC drugs during FNA in our centre.
Method
Retrospective observational study of the FNAs performed between the 1st of may 2019 and the 31st of december 2021. Records of haemorrhage and drug treatment were made prospectively during FNA. All FNAs were performed by the same operator, using the same technique and needle gauge. In warfine treated patients FNA was performed if INR was 2-3.
Results
We evaluated 491 FNAs, patients average age was 61y.o. The general incidence of haemorrhage was 3.6%. Of the patients with this complication only 2 were taking AT/AC drugs (11%), one had stopped aspirin 3days, the other stopped dabigatran 1week and the rest was off any AT/AC drugs. The total of patients treated with AT/AC drugs was 78 (16%). In this group the incidence of haemorrhage was 2.5%, represents 2 patients both treated with antithrombotic drugs (one aspirin and the other clopidogrel). There were no haemorrhages with enoxaparin nor with any oral anticoagulant. There was no statistically significant difference (SSD) (p 0, 63) in the incidence of haemorrhages in the treated vs untreated group ($n=348$). There was no SSD (p 0, 30) in the incidence of haemorrhages in the treated group vs the group that stopped therapy 24h to 3days before the procedure ($n=16$). There was no SSD (p 0, 46) in the incidence of haemorrhages between the group that stopped therapy 24h to 3days before the procedure and the group that stopped therapy 4days to 1month before the procedure ($n=13$).
Conclusion
There was no significant association of haemorrhage with drug treatment. The incidence of complications was lower in the treated group. There were no complications in patients treated with anticoagulants, haemorrhage occurred in patients taking antithrombotic drugs only (the incidence was lower than in the untreated group). To withdrawal AT/AC drugs before the procedure did not provide a statistically significant decrease in haemorrhagic complications.

Simultaneous presentation of thyrotoxicosis and diabetic ketoacidosis in two previously healthy men

Hani Meriem[1], Boucelma Fedwa[1], Allal Hanane[1], Imane el ghebir[1] & Ait Abderrahmane Samir[1]
[1]Algiers Province, Algeria

Graves' disease and type 1 DM (T1DM) both have an autoimmune aetiology. Also, Thyrotoxicosis (TT) has previously been described as a possible precipitant of diabetic ketoacidosis (DKA) in patients with T1DM. Due to the similarities in their clinical presentation, DKA can mask the diagnosis of TT and vice versa. We report two cases of the simultenous presentation of thyrotoxicosis and diabetic keto-acidosis in two previously healthy men. Case 1: A 27-year-old man with no history of any disease presented to the emergency department (ED) with unintentional weight loss of 15 kg in 1 month, excessive sweating, abdominal pain, anxiety and tremors of the extremities. On examination, the patient appeared anxious, dehydrated. Blood pression was 107/68 mmHg and heart rate at 98 beats/min. He had palpable goitre. Investigations revealed that HbA1c was 10.7%, blood glucose was 19 mmol/l with 3+ ketonuria and compensated mild acidosis. Thyroid function test revealed TSH (0.01 mIU/L), free T4 (35 pmol/L). Thyroid scintigraphy revealed a diffuse hypercaptating goiter. Both anti-GAD and anti-TSH receptor antibody were positives. The patient was managed with carefully administered intravenous fluids, intravenous insulin and electrolyte replacement. After resolution of DKA, the patient was transitioned to subcutaneously administered insulin and Carbimazole 20 mg was added. Case 2: A 24-year-old man with familial history hashimoto's disease presented to the emergency department (ED) with unintentional weight loss of 14 kg in 6 months, excessive sweating and palpitations. On examination, Blood pression was 121/64 mmHg and heart rate at 104 beats/min. He had palpable goitre. Investigations revealed that HbA1c was 14.9 %, blood glucose was 19 mmol/l with 2+ ketonuria and compensated mild acidosis. Thyroid function test revealed TSH (0.006 mIU/L), free T4 (57 pmol/L). Thyroid scintigraphy revealed a diffuse hypercaptating goiter. The patient was managed with carefully administered intravenous fluids, intravenous insulin and electrolyte replacement. After resolution of DKA, the patient was transitioned to subcutaneously administered insulin and Carbimazole 30 mg was added.
Discussion
Thyroid hormones affect glucose metabolism at the cellular level by causing insulin resistance, upregulating glucose production by glycolysis and gluconeogenesis pathways and increasing gut absorption of glucose. Thyroxine also decreases serum insulin levels by increasing renal excretion. The resulting state of insulinopenia and insulin resistance causes disinhibition of hormone-sensitive lipase. This leads to unchecked lipolysis and fatty acid oxidation with increased ketones production.

Echocardiographic differences between the mild form of subclinical hypothyroidism and healthy subjects

Valentina Velkoska Nakova[1], Brankica Krstevska[2], Elizabeta Srbinovska Kostovska[3], Ljubica Georgievska Ismail[3], Cvetanka Volkanovska Ilijevska[4] & Tatjana Milenkovic[5]
[1]Faculty of Medical Sciences, Goce Delcev University, Stip, Republic of North Macedonia, Clinical Hospital, Internal medicine, Stip, Macedonia; [2]Internal Medicine Center 'Srce', Skopje, Macedonia; [3]Medical Faculty, Ss. Cyril and Methodius University in Skopje, RN Macedonia, University Clinic of Cardiology, Skopje, Macedonia; [4]Medical Faculty, Ss. Cyril and Methodius University in Skopje, RN Macedonia, Skopje, Macedonia; [5]Medical Faculty, Ss. Cyril and Methodius University in Skopje, RN Macedonia, University Clinic of Endocrinology, diabetes and metabolic disorders, Skopje, Macedonia

Background
Treatment of subclinical hypothyroidism (ScH) when TSH is between the upper reference value and 7mU/L, especially in patients younger than 65 years is controversial.
Objectives
To compare the risk factors for atherosclerosis and echocardiographic parameters in patients with ScH1 (4, $2 \leq TSH \leq 7$mU/L) to euthyroid subjects and patients with ScH2 (TSH $>$ 7mU/L).
Material and Methods
Prospectively 54 consecutive patients with newly diagnosed ScH (19 with TSH $\leq$ 7mU/L (ScH1) and 35 with TSH $>$ 7mU/L (ScH2)) started for the first time with levothyroxine therapy, and 30 healthy subjects were recruited from the outpatient department of the University Clinic of Endocrinology in Skopje, R. of N. Macedonia. Laboratory analyses and an echocardiography study were done at the first visit and after 5 months in a euthyroid stage in patients with ScH.
Results
The mean age and TSH value in ScH group were 43.1 ± 12.4y., and 8.71 ± 1, 9mU/L. Compared to healthy controls, patients with ScH1 had a higher mean triglycerides and non-HDL-C ratio (1.52 ± 0.9 vs 1.1 ± 0.6, and 4.3 ± 1.1 vs 3.79 ± 0.9, $P < 0.05$), lower E/A ratio (1.05 ± 0.25 vs 1.26 ± 0.36, $P < 0.05$), higher E/e' sep. ratio (8.56 ± 2.63 vs 6.04 ± 1.64, $P < 0.01$), higher myocardial performance index (MPI) (0.47 ± 0.09 vs 0.43 ± 0.07, $P < 0.05$), lower global longitudinal strain (GLS) (-19.34 $\pm$ 2.0 vs -20.9 $\pm$ 1.7%, $P < 0.05$), and lower S wave derived by tissue Doppler imaging (0.074 ± 0.01 vs 0.092 ± 0.01 m/s, $P < 0.01$). Compared to ScH2, patients with ScH1 have lower GLS but without statistical significance. Levothyroxine treatment (L-T4T) in patients with ScH1 contributed to higher EF (61.9 ± 5.2 vs 63.1 ± 4.6%, $P < 0.05$), lower E/e' sep. ratio (8.56 ± 2.63 vs 7.21 ± 2.23, $P < 0.05$), and lower MPI (0.47 ± 0.09 vs 0.43 ± 0.05%, $P < 0.05$), compared to values in ScH1 patients at baseline. The same parameters were improved in the ScH2 group after L-T4T.
Conclusions
In a small study, patients with ScH1 vs healthy individuals had subtle changes in certain parameters that indicate involvement of diastolic function of the left ventricle in ScH, and these parameters improved after L-T4T.

hCG-TSHR cross-interaction: a rationale for in hyperemesis gravidarum?

Carmela Perri[1, 2], Clara Lazzaretti[2], Lara Baschieri[2, 3], Lorenzo Marchetti[2], Samantha Sperduti[2, 4], Claudia Fusco[2], Manuela Simoni[2, 4, 5], Giulia Brigante[2, 5] & Livio Casarini[2, 4]
[1]International Ph.D. School in Clinical and Experimental Medicine (CEM), Department of Biomedical, Metabolic and Neural Sciences; [2]Unit of Endocrinology-University of Modena and Reggio Emilia, Department of Biomedical, Metabolic and Neural Sciences, Modena, Italy; [3]International Ph.D. School in Clinical and Experimental Medicine (CEM), Department of Biomedical, Metabolic and Neural Sciences, Modena, Italy; [4]Center for Genomic Research, University of Modena and Reggio Emilia, Modena, Italy; [5]Department of Medical Specialties, Azienda Ospedaliero-Universitaria di Modena, Modena, Italy

About 50% of women have nausea and vomiting during pregnancy. In about 35% of women who have these symptoms, nausea and vomiting are clinically significant, worsening their living conditions and consisting in a case of gender gap. The severe form, hyperemesis gravidarum, ranges from 0.3 to 1.0% of cases and is characterized by persistent vomiting, gestational thyrotoxicosis, weight loss of more than 5%, ketonuria, hypokalemia and dehydration, although the pathophysiological mechanism is unknown. Some studies found that increasing human chorionic gonadotropin (hCG) levels overlap the fall of thyroid stimulating hormone (TSH) levels, the increase of thyroid hormone (T3 and T4) levels, and the appearance of hyperemesis gravidarum. Thus, it was hypothesized that hCG binds to TSH receptor (TSHR), perturbing thyroid functions and triggering hyperemesis gravidarum. The aim of this study is to characterize hCG-TSHR cross-interactions *in vitro*, finding a rationale to support the clinical hints. Mechanistic experiments evaluating TSHR-dependent cell signaling pathways were performed in COS7 cell line. Cells were transfected with TSHR-coding plasmid and treated with pM-nM hCG doses before Gs and Gq protein-mediated pathway analysis. Intracellular levels of cyclic adenosine monophosphate (cAMP) and calcium ions (Ca^{2+}) increase were measured by bioluminescence resonance energy transfer (BRET), while inositol monophosphate (IP1) was evaluated by homogeneous time resolved fluorescence (HTRF). Results were compared by Kruskall-Wallis test ($n = 5$; $P < 0.05$) and corrected by Dunn's post-hoc test. Results demonstrated that 50 nM hCG activates the TSHR/Gαq pathway, resulting in intracellular IP1 and Ca^{2+} increase, while no cAMP activation occurred. Results were compared to those obtained from transfected cells treated with the vehicle, in the absence of hCG, which did not result in any Ca^{2+}/IP1 increase. These data support the clinical relationship between hCG and thyroid functions in hyperemesis gravidarum.

Pathogenic variants of CHEK2 gene in thyroid cancer (TC) patients with a personal and/or familial history of other malignancies

Dominika Kapusta[1], Bartosz Domagała[2], Norbert Kapczyński[1], Marek Kachnic[1], Anna Nogiec[3], Małgorzata Trofimiuk-Muldner[4] & Alicja Hubalewska-Dydejczyk[4]
[1]Jagiellonian University Medical College, Students' Scientific Group of Endocrinology at the Department of Endocrinology, Kraków, Poland; [2]University Hospital in Krakow, Department of Endocrinology, Endocrine Oncology, Nuclear Medicine and Internal Medicine, Kraków, Poland; [3]University Hospital in Krakow, Haematological Diagnostics and Genetcis Unit, Kraków, Poland; [4]Jagiellonian University Medical College, Chair and Department of Endocrinology, Kraków, Poland

CHEK2, located on chromosome 22q, is a tumor suppressor gene. Its' pathogenic variants are often associated with a tumor predisposition syndrome 4, with an increased risk of breast, prostate and colorectal cancers. There are some reports of an increased risk of papillary thyroid cancer (PTC) in carriers of the *CHEK2* pathogenic variants. Current guidelines, however, do not recommend general screening of TC patients. The study assessed the prevalence of pathogenic *CHEK2* variants in patients diagnosed with TC with a personal and/or familial history of other malignancies. The study was a retrospective analysis of a group of 163 patients (138 females and 25 males, mean age of 48.9 years) diagnosed with TC and with a positive personal and/or familial history of other mutation-related malignancies. *CHEK2* (exons 4, 5, 12) were analyzed by Sanger sequencing. If negative – deletions analysis was performed with MLPA. Pathogenic or likely pathogenic *CHEK2* variants were found in 25 patients (21 females and four males; 15, 3% of the study group). There was no significant difference in the mean age at diagnosis in patients positive and negative for *CHEK2* pathogenic variants (46 vs 49 years, respectively; $P = 0.39$). The average number of malignancies in the family members was higher in patients harboring *CHEK2* pathogenic variants; the difference was not statistically significant (1.88 vs 1.63; $P = 0.36$). There was no difference in the personal history (12% vs 29.7%, respectively) or family history (84% vs 83%, respectively) of other malignancies in *CHEK2*- positive and negative PT cancers. There was no significant difference between *CHEK2* positive and negative patients in number of breast, prostate and colon cancers combined in family members. Thyroid cancer was significantly more common in family members of patients with *CHEK2* pathogenic variants (9 cases vs 12 cases in *CHEK2* negative group, $P = 0.006$).
Conclusions
The frequency of *CHEK2* pathogenic variants in a preselected group of PT patients with a personal and/or familial history of other malignancies is similar to that previously reported in the unselected group of Polish patients with PTC. There is currently no convincing data justifying the selective screening for *CHEK2* in such a group. It seems reasonable to advise genetic testing for *CHEK2* pathogenic variants in TC patients with positive family history of thyroid cancer.

Molecular characterization of circulating tumor cells (CTCs) in sporadic medullary thyroid carcinoma (spMTC) patients

George Simeakis[1], Elina Lagopodi[2], Katerina Saltiki[3], Cristina Romei[4], Raffaele Ciampi[4], Teresa Ramone[4], Pantelis Constantoulakis[5], Maria Alevizaki[3], Rossella Elisei[4], Athina Markoy[2] & Evi Lianidou[2]
[1]401 General Military Hospital of Athens, Endocrine Deptartment Thyroid Cancer Outpatient's Clinic, Athens, Greece; [2]National and Kapodistrian University of Athens, Analysis of Circulating Tumor Cells (ACTC) Lab - Deptartment of Chemistry, Athens, Greece; [3]National and Kapodistrian University of Athens, Athens, Greece; [4]University of Pisa, Deptartment of Clinical and Experimental Medicine, Pisa, Italy; [5]Genotypos S.A., Athens, Greece

Objectives
Distant metastases (DM) and/or biochemical persistent disease (BPD) in MTC, adversely affect disease prognosis. Calcitonin and CEA doubling-times (DTs) are

the main prognostic indicators for disease progression. Liquid biopsy based on CTCs enrichment and characterization seems to be an intriguing non-invasive tool providing information about tumor biology and molecular identity. The aim of this study was the molecular characterization of CTCs in spMTC patients with DM and/or BPD using epithelial, mesenchymal as well as MTC-specific markers.
Methods
Nine spMTC patients (DM:3, BPD:6) carrying somatic mutations in *RET* ($n=7$) and *HRAS* ($n=2$) were included. Peripheral blood (10mL-EDTA) was obtained every six months. Using identical blood draws for 31 PB-samples, CTCs enrichment was directly compared by EpCAM-based positive immunomagnetic selection (EpCam-IMS) and the size-based Parsortix microfluidics system (Angle PLC-UK). The EpCam-IMS was superior in terms of sensitivity since a significantly higher percentage of identical PB-samples was found positive at the gene expression level ($P<0.05$) while specificity was not affected. CTCs gene expression analysis was based on RT-qPCR for epithelial (*CK-8, CK-18, CK-19*), mesenchymal (*Vimentin-VIM*), MTC-specific (*Calcitonin-CALCA*) and chemo-kine-receptor markers (*CXCR4*). Calcitonin and CEA DTs were calculated, and disease status was determined according to the RECIST criteria.
Results
Calcitonin and CEA DTs were >2 years in all but one patient (mean:11.28 and 9.23 years, respectively). No structural disease progression (SDP) was documented except for one patient with *HRAS* mutation (pt-X). Interestingly, Calcitonin and CEA DTs of pt-X were 5.08 and 3.00 years, respectively, although there was an upward trend in CEA while serum Calcitonin levels were significantly elevated one month after SDP. Overexpression of *CALCA* was detected in one sample, related to pt-X, at a time-point set 60-days before marked serum calcitonin increase and 30-days before SDP was documented. *CXCR4* was strongly expressed in 3 samples related to pt-X; *CXCR4* expression was absent only at the final time-point of pt-X, when disease stabilization (biochemical and structural) was documented, after changing systemic treatment. Epithelial markers were not expressed in any of our samples while *VIM* was overexpressed in most of them ($n=20/31$ samples).
Conclusion
EpCAM-IMS seems to be a better method for CTCs isolation in MTC patients with DM and/or BPD. Expression of *VIM* in most of our patients advocates towards an epithelial to mesenchymal transition (EMT) process possibly occurring in progressive MTC. *CALCA* and *CXCR4* expression in CTCs, along with other epithelial and mesenchymal markers, should be studied in larger patients' series and for longer follow-up periods.

Modified systemic inflammation score for prediction of malignancy in indeterminate thyroid nodules- an effective tool in low-resource settings!

Shreyamsa Manjunath[1] & Praveen Kumar Devarbhavi[2]
[1]Maax Superspecialty Hospitals, Endocrine & Breast Surgery, Shivamogga, India; [2]Maax Superspecialty Hospitals, Endocrinology & Metabolism, Shivamogga, India

Background
About 20% of thyroid-nodules have indeterminate-cytology (IDC), classified as Bethesda categories-III/ IV. They carry varying risks of malignancy (6-18%, 10-40% respectively). Ideal test to determine the risk of malignancy in IDC is unclear. Molecular-profiling has shown promise, but availability & affordability is an issue. We aim to evaluate diagnostic value of modified systemic inflammation score(mSIS) to determine malignancy in IDC.
Methodology
Retrospective study of 79 patients with IDC thyroid-nodules at Maax Super-specialty Hospitals (Shivamogga, India), from January/2022-October/2023. Patients with thyroiditis, active-infections, hematologic, immuno-rheumatological, recurrent thyroid cancer or other co-morbidities excluded. Pre-operative hematology records were exmanined. Albumin(Alb) & lymphocyte-monocyte ratio(LMR) calculated and variables that may affect the development of malignancy studied.
Patients were divided into 3 groups:
mSIS-0: Alb >/= 4.0 g/ dL, LMR </= 3.4
mSIS-1: Alb <4.0 g/ dL OR LMR <3.4
mSIS-2: Alb <4.0 g/ dL, LMR <3.4
Relationship between mSIS and postoperative pathology, and the diagnostic value of mSIS was investigated.
Results
F:M=70:9. Mean age of patients was 35.8 (+/-9.076). The mean nodule size was 3.15 (+/-1.08)cm. 45 (57%) were Bethesda-III and 34 (43%) nodules were Bethesda-IV. Overall, of the 79 patients, 39 had benign nodules (BN), while 40 had malignant nodules(MN). Among MN, 25 were PTC, 5 FTC, 8 FVPTC & 2 were papillary microcarcinoma. There was no significant difference in baseline parameters in either groups. Mean LMR in BN group was 5.023 (+/-1.45), while that in MN group was 3.11 (+/-0.66). With a p-value=0.001, difference was significant. Mean albumin in BN group was 4.61 (+/-0.49) and MN group was 3.63 (+/-0.48). The difference was significant (p-value:0.001). Twenty nodules each in Bethesda-III(45%) and Bethesda-IV (59%) were malignant. 61% in mSIS-1, 92.8% in mSIS-2 were malignant. When risk-stratified for mSIS-1 and mSIS-2 groups, it showed a sensitivity-71.8%, specificity-97.5%, PPV-96.6%, NPV-79.6%.

		mSIS-0 ($n=30$)	mSIS-1 ($n=21$)	mSIS-2 ($n=28$)	p-value
Bethesda-III	Benign	19	5	1	0.001
	Malignant	1(5.2%)	6(54.5%)	13(93%)	
Bethesda-IV	Benign	10	3	1	0.012
	Malignant	0	7(70%)	13(93%)	

Conclusions
mSIS-1 & mSIS-2 groups carry high risk of malignancy. Though not a substitute, mSIS is a cost-effective & easy to perform test when molecular-profiling is not possible. It can help in selecting appropriate patients for surgical management

Genetic and environmental factors in autoimmune thyroid disease: exploring the associations with selenium levels and novel genetic loci in a latvian cohort

Sabine Upmale-Engela[1, 2], Ieva Kalere[3], Raitis Pečulis[4], Raimonds Rescenko[4], Helena Litvina[4], Tatjana Zake[5], Andrejs Skesters[6], Deniss Gogins[1], Vita Rovite[4] & Ilze Konrade[2, 5]
[1]Riga Stradins University, Faculty of Residency, Rīga, Latvia; [2]Riga East Clinical University Hospital, Department of Endocrinology, Rīga, Latvia; [3]Riga Stradins University, Daculty of Doctoral Studies, Rīga, Latvia; [4]Latvian Biomedical Research and Study centre, Rīga, Latvia; [5]Riga Stradins University, Department of Internal Diseases, Rīga, Latvia; [6]Riga Stradins University, Laboratory of Biochemistry, Rīga, Latvia

Background
The interplay of genetic, immune and environmental factors strongly contributes to the development of autoimmune thyroid disease (AITD) in the form of Graves' disease (GD) and Hashimoto thyroiditis (HT). One of the most studied exogenous factors in the pathogenesis of AITD is selenium, which in the form of selenoproteins strengthens the antioxidative defence system of thyroid cells against superoxide production. Furthermore, it modulates inflammatory cytokine release and autoantibody production.
Purpose
The aim of this study was to assess the association of genetic factors with selenium levels in an adult cohort with HT and GD, and healthy controls from Latvia.
Materials and Methods
A total of 2692 subjects were included in a cross-sectional study. They were divided into 3 groups:GD($n=148$), HT($n=102$), and a control group($n=2442$). Diagnosis of AITD was based on laboratory evaluation. In addition, serum selenium levels were measured and selenium intake score was assessed. The genotypes were determined using genome wide genotyping, imputation was carried out using TOPMed r2 imputation panel, and association analysis was performed with PLINK2.9.
Results
Out of 2692 participants 1684 were female (62.6%), 1008 – male (37.4%). Mean age was 54.3 years (SD 14.0) in the Control Group, 48.4 (SD 15.6) in GD, and 48.3 (SD 15.6) in HT patients. Mean selenium level was 84.4µg/L (SD 31.3), 69.3 µg/L (SD 17.1), and 83.4 µg/L (SD 27.0) in the respective groups. The overall cohort selenium level was below the reference levels(80-125 µg/L) for 62% of the participants (49% controls, 77% GD and 54% HT), with GD patients having significantly lower levels. Additionally, we found three loci associated with GD (LSAMP, HNRNPA3P5, NTN1) on chromosomes 3, 13, 17, respectively, and one locus associated with HT (VAT1L) on chromosome 16. Most of these lead SNPs of significantly associated characteristics have low population minor allele frequencies (<5%) and a fairly large effect (OR>3). Furthermore, one locus rs6567243 was associated with serum selenium >80 µg/L (LINC01544/RNF152/PIGN) on chromosome 18 [OR (95% CI) = 2.46 (1.76-3.43); $P<0.001$]. This SNP has a high minor allele frequency (54.8%) in a Non-Finnish European reference population.
Conclusion
The associations with the novel loci could be attributed to population-specific effects or unknown stratification in our cohort, and further assessment of these hits

are required to explain the relation of genetic traits with studied AITD and other phenotypes. This study was supported by the Latvian Council of Science(Grant No:lzp-2018/2-0059).

Long-term outcomes in children and young adults with graves' disease

Klara Gewert[1], Ruzan Udumyan[2], Gabriel Sjölin[3], Mikael Lantz[4], Helena Filipsson Nyström[5], Selwan Khamisi[6], Mats Holmberg[7], Jan Calissendorff[8], Bengt Hallengren[4], Göran Wallin[3] & Tereza Planck[4]
[1]Lund University, Department of Clinical Sciences, Lund, Sweden; [2]Örebro University, Clinical Epidemiology and Biostatistics, Department of Medical Sciences, Faculty of Medicine and Health, Örebro, Sweden; [3]Örebro University, Faculty of Medicine and Health, Örebro, Sweden; [4]Lund University, Department of Clinical Sciences, Lund, Sweden; [5]University of Gothenburg, Sahlgrenska Academy, Department of Medicine, Gothenburg, Sweden; [6]Uppsala University, Department of Medical Sciences, Uppsala, Sweden; [7]Karolinska Institutet, Department of Medicine, Huddinge, Stockholm, Sweden; [8]Karolinska Institutet, Department of Molecular Medicine and Surgery, Stockholm, Sweden

Introduction
Graves' disease (GD) can negatively affect the quality of life. Research on GD in childhood, accounting for 1-5% of cases, has so far predominantly focused on treatment results. There is limited knowledge about association with other diseases and long-term psychosocial effects.
Aims
We aimed to compare disease burden and psychosocial outcomes between childhood/young adult GD patients and unexposed population controls.
Methods
This was a retrospective, matched cohort study using prospectively collected data from medical records and multiple Swedish registers. GD patients aged <21 years ($n=87$, of whom 55 were <18 years) were selected from an incidence study cohort including patients with newly diagnosed hyperthyroidism in 2003-2005 across 13 Swedish centres ($n=2916$). Each GD patient was matched through Statistics Sweden with ten population controls without GD ($n=29160$) based on age, sex, and county. The matched cohort was followed until December 31, 2019. Information on primary diagnoses, hospitalizations, education, sick leave, disability pension, and number of own children was collected. Results of a 10-year follow-up analysis are being presented here.
Results
Patients with GD exhibited a significantly higher incidence of 'endocrine, nutritional, and metabolic diseases' (ICD-10 E00-E90, excluding E05.0) with a hazard ratio (HR) of 19.7 ([10.7, 36.6], $P<0.001$) and 'diseases of the digestive system diseases' (ICD-10 K00-K95) with a HR of 7.39 ([1.7, 33.0], $P=0.009$) compared to matched population controls. Additionally, patients with GD had an increased risk of having two or more primary diagnoses besides GD (relative risk [RR]$=4.4$ [2.4, 7.8], $P<0.001$), more than three days of hospitalization (RR$=$ 5.5 [2.7, 10.9], $P<0.001$), over 60 consecutive days of sick leave (RR$=2.1$ [1.1, 3.9], $P=0.016$), and receiving disability pension (RR$=4.2$ [2.3, 7.8], $P<0.001$) compared to controls. Furthermore, patients with GD were more likely to only have completed compulsory education by the age of 30 (RR$=2.5$ [1.1, 5.8], $P=0.029$). No statistically significant differences were observed regarding other ICD categories or number of own children.
Conclusion
In conclusion, childhood/early adulthood GD leads to increased long-term morbidity, healthcare needs, and socioeconomic challenges, marked by more hospitalizations, sick leaves, disability pensions, and lower educational levels. These results highlight GD's status as a chronic condition, emphasizing the need for more research to reduce its long-term effects.

Thyroid core-needle biopsy. first experience in romania. 281 cases with only 1% non-diagnostic results

Emin Mammadov[1], Dana Terzea[2] & Mihai Ciprian Stoicea[1]
[1]Regina Maria Private Healthcare Network, Bucureţi, Romania; [2]Onco Team Diagnostic, Bucureţi, Romania

Background
There are two types of thyroid nodule biopsy: fine-needle aspiration (FNAB) and core-needle (CNB). Multiple studies mainly from Eastern Asia demonstrate safety and efficacy of CNB, however it is very rarely used in Europe.
Methods
Retrospective analysis of the first 281 CNBs performed in Romania, including 8 lymph nodes and 3 thyroid bed lesions. We used the Korean Thyroid Association reporting system (KTA-CNB) for histology reports.
Results
Of 281 CNBs, there were only 3 non-diagnostic results (1.1%), 21 category III results (7.5%) and 22 category IV results (7.8%). Categories IIIa and IVa were almost exclusively benign ($n=17$, of them 6 underwent surgery, 5 were confirmed benign, 1 NIFTP). Out of 7 patients with category IVc results, 6 underwent surgery, 4 of them had malignant results postoperatively. All category V ($n=5$) and VI ($n=18$) results were confirmed to be malignant on postoperative histology. Two of thyroid bed lesions were malignant, one benign (all confirmed on postoperative histology). One of 8 lymph nodes was malignant. There was one case of Hurthle cell carcinoma diagnosed preoperatively based on invasion observed at one of the passes, and one case of the lung adenocarcinoma metastasis diagnosed based on IHC. There were 2 cases of papillary microcarcinoma with confirmed extrathyroidal extension which lead to more curative surgical approach, and patients could avoid second surgery or radioiodine therapy. We performed on average 2.2 passes per lesion. There were no major complications, some minor adverse events were limited to bruising, perithyroidal hematoma and pain during or after procedure. Two patients had intrathyroidal hematoma.
Conclusion
The CNB is a safe and reliable diagnostic procedure for thyroid nodules, thyroid bed lesions and cervical lymph nodes. It offers very low chance of non-diagnostic results, lower chance of inconclusive results with a better stratification of risk between different subcategories (III a-d, IV a-c), among them the highest chance of malignancy was observed in category IVc in our study. CNB is a procedure which improves patient experience by reducing the number of procedures needed to make a clinical decision. It also offers possibility to use IHC and observe extrathyroidal extension.

Impact of the introduction of minimally invasive treatments of the thyroid (MITT) for benign thyroid nodules in an italian hospital: a cost-minimization analysis

Roberto Novizio[1], Martina Cicia[1] & Giampaolo Papi[2]
[1]Catholic University of the Sacred Heart, Rome, Italy; [2]Azienda Usl Modena, Italy

Background
Thyroid nodules prevalence is high in adult population, approaching 60% in women and older people. Most thyroid nodules are benign and asymptomatic. However, a not negligible part of them causes compressive symptoms and/or cosmetic concerns and need treatment. In the last decades, minimally invasive treatments of the thyroid (MITT) have been proposed in clinical practice as reliable cost-effective alternative to surgery in patients with symptomatic benign thyroid nodules (SBTNs).
Aim
Cost-minimization analysis comparing direct, indirect and intangible costs of radiofrequency (RFA) and laser thermal ablation (LTA) with traditional surgery in patients with SBTNs.
Methods
Data of patients treated by MITT for SBTNs from October 1st 2019 to September 30th 2022 in a single Italian Center were analyzed. Costs were compared to those of traditional surgery reported in the 2022 Associazione Medici Endocrinologi Guidelines on the Management of SBTNs.
Results
157 MITT of SBTNs were performed in 148 patients, 114 females and 34 males (mean age: 59 yrs). Before MITT, mean thyroid nodule volume was 19 ml; 1 year after MITT, volume reduction rate $>50\%$ and symptom relief were achieved in 89% and 93% of patients, respectively. No major complications occurred. Adding up pre-operative, operative and post-operative costs, total direct costs per single procedure are the following: 1361.43 € for LTA, using one optic fiber; 1761.43 € for LTA, using two optic fibers; 1968.53 € for RFA; 3338.39 € for hemithyroidectomy plus isthmectomy; 4034.99 € for total thyroidectomy. Surgery was impactful on direct-i.e., preoperative, operative and postoperative-costs, due to longer operating room occupation time and hospital stay. Overall, a total saving for the Italian National Health Service of 285, 377.15 € has been obtained treating the 148 patients by MITT instead of surgery. MITT was advantageous also for indirect costs-i.e., those related to "loss of productivity" caused by time off work-, for both the self-employed workers and the Government, the latter saving 53, 838.50 €. Intangible costs, related to patients' quality of life-e.g., residual surgical scar, convalescence, and life-long intake of L-Thyroxine replacement therapy-were all in favor of MITT.

Conclusion
This real-life cost-minimization analysis demonstrates that LTA and RFA are safe and cost-effective procedures for the treatment of SBTNs. In our 3 years experience, adding the savings of 285, 377.15 € for direct costs to those of 53.838, 50 € for indirect costs, in total 339, 215.65 € were saved. The saving concern patients, the National Health System and the Government.

Enhanced predictive validity of integrative models for refractory hyperthyroidism considering baseline and early therapy characteristics: a prospective cohort study

Xinpan Wang[1], Tiantian Li[1], Yue Li[1], Qiuyi Wang[1], Yun Cai[1], Zhixiao Wang[1], Yun Shi[1], Tao Yang[1] & Xuqin Zheng[1]
[1]The First Affiliated Hospital of Nanjing Medical University

Background
A subset of Graves' disease (GD) patients develops refractory hyperthyroidism, posing challenges in treatment decisions. The predictive value of baseline characteristics and early therapy indicators in identifying high risk individuals is an area worth exploration.
Methods
A prospective cohort study (2018-2022) involved 597 newly diagnosed adult GD patients undergoing methimazole (MMI) treatment. Baseline characteristics and 3-month therapy parameters were utilized to develop predictive models for refractory GD, considering antithyroid drug (ATD) dosage regimens.
Results
Among 346 patients analyzed, 49.7% developed ATD-refractory GD, marked by recurrence and sustained Thyrotropin Receptor Antibody (TRAb) positivity. Key baseline factors, including younger age, Graves' Ophthalmopathy (GO), larger goiter size, and higher initial free triiodothyronine (fT3), free thyroxine (fT4), and TRAb levels, were all significantly associated with an increased risk of refractory GD, forming the baseline predictive model (Model A). Subsequent analysis based on MMI cumulative dosage at 3 months resulted in two subgroups: a high cumulative dosage group (average $\geq$1 mg/d) and a medium-low cumulative dosage group (average $<$1 mg/d). Absolute values, percentage changes, and cumulative values of thyroid function and autoantibodies at 3 months were analyzed. Two combined predictive models, Model B (high cumulative dosage) and Model C (medium-low cumulative dosage), were developed based on stepwise regression and multivariate analysis, incorporating additional 3-month parameters beyond the baseline. In both groups, these combined models outperformed the baseline model in terms of discriminative ability (measured by *AUC*), concordance with actual outcomes (66.2% comprehensive improvement), and risk classification accuracy (especially for Class I and II patients with baseline predictive risk $<$71%). The reliability of the above models was confirmed through additional analysis using random forests. This study also explored ATD dosage regimens, revealing differences in refractory outcomes between predicted risk groups. However, adjusting MMI dosage after early risk assessment did not conclusively improve the prognosis of refractory GD.
Conclusion
Integrating baseline and early therapy characteristics enhances the predictive capability for refractory GD outcomes. The study provides valuable insights into refining risk assessment and guiding personalized treatment decisions for GD patients.

Regulatory T and B cells in autoimmune thyroiditis

Maria Kazakova[1], Ekaterina Troshina[2] & Ilya Dyakov[3]
[1]Endocrinology Research Center, Moscow; [2]Endocrinology Research Center, Moscow; [3]Mechnikov's research institute of vaccine and sera, Moscow

Introduction
Hashimoto's thyroiditis (HT) is multifactorial disease, caused by a complex interplay of genetic, hormonal, and environmental influences that provoke the development of inappropriate immune responses against thyroid on multiple levels and the initiation of a long-standing autoimmune reaction. Interaction between cellular and humoral immunity is base of HT's pathogenesis. Our research focuses on the functional activity and the quantity of T regulatory and B regulatory lymphocytes in blood from patients, who have features of HT. A more accurate understanding of role of regulatory cells in the immunotolerance disorders could be a base for the development of new prognostic markers and therapeutic strategies in the treatment of patients with HT.
Main part
We analyzed amount and functional activity subsets of regulatory T and B cells (CD3hiIL-10hi and CD19hiCD38hiCD24hi) in subjects's blood: patient with isolated hypothyroidism in the outcome of HT (n=23), carriers of antibodies to thyroid tissues (n= 18), patients with HT as a part of autoimmune polyglandular syndrome (APS) (n= 20), healthy donors (HD) (n=13). We found significant differences in the amount of regulatory cells (CD19hiCD38hiD24hi B reg) during *in vitro* incubation without additional activation in groups carriers of antibodies (1.75% vs 3.0%; P=0.0003) and in groups patients with HT as part of APS (1.5% vs 3.0% P=0.0002) as compared with HD. A decrease in the induction of regulatory B cells was found only in the group of patients with HT as part of APS (2.3%, P=0.04)
Conclusion
Our research has shown that carriers of autoantibodies and patients with HT as part of APS have reduced spontaneous activation of regulatory B cells *in vitro* and the latter has activation-induced induction of regulatory B cells in the comparison with HD. The quantity and induction of IL-10-producing T cells in the compared groups weren't significantly differ. The study is supported by the Russian Science Foundation, Grant No.22-15-00135

Focal thyroid incidentalomas in 18F-PSMA PET/CT – a retrospective analysis of incidence and clinical significance

Emilia Niedziela[1, 2], Łukasz Niedziela[1, 3], Iwona Palyga[1, 2], Janusz Kopczyński[4], Jarosław Jaskulski[1, 3], Janusz Braziewicz[5] & Aldona Kowalska[1, 2]
[1]Collegium Medicum, Jan Kochanowski University, Kielce; [2]Holy Cross Cancer Center, Department of Endocrinology, Kielce; [3]Holy Cross Cancer Center, Department of Urology, Kielce; [4]Holy Cross Cancer Center, Department of Pathology, Kielce; [5]Holy Cross Cancer Center, Department of Nuclear Medicine, Kielce

Introduction
^{18}F- Prostate-Specific Membrane Antigen Positron Emission Tomography/Computed Tomography (^{18}F-PSMA PET/CT) is currently used in the evaluation of prostate cancer. Due to increased expression of PSMA in the neovascular endothelial cells of malignant lesions other than prostate cancer, PSMA PET/CT has become of interest to researchers in the management of thyroid cancer. The goal of this study was to evaluate the incidence and clinical significance of PSMA thyroid incidentaloma (PTI) detected by ^{18}F-PSMA PET/CT scans.
Methodology
We retrospectively analyzed the clinical data of 23 patients with prostate cancer, who underwent endocrine follow-up for increased uptake in at least one focal thyroid lesion on ^{18}F-PSMA PET/CT performed between 2018 and 2023. The indications for ^{18}F-PSMA PET/CT were primary staging or diagnosis of biochemical recurrence after radical treatment of prostate cancer. We established our outcomes on the ^{18}F-PSMA PET/CT reports, indications for fine needle aspiration biopsy (FNAB) according to EU-TIRADS, and cytological results according to the Bethesda Thyroid Cytology Classification. Only patients with cytological verification of PTI were included into final analysis.
Results
Data of 22 patients with 23 PTI were analyzed. The median SUVmax of PTI on ^{18}F-PSMA PET/CT scans was 5.66 (range 2.3 - 48.39). In seven cases (31.8%), there were no indications for FNAB according to EU-TIRADS. Those patients were referred to FNAB only due to increased uptake in thyroid lesions on PSMA PET/CT. The results of FNAB were as follows: 19 (82.6%) benign; 2 (8.7%) atypia of undetermined significance; 1 (4.3%) follicular neoplasm; 1 (4.3%) malignant. The only malignant lesion was diagnosed as papillary thyroid cancer on cytology. The SUVmax of corresponding lesion on PSMA PET/CT was 3.6, and US revealed no indications for FNAB with EU-TIRADS 4 and size of the lesion of 8 mm. Due to the low stage of the tumor, this patient remains on active surveillance. Any other lesion that was subjected to further follow-up [median 5 months (0-42)] did not become clinically significant.
Conclusions
^{18}F-PSMA PET/CT seems not to be a useful modality for the differentiation of benign and malignant thyroid lesions. Standard methods of evaluating thyroid nodules are sufficient for further diagnosis of PTI, without the need to verify all lesions on FNAB. The only detected thyroid cancer in our study was a lesion with an indolent course. Further research on larger cohort is necessary to explore the role of PSMA PET/CT in management of thyroid nodules.

Thyrotoxicosis in metastatic choreocarcinoma

Vidya Nair[1], Rob Marwood[1] & Cecil Eboh[1]
[1]St Richards Hospital, Endocrinology and Diabetes, Chichester, United Kingdom

Introduction
Choriocarcinoma is a rare gynaecological cancer arising from the trophoblastic epithelium of the placenta. HCG induced thyrotoxicosis is a rare but recognised paraneoplastic phenomenon. The association of high BHCG levels and thyrotoxic state is thought to be secondary to similarities in the structure between HCG and pituitary hormones including TSH which share the same alpha unit and enables HCG to activate the TSH receptor at high levels. Kato et al in 2004 reported that the incidence of hyperthyroidism in choriocarcinoma is around 57%. Choriocarcinomas are highly susceptible to treatment with a cure rate of >90% even in metastatic gestational choriocarcinoma.
Case report
A 41-year-old female gravida5 para1, with a history of 4 previous first trimester miscarriages, positive IgM anticardiolipin antibody13 presented to A&E 4 months postnatal with chest pain, palpitations, breathlessness. Blood tests showed B-HCG level > 225, 000, d-dimer -1584, TSH < 0.03 and Free T4-29.1. She was started on carbimazole, propranolol for thyrotoxicosis. Thyroid antibodies were negative. Due to high BHCG values, transabdominal ultrasound was requested which showed no active pregnancy but an increased volume in left ovary. A CTPA with abdominal and pelvic views were negative for a PE but suspicious for pulmonary metastasis and a large left adnexal mass which was confirmed in MRI. The patient was diagnosed with choriocarcinoma, and B-HCG induced thyrotoxicosis and anti-thyroid medication was stopped and patient was commenced on chemotherapy. Her thyrotoxic symptoms were managed symptomatically with propranolol. Following treatment of the Choriocarcinoma, the thyrotoxicosis resolved with normalization of thyroid function tests. (table 1 below)

		post chemo
TSH(mu/L)	<0.03	0.52
Free T4(pmol/L)	29.1	11.9

Discussion
There have been studies in men with germ cell tumours producing HCG, women with choriocarcinoma, animals showing an association between high levels of HCG and hyperthyroidism. The primary treatment for this phenomenon is chemotherapy with symptomatic control for hyperthyroidism. It is important to note that initially the chemotherapy treatment may produce an initial surge in HCG levels, and it is important to monitor these patients for signs of thyroid storm, however, the thyroid function will usually normalise if the choriocarcinoma is susceptible to treatment.

Endoscopic ultrasound guided fine needle aspiration (EUS-FNA) with aspirate parathormone (PTH): a case report and review of the literature

Matteo Parolin[1], Antonino Caruso[2], Paola Sartorato[1], Pietro Fusaroli[3] & Ernesto Pasquale De Menis[1]
[1]Ospedale Ca' Foncello, Medicina Generale 2, Italy; [2]Ospedale Ca' Foncello, Gastroenterologia, Italy; [3]Ospedale S. Maria della Scalett, UOC di Gastroenterologia ed Endoscopia Digestiva, Bologna, Italy

Introduction
The prevalence of primary hyperparathyroidism is increasing owing to the more the routinely measurements of serum calcium. A single benign para-thyroid adenoma is the most frequent cause of sporadic PHPT. Primary hyperparathyroidism can also be due to ectopic mediastinal parathyroid adenoma in 11-25% of patients, more frequently involving inferior parathyroid translated in anterior mediastinum. In general to detect ectopic adenoma recent guidelines recommend the use of high resolution neck ultrasound, technetium-99 m-sestamibi subtraction scintigraphy, and contrast-enhanced four-dimensional (4D) computed tomography (CT). The use of endoscopic ultrasound (EUS) is reported in some case reports in literature and some cases in has been integrated with fine-needle aspiration and PTH sampling in the eluate.
Case report
A 68-year old female was admitted in our department for a spontaneous neck hematoma. She was overweight and had parossistic atrial fibrillation (she was not taking anticoagulative drugs), and dyslipidaemia. Laboratory exams revealed primary hyperparathyroidism with elevated total serum calcium 10, 9 mg/dl (8, 8-10, 1), decreased serum phosphorus 2, 1 mg/dl (2, 5-4, 5) and high parathormone 150 pg/mL (12-72). Neck ultrasound did not show images compatible with parathyroid, but a multinodular goitre. Computed tomography of neck revealed complex vascular anatomy of the thyroidal vascularization and a fusiform nodule between posterior side of right thyroid lobe and paraesophageal region, which was compatible with parathyroid gland (axial diameters were 18*12 mm). A double-tracheant scintigraphy revealed a 15 mm nodule in right posterolateral paraesophageal compatible with ectopic parathyroid. A echoendoscopy detected a dysomogeneus, hyperechoic and elonged lesion was noted, with iperenhancement using ultrasonographic contrast media (CEUS). FNAB was performed without complications. The cytological exam revealed minute and rare non-atypical epithelial aggregates, results at PTH + and TTF1 – at immunophenotypic investigations. PTH dosage on the washing liquid was > 2500 pg/ml, diagnostic of ectopic parathyroid.
Conclusions
In selected patients with primary hyperparathyroidism, second and third level diagnostic procedures as in this case could be useful to be sure of diagnosis, in particular if pluricomorbid and frail patients must receive parathyroidectomy with major surgery could include potential severe complications.

Radiofrequency ablation is an effective treatment for bethesda iii nodules without genetic alterations

Laura Fugazzola[1], Maurilio Deandrea[2], Stefano Borgato[1], Marco Dell'Acqua[1], Francesca Retta[2], Alberto Mormile[2], Chiara Carzaniga[1], Giacomo Gazzano[1], Gabriele Pogliaghi[1], Marina Muzza[1] & Luca Persani[1]
[1]Italian Auxological Institute San Luca Hospital, Endocrinology, Milano, Italy; [2]Mauriziano Umberto Hospital, Torino, Italy

Radiofrequency ablation (RFA) is effective in the treatment of thyroid nodules, leading to a 50-90% reduction with respect to baseline. Current guidelines indicate the need for a benign cytology prior to RFA, though, on the other side, this procedure is also successfully used for the treatment of papillary microcarcinomas. No specific indications are available for nodules with an indeterminate cytology (Bethesda III and IV). Aim of the present study was to evaluate the efficacy of RFA in Bethesda III nodules without genetic alterations as verified by means of a customized panel based on matrix-assisted laser desorption/ionization time-of-flight mass spectrometry, and previously set up for the simultaneous identification of 13 known hotspot mutations and six recurrent fusion genes. We treated 33 patients (mean delivered energy 1069 ± 1201 Joules/ml of basal volume) with Bethesda III cytology, EU-TIRADS 3-4, and negative genetic panel. The mean basal nodular volume was 17.3 ± 10.7 ml. Considering the whole series, the mean volume reduction rate (VRR) was 36.8 ± 16.5% at 1 month, 59.9 ± 15.5% at 6 months and 62 ± 15.7% at 1-year follow-up. The sub-analysis done in patients with 1 and 2 years follow up data available, confirmed a progressive nodular volume decrease. At all-time points, the rate of reduction was statistically significant ($P < 0.0001$), without significant correlation between the VRR and the basal volume. Neither cytological changes nor complications were observed after the procedure. In conclusion, we show for the first time that one RFA session is extremely effective in the volume reduction of Bethesda III nodules whose very low risk of malignancy has been established on the bases of the lack of the most common oncogene variations. The procedure is applicable for indeterminate nodules of any size, treated with an appropriate energy per volume and the volume reduction is maintained at 1-2 years after treatment, but a longer follow up is needed to identify a further reduction or a possible progressive regrowth.

Background
Indirect methods is developed to estimate reference limits from patient data, i.e. data from a mix of sick and healthy people. The indirect methods use a large number of results. A prerequisite for the methods to work satisfactorily is that the proportion of patients is not too large (typically $<$ 20-30%).
Methods
We used direct and indirect methods for estimating reference limits for TSH, FT4, FT3, total T4 and total T3. All analysis were done with Abbot Alinity. We used was refineR and RefLim in addition to the simple non-parametric percentile method. All patients who have had thyroid parameters analyzed at the Hormone Laboratory in Oslo from December 2021 to June 2023 was included ($n=21\,539$).
Results
We analyzed the thyroid parameters by direct method form 140 healthy participants from the population based HUNT4 study in Norway. In the indirect method we first used our entire database (Hlu, n = 21 539). Then a selection were we excluded any sample form hospitals, or were TSH $<$ 0.1mIU/l and $>$ 10, or positive on anti-TPO or TRAb and only the first measurement of a patient were included (HLc, n = 3 366). To validate we included patient sample for the county of Innlandet, Norway, only analyzing samples received from GPs and only one sample from each patient (IH, n = 49 433).
Conclusion
In our Norwegian population it seems like the direct method using healthy individuals form a population based study, is not superior to using indirect methods form our own routine laboratory database.

12-month outcome with microwave ablation in benign thyroid nodules

Kelly Villa[1], Maite Rodrigo[1], Mattia Squarcia[1], Felicia A Hanzu[1], Aida Orois[1], Maria Claro[1], Karen Andrea Castillo Arias[1] & Mireia Mora[1]
[1]Hospital Clinic Barcelona, Barcelona, Barcelona, Spain

Most thyroid nodules are benign and majority do not require treatment, except for those large nodules that cause symptoms (compression, hormonal dysfunction and/or esthetic problems). Microwave ablation (MWA) is an attractive therapeutic option because it is minimally invasive, relatively inexpensive, capable of providing coagulative necrosis, and has a short treatment time. In the following, we present the experience of our hospital.
Objective
To evaluate the volumen (V) reduction (VRR: (initial V - final V)/(initial V $\times$ 100)) and the evolution of symptoms of thyroid nodules treated with AMO.
Material and methods
Prospective study of 20 patients (17 females, 3 males) with 22 benign, euthyroid thyroid nodules with mild to moderate compressive symptoms, treated with ultrasound-guided AMO, between 2021 and 2023, who were followed for 12 months (evaluated at month 1, 3, 6 and 12 after AMO). Success was defined as VVR greater than 50%.
Results
Twenty patients were evaluated, mean age 64 years, 22 nodules (13 solid and 9 mixed). The VRR during follow-up at 1, 3, 6 and 12 months was 12%, 55%, 56% and 69% respectively. Mean initial volume was 27 mL $\pm$ 19, and 10 mL $\pm$ 11.92 at 12 months. Ablation time was 657 sec $\pm$ 369 sec, power 30 W, mean energy used was 1219 $\pm$ 1194 (J/mL). Symptomatology remission was present in 18 patients. RRV $>$ 50% was observed at 1, 3, 6 and 12 months in 27%, 56%, 64% and 75% of the nodules, respectively.
Conclusions
Our study suggests that ultrasound-guided AMO is an effective and safe procedure for the treatment of thyroid nodules, with remission of symptoms at 12 months in 90% of patients and showing a successful volume reduction (VRR $>$ 50%) from the first control, reaching 75% at 12 months.

Is autoimmune thyroiditis in females with ehlers–danlos syndrome associated with lower bone density?

Babula Emilia[1, 2], Żuk-Łapan Aleksandra[1, 2], Poprawa Iga[1, 2], Podstawka Jakub[1, 2], Domański Jan[1, 2], Julia Latocha[1, 2], Zuzanna Szymańska[1, 2], Bernadetta Kaluza[1, 2] & Franek Edward[1, 2, 3]
[1]National Medical Institute of the Ministry of the Interior and Administration, Department of Internal Medicine, Endocrinology and Diabetology, Warsaw, Poland; [2]National Medical Institute of the Ministry of the Interior and Administration, Students Scientific Group of the Medical University of Warsaw at the Department of Internal Medicine, Endocrinology and Diabetology, Warsaw, Poland; [3]Mossakowski Medical Research Centre Polish Academy of Sciences, Warsaw, Poland, Department of Human Epigenetics, Warsaw, Poland

Background
Collagen, whose biosynthesis is regulated by thyroid hormones, is the most abundant connective tissue protein. Ehlers–Danlos syndrome alters collagen structure, which may affect bone mineral density (BMD). The purpose of this study was to assess the effect of autoimmune thyroiditis on BMD in females with Ehlers–Danlos syndrome.
Material and methods
The study involved a prospective assessment of 30 female patients, aged 20–53 years, with either hypermobile or classical Ehlers–Danlos syndrome. All patients underwent thyroid function tests, calcium and phosphorus metabolism tests, and BMD scans of the femoral neck and lumbar spine. Patients were divided into two groups: those with no autoimmune thyroiditis (group 1, n = 24) and those with autoimmune thyroiditis (group 2, n = 6).
Results
Study groups 1 and 2 showed no significant differences in terms of hypothyroidism ($n=4$ (16.7%) vs n = 2 (33.3%), $P=0.39$), thyroid-stimulating hormone (TSH) levels (2.06 $\pm$ 1.16 µIU/ml vs 2.35 $\pm$ 2.16 µIU/ml, $P=0.59$), free triiodothyronine levels (3.43 $\pm$ 0.64 pg/ml vs 3.19 $\pm$ 0.72 pg/ml, $P=0.42$), or free thyroxine levels (1.35 $\pm$ 0.25 ng/dl vs 1.34 $\pm$ 0.12 ng/dl, $P=0.44$), respectively. Moreover, no significant differences were noted in bone turnover markers, such as bone-specific alkaline phosphatase (9.89 $\pm$ 2.88 µg/L vs 8.1 $\pm$ 0.81 µg/L, $P=0.19$), beta-crossLaps (0.411 $\pm$ 0.19 ng/ml vs 0.3 $\pm$ 0.15 ng/ml, $P=0.2$), and osteocalcin (21.32 $\pm$ 7.82 ng/ml vs 17.62 $\pm$ 4.76 ng/ml, $P=0.34$), or in the BMD of the femoral neck (0.93 $\pm$ 0.12 vs 0.96 $\pm$ 0.15, $P=0.59$) or lumbar spine (0.95 $\pm$ 0.12 vs 0.94 $\pm$ 0.17, $P=0.98$). Furthermore, no significant correlation was observed between the levels of TSH, anti-thyroperoxidase autoantibodies, or anti-thyroglobulin antibodies on one hand and femoral neck BMD on the other (r_s 0.09, $P=0.61$; r_s 0.1, $P=0.59$; and r_s -0.03, $P=0.89$, respectively) or between any of those three markers and lumbar BMD (r_s 0.11, $P=0.56$; r_s 0.02, $P=0.93$; and r_s -0.03, $P=0.84$).
Conclusions
This study showed no relationship between autoimmune thyroiditis, bone turnover markers, and the BMD of either the femoral neck or the lumbar spine in women with Ehlers–Danlos syndrome.

Correlation between the expected risk of malignancy according to FNA and the actual percentage of malignancy found on pathological anatomy in thyroidectomies and hemithyroidectomies

Aurelio López Guerra[1], Isabel Losada Gata[1], Mónica Gómez-Gordo Hernanz[1], Gloria Collado González[1], Marta Pérez Noguero[1], Ignacio Jiménez Hernando[1], Blanca Farache Suberviola[1], Amaya Morales Jaurrieta[1], Laura Gonzalez Fernandez[1] & Alberto García Piorno[1]
[1]Gregorio Marañón General University Hospital, Madrid, Spain

Introduction
The Bethesda system gives each Fine Needle Aspiration (FNA) category a risk of malignancy (B1: 5-10%, B2: 0-3%, B3: 10-30%, B4: 25-40%, B5: 50-75%, B6: 97-99%). Based on this risk, therapeutic decisions are made that influence the patient's life. It is important to check whether the percentage of malignancy obtained in our daily clinical practice is similar to that expected according to this system.
Aim
To check whether the percentage of malignancy in the FNA performed in our hospital is similar to that expected according to the Bethesda system for each of its different categories.
Methods
The pathological anatomy service was asked for the list of thyroidectomies and hemithyroidectomies of thyroidectomies and hemithyroidectomies performed in the hospital from 2018 to 2021. The interventions that had FNA prior to surgery were analyzed, noting the Bethesda category of each one. The anatomopathological analysis of the surgical specimens was evaluated, differentiating between positive and negative for malignancy. Among those positive for malignancy, a subsequent adjustment was made, excluding those specimens that had been positive for malignancy because they presented a finding of incidental microcarcinoma (IM) in an area of the thyroid other than the one corresponding to the previous FNA.
Results
A total of 569 thyroid samples were received from thyroidectomies and hemithyroidectomies performed at the Hospital GregoRio Marañón. Preoperative FNA was performed in 450 procedures, distributed across Bethesda categories as follows: B1 (6.2%; n = 28), B2 (45.7%; n = 206), B3 (15.5%; n = 70), B4 (8.2%; n = 37), B5 (11.5%; n = 52), B6 (12.6%; n = 57). Of these, 164 were positive for malignancy. Malignancy percentages on pathologic anatomy within each FNA category were: B1 (28, 5%; $n = 8$), B2 (9.2%; n = 19), B3 (30%; n = 21), B4 (37.8%; n = 14), B5 (86.5%; $n = 45$), B6 (100%; n = 57). Excluding incidental microcarcinomas detected in the sample not corresponding to the evaluated nodule, the following percentages were obtained: B1 25%, B2 3.4%, B3 21.4, B4 35%, B5 84.6%, B6 100%.
Conclusions
The observed malignancy rate in our setting, after excluding non-concordant incidental microcarcinomas, aligns with Bethesda system expectations for categories B3, B4, and B6. The malignancy rate was notably higher in category B1 (25% vs 5-10%) and category B5 (84.61% vs 50-75%), with category B2 slightly exceeding the upper limit (3.4% vs 0-3%).

Thyroid function might decrease after adjuvant chemotherapy in postmenopausal women with early breast cancer

Djordje Marina[1], Kristian Buch-Larsen[2], Linn Gillberg[3], Mads Andersen[4], Michael Andersson[1], Åse Krogh Rasmussen[1] & Peter Schwarz[1]
[1]Rigshopitalet, Department of Endocrinology, Copenhagen, Denmark; [2]Rigshospitalet, Department of Endocrinology, København, Denmark; [3]University of Copenhagen Panum and Mærsk Tower, Department of Biomedical Sciences, København, Denmark; [4]Rigshospitalet, Department of Oncology, Centre for Cancer and Organ Diseases, København, Denmark

Objective
Adjuvant chemotherapy is often indicated in patients diagnosed with early breast cancer. Weight gain is one of the observed side effects of both chemotherapy and other cancer treatments, however, the mechanism is not well-described. In this study, we aimed to assess thyroid function before- and after the course of chemotherapy for early breast cancer.
Methods
This study is a 5-year prospective cohort study of patients diagnosed with early breast cancer. The main outcome was the thyroid function and body weight before and after completing chemotherapy. Secondary outcomes were the presence of thyroid autoantibodies and treatment radiation dosage. We included 72 patients. All patients received adjuvant chemotherapy, whereas 59 patients also received supraclavicular locoregional radiotherapy.
Results
At an average of 86 days after chemotherapy, we observed an increase in thyroid-stimulating hormone ($P = 0.03$) and a decrease in free-thyroxine ($P = 0.0006$), whereas no significant weight change. The prevalence of autoimmune thyroiditis was low, and we found no statistically significant difference in the thyroid function of women treated vs not treated with locoregional radiotherapy.
Conclusion
The present study suggests that thyroid function might be decreased in women with early breast cancer after adjuvant chemotherapy. The decrease in thyroid function was neither related to autoimmunity, low T3 syndrome, radiotherapy, nor high-dose corticosteroids, and an effect of adjuvant chemotherapy is suggested. It is still unknown whether the observed decrease in thyroid function is transient or permanent, and further studies with a longer follow-up of thyroid hormones are needed to observe the clinical significance of these changes.

Epidemiology of primary hypothyroidism in the republic of moldova

Stela Vudu[1]
[1]Nicolae Testemitanu State University of Medicine and Pharmacy, Endocrinology, Chịinău, Moldova

Disorders of the thyroid gland in the Republic of Moldova rank second among endocrine diseases (after diabetes mellitus), hypothyroidism being one of the most widespread diseases. In communities, the prevalence of overt hypothyroidism is from 0.1 to 2 percent, and that of subclinical hypothyroidism is up to 10 percent of adults (increasing even more in women, and with advanced age). Regarding the prevalence of hypothyroidism in the Republic of Moldova, it is necessary to mention the characteristics specific for the country: 1) a mild iodine deficiency; 2) the consequences of the nuclear explosion at the Chernobyl nuclear power station; 3) insufficient detection of primary hypothyroidism in the region. The above mentioned determined the need to study the prevalence of hypothyroidism in different districts of Moldova. The subjects were traced via the General Practitioners and Endocrinologists registers. The results of this cross sectional study conducted in 2021 revealed that, among endocrine diseases, thyroid gland disorders represent 30, 7 %, hypothyroidism (as a result of surgical treatment of thyroid cancer, toxic diffuse goiter, nodular goiter, and autoimmune thyroiditis) represents 9, 5 %, hypothyroidism due to Hashimoto thyroiditis constitutes 6, 1 %, and autoimmune thyroiditis – 11, 3 %. Among thyroid disorders, hypothyroidism (as a consequence of surgical treatment of thyroid cancer, toxic diffuse goiter, nodular goiter, and autoimmune thyroiditis) has a 31 % prevalence, and autoimmune hypothyroidism – 19, 9 %. Thus, in 2021, thyroid gland pathologies constituted about a third, *de facto* occupying the second place after diabetes mellitus, which prevails among endocrine diseases; autoimmune thyroiditis represented 11.3%; hypothyroidism – 9, 5 %, and autoimmune hypothyroidism – 6, 1 %. Among thyroid gland diseases, autoimmune thyroiditis and hypothyroidism constituted about a third each, and autoimmune hypothyroidism – a fifth. Comparing the data mentioned above with those obtained in 1997, the prevalence of thyroid gland disorders, autoimmune thyroiditis, and hypothyroidism of different ethiologies is increasing.
Conclusions
1. Thyroid gland disorders constitute one of the main endocrine diseases in the Republic of Moldova. 2. Autoimmune thyroiditis constitutes one third of the total number of diseases of the thyroid gland. 3. Hypothyroidism as a consequence of autoimmune thyroiditis, which affects almost all functions of the vital organs and systems of the body, was seen in 19.9 %. 4. The vector of thyroid gland diseases in the Republic of Moldova has an ascending character.

Novel homozygous pathogenic variant in the Vitamin-D binding protein in a patient with undetectable Vitamin D levels despite treatment with high doses of vitamin D

Eleni Terezaki[1,2], Mikael Oscarson[1,2] & Katarina Berinder[1,3]
[1]Karolinska University Hospital, Endocrinology; [2]Karolinska University Hospital, Centre for Inherited Metabolic Diseases; [3]Karolinska Institutet, Department of Molecular Medicine and Surgery

Vitamin-D binding protein (VDBP) is the main reservoir of circulating vitamin D and its metabolites in blood. VDBP deficiency leads to a benign phenotype of undetectable vitamin D in the blood without remarkable effects in the calcium and bone metabolism if dietary vitamin D is sufficient ((Safadi *et al* 1999, Banerjee *et al* 2021)). This paradoxical phenotype is probably explained by the free-hormone hypothesis, which suggest that only the unbound vitamin D fraction has biological effects. Besides the null mouse model, to date only three cases of patients with verified DBP deficiency have been described in the literature. Here we present a case of a 33-year-old man adopted from India, with undetectable vitamin D, despite intramuscular injection of 100.000 IE cholecalciferol every 6 weeks, normocalcemia, and reversible mild hyperparathyroidism. Besides two finger fractures at an early age, no other fractures occurred later in life. He has a progressing osteopenia, which can be at least partially attributed to treatment with supraphysiological doses of corticosteroids due to minimal change disease-nephrotic syndrome with preserved eGFR, severe food allergies, treatment of iatrogenic adrenal insufficiency and newly diagnosed Crohn's disease. Other factors that might have contributed to osteopenia were lactose intolerance with restricted dietary calcium intake and secondary hypogonadism with marginally reduced testosterone levels. Genetic analysis of the GC gene, encoding VDBP, revealed a homozygous pathogenic frame shift variant (c.1238del) in exon 11, which leads to a premature stop codon and probably a non-functional protein. In this 33-year-old male patient with apparently treatment resistant vitamin D deficiency we present a novel homozygous pathogenic variant in VDBP. This is line with three previously described cases with different mutations in VDBP all with undetectable levels of VDBP. Taken together, these cases highlight the importance to recognize this condition in patients with ';intractable'; vitamin D deficiency.

[18F]FET PET-MRI; A diagnostic tool to improve medical decision-making for small functioning pituitary adenomas in acromegaly patients

Romy van der Groef[1], Ilanah Pruis[2], Rutger Balvers[3], Julie Celine Refardt[1], Sophie Veldhuijzen van Zanten[2] & Sebastian Neggers[1]
[1]Erasmus University Medical Center, Internal Medicine Section Endocrinology, Rotterdam, Netherlands; [2]Erasmus University Medical Center, Radiology and Nuclear Medicine, Rotterdam, Netherlands; [3]Erasmus University Medical Center, Neurosurgery, Rotterdam, Netherlands

Background
Patients with acromegaly without detectable pituitary adenoma on conventional MRI are often excluded from adenomectomy due to inherent challenges of precise surgical planning, significantly limiting both their therapeutic options and chances of curation. Previous research showed that O-(2-[18F]fluoroethyl)-L-tyrosine ([18F]FET) PET-MRI is an accurate diagnostic tool to detect small functional pituitary adenomas (1). The present study aims to investigate the diagnostic yield of [18F]FET-PET-MRI in a cohort of acromegaly patients with suspected small adenomas.
Methods
Patients with acromegaly and a suspected primary or recurrent small functional pituitary adenoma underwent [18F]FET PET-MRI with administration of gadolinium, at 20 minutes post-injection. A PET-scan was defined as positive in case focal uptake of [18F]FET was detected as assessed by a nuclear radiologist. The accompanying MRI was evaluated separately by a single neuroradiologist. Outcomes were compared with clinical follow-up and sensitivity and positive predictive value (PPV) were calculated using post-operative pathology reports as reference.
Results
Fourteen acromegaly patients, 71.4% female, mean age 55 years (range 35-73 years) were included. Six patients (42.9%) had undergone transsphenoidal surgery prior to PET imaging. Positive [18F]FET uptake was seen in ten patients (71.4%), identifying five additional lesions missed by previous MRIs. During PET imaging, 8/14 patients used somastotatin analogues, and 2/14 cabergoline. The accompanying MRI showed a lesion in eight patients (57.1%), including one cystic lesion. Following positive PET, 1/10 patients received adjuvant radiotherapy and 4/10 underwent surgery. The other 5/10 are awaiting or have declined surgery. Histopathological examination confirmed that 4/4 resected tumours were adenomas staining positive for growth hormone, yielding an estimated sensitivity of 71.4% (95% CI 41.9 – 91.6%) and a PPV of 100% (95% CI 69.2-100%) for the detection of small GH-producing adenomas. Following transsphenoidal surgery, 2/4 patients achieved biochemical remission, the third patient was able to reduce the dose of medication and the last patient switched from pegvisomant to lanreotide. The patient who received adjuvant radiotherapy had no change in medication use.
Conclusion
[18F]FET PET-MRI increases the yield for detection of small GH-producing pituitary adenomas. [18F]FET PET-MRI emerges as a superior diagnostic tool to detect small functional pituitary adenomas and may enhance surgical planning and outcomes for acromegaly patients.

Patient profile of asymptomatic primary hyperparathyroidism (APHPT) at tertiary care riga east clinical university hospital

Diana Sturite[1] & Ingvars Rasa[2]
[1]Rīga Stradiņs University, Faculty of Medicine, Rīga, Latvia; [2]Riga East Clinical University Hospital, Rīga, Latvia

Objective
Primary hyperparathyroidism is the third most common endocrine disorder, which often causes hypercalcemia in outpatient cases. This study aimed to evaluate the various demographic and clinical characteristics, biochemical data, as well as the prevalence of associated conditions, diagnostic accuracy of imaging modalities, and treatment outcomes in patients with APHPT.
Methods
We analyzed data collected from 168 individuals diagnosed with APHPT and treated at Riga East Clinical University Hospital from January 2021 to January 2024. This involved thoroughly examining their medical records, laboratory results, imaging scans, and surgical procedures. Statistical analysis was conducted using IBM SPSS 29.0.
Results
168 patients (mean age: 63.7 ± 11.8 years), 86.3% were females, 13.7% – males. The mean preoperative maximal calcium level was 2.9 ± 0.3 mmol/l, iPTH level – 247.6 ± 224.9 pg/mL, minimal phosphorus – 1.3 ± 6.7 mmol/l and 25-OH vitamin D level 28.3 ± 14.7 ng/mL. A positive correlation was observed between preoperative calcium levels and adenoma cross-sectional area (rs = 0.187, P = 0.029) and maximal dimension (rs = 0.215, P = 0.011). Ultrasonography verified parathyroid adenomas in 63.9% (107/168), SPECT/CT – 68.4% (52/76), 99mTc-sestamibi scan – 65.6% (61/93), 3D-CT - 70.6% (24/34), contrast-enhanced ultrasonography (CEUS) – 84% (21/25) and MRI in 40% (2/5) cases. 12.5% (n = 21) of patients had unlocated parathyroid adenoma. 22.0% (n = 37) of patients had kidney stones, 17.3% (n = 29) – gallstones, 34.5% (n = 58) – osteoporosis, 12.5% (n = 21) – osteoporotic fractures and 47.6% (n = 80) – osteopenia. 17.9% (n = 30) of patients received oral bisphosphonates, 4.0% (n = 7) intravenous bisphosphonates, 8.0% (n = 14) denosumab, and 1.1% (n = 2) had medication holidays. 80.4% (n = 135) of patients had thyroid nodules, 48.2% (n = 81) had nontoxic goitre, 24.4% (n = 31) had autoimmune thyroiditis, 41.7% (n = 70) had hypertension and 10.5% (n = 18) type 2 diabetes. 18.5% (n = 31) of patients were found to have a diagnosis of malignancy. 61.9% (n = 104) underwent parathyroidectomy. Histopathology and radiologic imaging of operated patients revealed a single parathyroid adenoma in 93.3% (n = 97), double parathyroid adenomas in 1.9% (n = 2), parathyroid hyperplasia in 2.9% (n = 3) and parathyroid carcinoma in 1.9% (n = 2) patients. The mean maximal postoperative calcium level (n = 103) was 2.4 ± 0.1 mmol/l, iPTH (n = 101) 63.5 ± 27.7 pg/mL, 25-OH vitamin D 41.5 ± 13.3 ng/mL and mean minimal phosphorus (n = 56) 1.1 ± 0.2 mmol/l. 3 patients developed hungry bone syndrome following parathyroidectomy.
Conclusion
Our findings highlight the complex nature of APHPT and emphasize the importance of recognizing complications and associated conditions to optimize outcomes for APHPT patients.

TNXB genotype and serum levels in individuals with and without congenital adrenal hyperplasia due to 21-hydroxylase deficiency

Marie Helene Schernthaner-Reiter[1], Nina Schmid[1], Oliver Koldyka[1], Boskovic Jelena[1], Gard Liliana-Imi[1], Bayerle-Eder Michaela[1] & Sabina Baumgartner-Parzer[1]
[1]Medical University of Vienna, Clinical Division of Endocrinology and Metabolism, Department of Internal Medicine III, Vienna, Austria

Introduction
In congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency (21-OHD), large *CyP21A2* deletions can also affect the adjacent tenascin-X (*TNXB*) gene. In patients with or without 21-OHD, pathogenic variants in the *TNXB* gene cause Ehlers-Danlos syndrome (EDS), a connective tissue dysplasia associated with cardiovascular complications. CAH in conjunction with *TNXB*-dependent EDS has been termed CAH-X. This study aims to characterize the genetic, biochemical and clinical characteristics of patients with CAH and monoallelic or biallelic *TNXB* deletions and compare them to patients with CAH and intact *TNXB* as well as to individuals without CAH.
Methods
CyP21A2 and *TNXB* genotypes were determined by Sanger sequencing and multiplex ligation-dependent probe amplification (MLPA). Sequence analysis was performed by Alamut. Serum TNX levels were measured by ELISA.
Results
Our cohort comprises 1315 individuals genetically analyzed due to suspicion of CAH. Of 100 patients with classic CAH, we have identified 12 (12%) with heterozygous deletions and 2 (2%) with duplications of *TNXB* exon 35. In patients with nonclassic CAH, *TNXB* exon 35 deletions were identified in 1 patient (1.4%). In individuals without 21-OHD, deletions of *TNXB* exon 35 were rarely detected (0.4%) whereas duplications were more frequent than in the other groups (4.4%). The clinical significance of *TNXB* duplications is currently not known. Sanger sequencing of *TNXB* exons 33-44 was performed in 23 samples. A total of 20 different genetic variants were detected, including 4 missense variants, 3 synonymous and 13 intronic variants; 17 were classified as benign or likely benign and 3 were classified as variants of uncertain significance (VUS). The highest serum TNX levels were detected in controls not affected by CAH, whereas patients with CAH-X (genetically characterized by deletion of *TNXB* exon 35) demonstrated TNX levels significantly lower than those of patients with CAH and intact copy number of *TNXB* exon 35 as well as controls.
Conclusion
The spectrum of genetic variation affecting *TNXB* in individuals with or without CAH includes large deletions, often in conjunction with large *CyP21A2* deletions, as well as duplications and single nucleotide variants. Further studies are necessary to characterize the clinical relevance of these genetic variants.

Mortality in young women with turner syndrome is mainly due to aortic dissection - a 25-year follow-up in sweden

Sofia Thunström[1], Erik Thunström[1], Sabine Naessén[1], Kerstin Berntorp[1], Margareta Kitlinski[1], Bertil Ekman[1], Jeanette Wahlberg[1], Ingrid Bergström[1], Magnus Isaksson[1], Carmen Basic[1], Teresia Svanvik[1], Inger Bryman[1] & Kerstin Landin-Wilhelmsen[1,1,1]
[1]

Context
Turner syndrome (TS) is the most common sex chromosome aberration, affecting 1/2500 born girls. Reduced life expectancy has been reported.
Objective
The objective was to investigate the causes of mortality and identify the risk factors that contribute to death in women with TS.
Design and setting
A matched retrospective observational study of women with TS from the Turner centers in Sweden was conducted. Echocardiography was performed on average every 5th year according to the guidelines in TS.
Patients
A total of 472 women with TS, monosomy 57%, and 2357 controls, matched for birthyear and sex, mean age 28 (12) years, (range 16 - 78) years at inclusion were studied on a mean follow-up period of 17 years (range 1 - 26). Growth hormone had been given to 53%, ongoing estrogen was present in 85% and 13% of the women with TS had given birth to a child.
Outcome Measures
Survival analyses were performed with Cox proportional hazard models. Kaplan-Meier curves were generated. Cumulative incidence rates were evaluated by competing risks analysis, using cumulative incidence function.
Results
During a mean follow-up of 17 years, 35 (7.4%) women with TS and 70 (3.0%) controls died. Mean age at death was 54 (18) years in TS and 60 (15) years in controls. All-cause mortality was raised in TS, hazard ratio (HR) 2.90 (1.9-4.4), especially deaths related to cardiovascular diseases showed significantly higher HR: 9.11 (4.5-18.3). During the follow-up period, 20 women with TS experienced aortic dissection (4%) of whom eight died (40%). Death by aortic dissection occurred in two women (0.1%) among the controls. The main contributor to the increased mortality in young women with TS was aortic dissection with 5 deaths below the age of 45 while cardiovascular disease, other than aortic dissection, was not increased in young TS women. Death by cancer or external causes were not raised in TS. No women with TS died of breast cancer. Bicuspid aortic valves and enlarged aortic diameter were risk factors for death in TS. Karyotype, hypertension, previously given growth hormone or ongoing estrogen treatment were not associated with mortality in TS. None died during pregnancy.
Conclusions
The increased mortality observed in women with Turner syndrome in Sweden primarily resulted from cardiovascular disease, with aortic dissection being the single largest specific cause of death among the young. Life-long evaluation of the aortic size is recommended. Special care is needed before and during pregnancy.

Immunohistochemistry in the differential diagnosis of atypical tumor and parathyroid carcinoma

Ekaterina Kim[1,1], Anastasiia Lavreniuk[1], Alina Elfimova[1], Anna Eremkina[1], Lilia Selivanova[1], Rustam Salimkhanov[1] & Natalia Mokrysheva[1]
[1]Endocrinology Research Centre, Moscow

Background
Atypical parathyroid tumor (APT) generally has a better prognosis compared to parathyroid carcinoma (PC). The differential diagnosis of APT and PC is crucial for further management. Diagnosis of both is based on morphological examination but sometimes can be challenging. In such cases immunohistochemistry (IHC) should be used.
Objective
To estimate the utility of IHC in the differential diagnosis of APT and PC.
Materials and Methods
We conducted a single-centre retrospective study of 44 patients with morphological diagnosis ";APT"; who underwent parathyroidectomy between 2018 and 2023. Method of sampling was continuous. The research complied with the principles of the Helsinki Declaration. IHC was performed in all cases: assessment of CD31/CD34 (to identify vascular invasion), parathyroid hormone (PTH) and parafibromin expression; Ki-67 evaluation. According to IHC results patients were divided into 2 groups: APT and PC followed by comparative analysis. This analysis included biochemical markers of Ca-P metabolism (Ca adj., P, PTH, eGFR CKD-EPI, ALP, osteocalcin, CT×); the frequency of ";classic"; PHPT complications and intraoperative signs of surrounding tissue invasion; size and volume of tumor according to US; morphological features of uncertain malignant potential. Comparison of two independent groups for quantitative data was performed using the Mann–Whitney test (U-test), the frequencies of binary variables using the two-tailed Fisher exact test. The Bonferroni correction was applied by correcting the significance threshold ($P = 0.002$).
Results
Based on the IHC results in 8/44 patients (18.2%) the diagnosis was reclassified as PC. In 7/8 (87.5%) vascular invasion was identified by CD31/CD34 expression (endothelial markers). In 1/8 (12.5%) additional sections revealed a foci of the tumor growth detected with PTH expression in the surrounding fatty tissue. PC and APT groups were comparable for high values of PHT, Ca adj. and 24-h urinary Ca excretion, the frequency of bone and kidney disorders. Moreover, there was no difference in morphological features of uncertain malignant potential. Statistically significant trend was defined only for the frequency of pathological mitosis (more typical in patients with PC). Ki-67% and parafibromin expression also did not differ between groups.
Conclusion
Evaluation of preoperative clinical and laboratory-instrumental data does not allow to differentiate APT and PC. If APT is morphologically suspected, IHC is strongly recommended to exclude PC.

The relationship between glycated hemoglobin and glycemic variability in type 1 diabetics

Faten Mahjoub[1], Ines Bani[1], Nadia Ben Amor[1], Ramla Mizouri[1] & Jamoussi Henda[1]
[1]National Institute of Nutrition in Tunis, A, Tunisia

Introduction
Glycated hemoglobin has long been considered the gold standard for monitoring diabetic patients. however, the advent of CGM, revolutionized the monitoring of diabetics with the possibility of detecting glycemic variability in patients.
Method
This is a descriptive cross-sectional study conducted at the National Institute of Nutrition in Tunis. Adolescents with type 1 diabetes were recruited and they wore a CGM device for 7 days. A1C and clinical information were collected. We analyzed the CGM data for each patient and we calculated the coefficient of variability of glucose (CV), mean of glycemic excursions (MAGE) and the mean of daily differences (MODD).
Results
We included 81 patients with type 1 diabetes in our study, with an average age of 162 years old. A female predominance was noted (58%). The mean duration of diabetes was 6 4 years. A1C ranged from 5.7% to 14%, with a mean of 9.8 1.8%. The average of CV, MAGE and MODD was: 39.812%; 14145 mg/dl; and 8141 mg/dl respectively. Participants were stratified by high CV ($>36\%$; $n=48$) and low CV ($\leq 36\%$; $n=33$). A statistically significant difference was objectified in A1C levels between the groups In fact, patients in group low CV had higher A1C levels (10.3 1.7%) than those in group high CV (9.4 1.9%) with($P=0.042$). The high CV group spent more time in hypoglycemia compared with the group low CV (The average of Time Below Range (TBR) was 10.611% vs 1.52.5%) with $P=0.000$. The time spent in nocturnal hypoglycemia (calculated by CGM) was significantly higher in patients with high CV (15,712% vs 3.68.8%; $P=0,000$)
Conclusion
In our study, we found that A1C levels were higher in the low CV group, this underlines the fact that patients with target A1C levels may have high glycemic variability. The CV can better identify individuals at high risk of hypoglycemia compared with A1C alone. To conclude that glycemic variability metrics should be combined with A1C for better diabetes management in people with type 1 diabetes.

Sticks and stones could break my bones: a rare case of adult hypophosphatasia (HPP) at 24 weeks of pregnancy

Sargunann Naidu Krishnasamy Naido[1] & Tristan Richardson[1]
[1]Royal Bournemouth Hospital, Diabetes and Endocrinology, Bournemouth, United Kingdom

Hypophosphatasia (HPP) is a genetic condition affecting teeth and bones, identified by low levels of alkaline phosphatase (ALP) activity in the blood. This deficiency is caused by mutations in the ALPL gene, leading to an accumulation of substances that hinder bone mineralization. In adults, this can result in osteomalacia, frequent fractures, premature tooth loss, and arthralgia. We describe the case of a 38 year old Caucasian woman who was 24 weeks into her third pregnancy and was referred for a persistently low alkaline phosphatase enzyme (ALP). Her ALP has been low for over a decade (see graph), likely due to a genetic predisposition. She had a history of childhood fractures from low-impact trauma. She denies early loss of baby teeth. She reported myalgia during pregnancy with increased pain over the shoulder and pelvic girdles. Her first child, had metatarsal and metacarpal fractures from low- impact trauma and had lost dentition quite early in life. Her younger child, diagnosed with Tourette syndrome, had lost dentition and broken metatarsal and metacarpal bones from repetitive involuntary muscle twitching. Testing plasma copper level and serum selenium levels revealed normal results, however her plasma zinc levels were borderline and was replaced. A genetic testing revealed that she was a heterozygous for a likely pathogenic ALPL missense variant. Although the option for amniocentesis for prenatal diagnosis was discussed, it was decided against due to the advanced stage of pregnancy and the unlikelihood of changing pregnancy plans based on the results. This woman has been referred to the clinical geneticist for further evaluation. Currently, there is no approved treatment for adult HPP in the UK, but treatment is available, in the USA for pediatric cases using Asfotase alfa. This is a human recombinant tissue-nonspecific alkaline phosphatase that promotes mineralization of the skeleton. However, in spite of the limited treatment options, endocrinologists should have high suspicion of the clinical and biochemical features of adult HPP and refer them early to clinical geneticist for genetic counselling.

Clinical spectrum associated with variants in the ins gene in patients with suspected monogenic diabetes

Mariana Gomes Porras[1], Rosario Vallejo Mora[1], Maria Soledad Ruiz De Adana Navas[1] & Ángel Campos Barros[2,3]
[1]Regional Universitary Hospital of Málaga, Endocrinology and Nutrition, Málaga, Spain; [2]Institute of medical and molecular genetics (INGEMM), Health Research Institute of the La Paz University Hospital (IdiPAZ), Molecular Endocrinology, Málaga, Spain; [3]Institute of Medical and Molecular Genetics (INGEMM), Health Research Institute of the La Paz University Hospital (IdiPAZ), Molecular Endocrinology, Madrid, Spain

Background and aims
*INS*mutations can cause INS-MODy and have been described more frequently in cases of neonatal diabetes mellitus. The reported phenotypic expression of INS-MODy is quite variable.
Objective
To clinically, biochemically and molecularly characterize INS-MODy patients in two Spanish tertiary level hospitals during the period 2009-2023.
Methods
Cross-sectional study that included 121 pediatric patients with suspected monogenic diabetes analyzed by targeted NGS with a custom panel (MonDIABV1-4) including up to 482 genes involved in or associated with different types of dysglycemia. Variants were classified according to ACMG and prioritized using confidence and quality criteria, coverage (20x/pb $>95\%$), allele frequency ($<1\%$ gnomAD controls), impact and *in silico* prediction of pathogenicity (CADD V1.6, score >15).
Results
3/121 patients (2.5%), 2 males and 1 female, aged 154.58 years and with BMI 21.83.5 Kg/m2, presented with heterozygous *INS* deleterious variants. Segregation analysis revealed that the previously described (HGMD) pathogenic INS variants NM_000207.3:c.140G>A, p.(Gly47Asp) and NM_000207.3:c.163C>T, p.(Arg55Cys) were *de novo*. No allelic segregation study could be performed for the NM_000207.3:c.62 C>T; p.(Pro21Leu) (VUS), located in the preproinsulin signal peptide. All patients had a family history of DM, with diabetic debut at 122.6 years as simple hyperglycemia without cardinal clinic, negative pancreatic autoimmunity, preserved C-peptide at diagnosis and 2/3 after 4 years from diagnosis. Initial HbA1c was 6.40.5% (currently 6.72.1%) and their lipoproteic profile was normal. None developed acute or chronic complications after 42 years of follow-up. The patient with the INS p.(Pro21Leu) variant was overweight and his HOMA-IR (7.2) indicated insulin resistance, treated with metformin. The patient with the INS p.(Gly47Asp) variant presented poor metabolic control due to poor adherence to low-dose insulin therapy (0.32UI/Kg/day), his DM was initially classified as type 1b, delaying the molecular diagnosis for about 3 years. The patient with the INS p.(Arg55Cys) variant presented good metabolic control with hygienic-dietary measures.
Conclusion
The prevalence of INS-MODy is higher than reported in the literature. In our experience, phenotypic expression occurred in early childhood, varying from mild to severe hyperglycemia with insulinopenia up to insulin resistance in association with other predicted deleterious variants in candidate genes (MODy-X). Suspicion of INS-MODy should be raised in patients with early diabetic debut without pancreatic autoimmunity, even in the absence of a family history of DM. Therefore, the analysis of *INS* should be included in the molecular diagnostic routine of suspected monogenic diabetes.

We used to be identical twins! a tale of MEN-1 and gigantism: the identical twin 1 foot taller than his brother

Caitlin McNeilage[1], Adhithya Sankar[1] & Tara Kearney[1]
[1]Salford Royal, Manchester, United Kingdom

A 24 year old male presented to his GP with rapid growth in height and joint pain and a physiotherapist suggested that he could have late stage gigantism. Upon presentation he had recently grown from 208 cm to 216 cm tall during a short number of months. His symptoms included fatigue, sweating, oily skin and deepening of his voice. Of note he had prognathism, frontal bossing, macroglossia, broadening of his nose and significant interdental spacing. His mother is 165 cm tall, his father is 172 cm tall. His paternal uncle is 188 cm tall and reportedly his paternal grandfather was over 183 cm tall. Interestingly he has an identical twin who is only 185 cm tall and wears shoes 6 sizes smaller than the patient. Childhood photos confirm that they are indeed identical twins and previously only close family could tell them apart. At the age of 16 he started to grow taller, and they now look remarkably different from each other in terms of both facial features and body size. Biochemical testing revealed an IGF-1 of 698ng/mL (98.7-289) with a growth hormone >40 on OGTT, confirming growth hormone hypersecretion and a diagnosis of gigantism. In addition, he was successfully treated for LH, FSH, TSH, ACTH deficiency with supplementary medication. Genetic testing was confirmatory for MEN-1. MRI pituitary scan identified a 4.7 cm giant pituitary macrodadenoma with bilateral cavernous sinus involvement. Visual field testing showed a significant left temporal field defect. He recently underwent transsphenoidal resection of the pituitary tumour. The histology showed a bone invasive densely-granulated somatotroph pituitary neuroendocrine tumour with Ki-67 $<1\%$. Post-operative recovery was complicated with meningitis and biochemistry on day 2 post-operation showed an IGF-1 of 586 with random GH of 15.8. However, further biochemical assessment will be required as an outpatient. This case highlights the importance of early identification and referral to specialist services. The patient reports distress that he visited his GP many times without a diagnosis or referral leading to irreversible physical changes. However, he is grateful that his family and any future offspring may be able to have genetic testing. This case raises several important discussion points including:

1. Why has one identical twin developed significant pathology whilst the other remains healthy?
2. How do we diagnose such a rare condition at an earlier stage to avoid preventable ongoing harm from excess GH secretion?

Spectacular liver tests improvement during osilodrostat treatment in patient with cushing syndrome and impaired liver function

Mari Minasyan[1], Anna Bogusławska[2], Andrzej Fedak[3], Alicja Hubalewska-Dydejczyk[2] & Aleksandra Gilis-Januszewska[2]
[1], Endocrinology, Oncological Endocrinology, and Nuclear Medicine Department, University Hospital, Krakow; [2], Chair and Department of Endocrinology, Jagiellonian University Medical College, Krakow, Poland; [3], Department of Radiology, Jagiellonian University Medical College, Krakow, Poland

A case presents a 35 year old woman with a history of Cushing Disease (CD) diagnosed in 2014, who developed multiple complications of long lasting hypercortisolemia- obesity (BMI 55), poorly controlled diabetes mellitus (DM), heart failure, hypertension, hypercholesterolemia, mental disturbances and significant hepatic impairment. She underwent a non-radical pituitary adenoma removal in 2014 with subsequent radiotherapy in 2018. Choice of pharmacological treatment was challenged by patient's great non-compliance and severe metabolic complications of CD. Due to significant elevation of liver function tests (LFT) she could not start either ketoconazole treatment or one of the clinical study drug. Pasireotid was contraindicated because of poorly controlled diabetes mellitus. Shortly she was treated with metyrapone, however due to side effects she refused therapy continuation. In December 2021 she consented to osilodrostat treatment. Pre-treatment laboratory evaluation showed sustained LFT elevation- alanine transaminase (ALT) $4\times$ULN, aspartate transaminase (AST) $1.7\times$ULN, gamma glutamyl transpeptidase (GGTP) $4\times$ULN, dyslipidemia (triglycerides 4 mmol/l, total cholesterol 7.4 mmol/l), non-controlled diabetes mellitus (glycohemoglobin-HBA1c%- 10.80 %), high free urine cortisol ($1.7\times$ULN), elevated morning cortisol (32.2 mg/dl). In abdominal MRI liver steatosis with no other abnormalities was described. Since December 2021 patient started osilodrostat treatment with initial daily dose of 2 mg, followed by dose escalation in February 2022 to 4 mg daily. After 4 months of treatment we observed normalizing of serum morning cortisol (13.1 mg/dl), urine free cortisol (55.9 mg/day) and low late night salivary cortisol (0.091 mg/dl). ALT and AST started to lower down 1 year after treatment initiation, normalizing totally within 18 months since treatment. HBA1c% was going down gradually with significant drop after 12 months of treatment (7.2%) and normalisation after 24 months (6.2%). Prominent triglicerydes drop was observed 6 months since osilodrostat start and it normalised after 24 months. During treatment patient lost 3% of her baseline weight, thus the metabolic parameters improvement seems to be not related with weight changes. Liver evaluation on elastography 1 year since therapy start, showed liver steatosis and liver stifness value of 7.91 kPA. Osilodrostat is a steroidogenesis inhibitor which can be safely used in patients with Cushing Disease complicated with liver function impairment. Our case showed normalisation of LFTs during treatment with osilodrostat. Further multicenter studies are needed to investigate the link between hypercortisolemia, liver function and steroidogenesis inhibitors.

Integrated analysis of fecal metagenomics and serum metabolomics reveals the role of gut microbiome-associated metabolites in detecting gestational diabetes mellitus

Chen Zhang[1], Shuo Ma[1] & Guoqiu Wu[1]
[1]Zhongda Hospital, Medical School of Southeast University, Center of Clinical Laboratory Medicine, Nanjing, China

Background
The gestational diabetes mellitus (GDM) is a metabolic disorder characterized by glucose intolerance in pregnant women without pre-existing diabetes, typically diagnosed in mid to late pregnancy. The global prevalence of GDM is on the rise, posing significant diagnostic and economic burdens on society and affecting the health of two generations, potentially impacting population quality. Early diagnosis or understanding of the pathophysiology of this disease in early pregnancy may effectively reduce its incidence. Emerging evidence indicates that the gut microbiome can modulate metabolic homeostasis, thereby influencing the development of GDM. However, it remains uncertain whether and how the gut microbiota and its blood-related metabolites change in GDM.
Methods
We collected serum samples from 698 pregnant women, including 190 in mid-pregnancy and 508 in early pregnancy, as well as partial fecal samples. Utilizing a combination of untargeted serum metabolomic analysis using liquid chromatography-mass spectrometry and fecal metagenomic sequencing, we identified significant changes in gut microbiome-associated metabolite abundance in GDM patients and matched controls. Subsequently, we developed diagnostic and early prediction models for GDM based on different modeling methods, which were evaluated in independent validation and other study cohorts.
Results
Our study revealed significant changes in 1024 serum metabolites in GDM patients, with 275 metabolites closely related to the gut microbiota. Among them, five metabolites showed significant differences in the early pregnancy stages of GDM development. Through repeated testing using untargeted metabolomics, these five metabolites could effectively distinguish GDM patients from normal individuals and even identify patients at risk of developing GDM. Constructing different diagnostic and predictive models based on these five metabolites yielded the highest AUC of 0.95 in the testing cohort and AUCs of 0.91 (sensitivity of 81.5%, specificity of 85.2%) and 0.88 (sensitivity of 79.5%, specificity of 82.4%) in the validation cohorts. Furthermore, the model demonstrated significant advantages in sensitivity, specificity, and accuracy in other studies.
Conclusion
The microbiota and serum metabolites of GDM patients significantly differ from those of matched controls, and the reprogramming of the gut microbiome in GDM patients is related to changes in the serum metabolome. The use of effective serum metabolite models can advance the prediction of GDM to early stages, thereby reducing the adverse consequences of GDM.

Radiological diagnosis of atypical femoral fractures using qualitative and quantitative criteria: a retrospective cohort analysis across two centres over 10 years

Aongus O'Brolchain[1], Zander Englebrecht[2], Richard Steer[2], Alfred Phillips[2], Chen-i Lin[2] & Ian Hughes[2]

[1]Griffith University, Gold Coast Campus, Southport, Australia; [2]Gold Coast University Hospital, Southport, Australia

Objective(s)
Atypical femoral fractures (AFFs) are an important complication of treatment with anti-resorptive treatment, which remains the cornerstone of osteoporosis treatment. Recognition of this rare clinical entity is exceedingly important, as ongoing treatment with anti-resorptives is contraindicated. The American Bone and Mineral Research (ASBMR) have devised diagnostic criteria which are qualitative and subjective. Recent attempts have been made to create more quantitative and objective guidance for clinicians, but diagnosis remains challenging. This study aimed to assess the global performance, sensitivity and specificity, and interobserver agreement/variability of both the ASBMR and the recently devised Sydney AFF Score (SAS) criteria (a score of ≥ 2, 1 point for each of the following: lateral cortical width (LCW) >5 mm, femoral neck width (LCW) <37 mm, age <80).
Design
Retrospective observational study involving inpatients at two teaching hospitals in Queensland, Australia. Adult patients aged 18 years or older presenting with low-energy mechanism, subtrochanteric fractures between January 2012 and February 2022.
Primary outcomes measure(s)
Sensitivity, specificity and performance of each of the ASBMR and SAS criteria. Patients were divided into two groups for comparison: AFFs and 'typical' femoral fractures (TFFs). Measurement of interobserver variability/agreement using ASBMR criteria and the SAS using Kappa Fleiss statistic (FK). Accuracy of radiological reports by retrospective review
Results
A total of 869 femoral shaft fractures were screened. 46 AFFs were identified following expert panel review by 2/3 majority. A comparator group of 40 were selected from the remaining 149 TFFs. The sensitivity and specificity of the ASBMR criteria were: predominantly transverse orientation (TO) (91.4% [range 85.42 – 95.24%], 89.1% [81-94.6%]), minimal comminution (MC) (99.2% [range 97.7-100%], 63.9% [51.4-72.9%]) and periostial reaction (PR) (89.4% [84.1 – 97.6%], 96.4% [91.8% - 100%]). The Sydney AFF Score had comparable performance in this cohort compared to the index and validation cohorts (AUC 0.73). The ASBMR criteria showed good interobserver agreement (FK TO 0.72, MC 0.64, PR 0.76, $P=<0.001$). The agreement with the anthropometric indices using the SAS were (FK LCW 0.25, FNW 0.66, $P=0.002$, <0.001) Of the AFFs, just 13.2% of radiology reports referenced atypical or drug-related fracture.
Conclusion
Qualitative criteria outperform the most accurate quantitative indices. Incorporating fracture angle into the the SAS may yield superior diagnostic value and remove. This study demonstrates that AFFs are under-recognised by reporting radiologists.

Relationship of lipoprotein-a levels with the metabolic profile, bone status and kidney function in patients with type 1 diabetes

Efstratios Kardalas[1], Dimitra Mpaikousi[1], Aikaterini Mpeka[1], Vasiliki Antonopoulou[1], Panagiotis Mouchtouris[1] & Marinella Tzanela[1]
[1]Evangelismos General Hospital, Department of Endocrinology 'D. IKKOS', Diabetes Center European and National Center of Excellence for Rare Endocrine Diseases

Background/aim
Lipoprotein a (Lpa) is a major atherogenic factor associated with increased cardiovascular risk among patients with type 1 diabetes (t1D). This study investigated the possible relationship of Lpa levels to the metabolic profile, bone status and kidney function of patients with T1D.
Materials and methods
122 adult patients with T1D (70 males and 52 females), were studied in an observational cross-sectional study. Demographic, clinical and laboratory data regarding glycemic regulation (HbA1c, Time in range 70-180 mg/dl [TIR])), lipid status (Tchol; Total cholesterol; HLD, LDL, triglycerides, Lpa) bone metabolism (BMD [bone mass density] and T-Score in FN [femoral neck] and LS [lumbar spine]) and renal function (eGFR [estimated glomelural filration rate] were recorded. Patients were divided in 2 groups based on their Lpa levels (low <30 mg/dl and high ≥ 30 mg/dl.) and on their HbA1c status (good, $<7\%$; bad $\geq 7\%$).
Results
Mean age and body mass index of the patients were 44.2 years and 26.6 kg/m^2 respectively. Mean HbA1c and Lp(a) values were 7.5% and 37 mg/dl respectively. Men exhibited notably higher HbA1c, Tchol, LDL and Lpa values (HbA1c: 7.67 vs 7.3%, $P=0.011$; Tchol: 221 vs 204 mg/dl, $P=0.06$; LDL: 112 vs 86 mg/dl, $P=0.043$; and Lpa:48 vs 24 mg/dl, $P=0.031$ respectively). Interestingly, patients with higher Lp(a) values had deteriorated metabolic profile (HbA1c: 7.7% vs 7.2%, $P=0.002$) and worse glycemic regulation (TIR: 64 vs 77%, $P=0.011$) than those with lower Lpa values. Furthermore, eGFR values were remarkably lower among the high Lpa group patients versus the low Lpa group ones (55 vs 62 mL/min/1.73m^2, $P=0.03$). Finally, patient with T1D and increased Lpa values exhibited decreased BMD and T-Score in the FN (BMD: 0.711 vs 0.784, $P=0.034$; T-Score: -1.1 vs -0.9, $P=0.04$) and the LS (BMD: 0.884 vs 0.901, $P=0.012$; T-Score: -0.95 vs -0.7, $P=0.033$) compared to those with increased Lpa values. Interestingly, patients with good metabolic control were found to have significantly lower Lp(a) levels than those with worse metabolic control (49 vs 28 mg/dl, $P=0.041$).
Conclusions
The results of our study indicate that Lpa could potentially be a major risk factor for worse metabolic, bone and renal profile among patients with T1D. Conversely, deteriorated glycemic regulation in patients with T1D is linked to markedly higher Lp(a) levels.

Advanced liver fibrosis is associated with the presence of type 2 diabetes rather than body mass index

Meliha Melin Uygur[1], Caglayan Keklikkiran[2], Süreyya Özgür Uygur[3], Hatice KaradurmuŞ[4], Mohammed Abdulrahman Alzandan[4] & Emine Bade Topal[4]
[1]School of Medicine, Recep Tayyip Erdogan University, Department of Endocrinology and Metabolism Disease, Rize, Turkey, [2]School of Medicine, Recep Tayyip Erdogan University, Department of Gastroenterology Disease, Rize, Turkey, [3]Faculty of Civil Engineering, yıldız Technical University, Department of Geomatic Engineering, Istanbul, Turkey, [4]School of Medicine, Recep Tayyip Erdogan University, Rize, Turkey

Objective
Higher obesity rates are related with increased non-alcoholic fatty liver disease (NAFLD) prevalence which may progress further to non-alcoholic steatohepatitis (NASH) and cirrhosis. The utility of Fibroscan was shown in stratifying risk for significant liver disease. The aim of the study was to evaluate the relation between body mass index (BMI) and liver stiffness measurements (LSM) in overweight and obese patients.
Methods
We conducted the study in 369 (145 men, 224 women) patients aged between 18-75 years old and body mass index over 25 kg/m^{2}from department of endocrinology and metabolism disease and gastroenterology, School of Medicine, Recep Tayyip Erdogan University. We performed a fibroscan assessment and collected biochemical, demographic, and clinical data. Patients were categorized as group I with mild/moderate fibrosis (MF) (F0- F2) and group II with advanced fibrosis (AF) (F3-F4).
Results
Overall, 42.8% of patients had liver fibrosis. Among these, 56 patients had AF whereas 102 patients had MF. Mean BMI was 36.467.77 in group 1 vs 34.596.27 in group 2 (*P*:0.04). Type 2 diabetes was seen in 54.7% of patients in group 1 vs 70.2% of patients in group 2 (*P*:0.03). In binary logistic regression analysis, there was a negative association between BMI and LSM (OR: 0.409, 95% CI 0.202-0.827) whereas a positive association was found with presence of type 2 diabetes (OR: 2.495, 95% CI 1.203-5.176), (*P*:0.006).
Conclusion
The study showed that presence of type 2 diabetes is a strong predictor of advanced liver fibrosis, and physicians should suspect diagnosis even in lower BMI values particularly in patients with diabetes.

Severe osteoporosis in a patient with APECED: atypical presentation

Anastasiia Lavreniuk[1], Ekaterina Kim[1], Rustam Salimkhanov[1], Anna Eremkina[1], Olga Spasskaya[1] & Natalia Mokrysheva[1]
[1]Endocrinology Research Centre

Hypoparathyroidism (HPT) is the most common autoimmune endocrine involvement of APECED syndrome (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy, 79-96% cases). HPT is associated with reduced bone remodeling, abnormalities in microarchitecture and bone strength, thus low-energy fractures occur despite normal or even high bone mineral density (BMD). Other APECED components (hypogonadism, malabsorption, growth hormone deficiency etc.), may also affect bone metabolism.

Case Report

A 48-year-old male patient N. was admitted with periodic seizures, decreased libido and mood lability. HPT was diagnosed at the age of 7 years, when seizures and episodes of loss of consciousness appeared. Initially he received Ca and cholecalciferol, at 15 years old alfacalcidol was added to therapy. Further, the patient did not particularly monitor Ca and P levels. In adolescence N. was diagnosed with Fahr's syndrome (CT signs of basal ganglia calcification, cranial hyperostosis), later – bilateral cataracts. Hypogonadotropic hypogonadism was diagnosed in childhood. He received courses of gonadotropins until the age of 18 years. The secondary sex characteristics appeared at the age of 25 years. In adulthood, androgen therapy was periodically prescribed. At admission he irregularly received alfacalcidol 2.0 mg, Ca carbonate 2000 mg and cholecalciferol. Laboratory tests revealed hypocalcemia – 1.9 mmol/l (2.15–2.55), hyperphosphatemia – 2.15 mmol/l (0.74–1.52), hypocalciuria – 1.52 mmol/d (2.5–8). Therapy was corrected (alfacalcidol 2.5 mg, Ca carbonate 2500 mg) with normocalcemia achievement – 2.2 mmol/l, however mild hyperphosphatemia persisted – 1.63 mmol/l. BMD at the lumbar spine, femoral neck and distal third of the radius by DXA were within the expected range for age but the patient had a height loss of 5 cm. X-ray revealed multiple vertebral compression fractures (Th7, Th10, L2-3, L5). HPT and hypogonadotropic hypogonadism allowed us to suspect APECED. We excluded adrenal insufficiency, hypothyroidism and autoimmune gastritis but diagnosed esophageal candidiasis for the first time. Genetic analysis showed homozygous mutation in the *AIRE* gene. Because of hypogonadotropic hypogonadism, mixed testosterone esters were added. Considering the combination of severe osteoporosis with HPT, teriparatide became the drug of choice. This also allowed us to reduce the dose of alfacalcidol, Ca supplements while maintaining target Ca and P values. X-ray 6 months after did not reveal vertebral fractures progression.

Conclusions

Achievement of HPT compensation in APECED patients is challenging due to polypragmasia and malabsorption. Autoimmune hypogonadism, including hypogonadotropic, is found in 14-60% cases and affects bone metabolism. Prescribing teriparatide presumably has benefits in HPT patients with osteoporosis.

Introduction

Prolactinomas are benign tumors usually well controlled with dopamine agonists; few progress on medical therapy through unclear molecular mechanisms. Although the *SF3B1* mutation has been recently associated with aggressive prolactinomas, in most cases, no genetic mutations have been reported. We aimed to identify somatic genetic alterations associated with prolactinomas using a gene panel.

Method and Results

Oncopanel, a massively parallel sequencing panel, was performed to identify somatic genomic variants and copy number variation (CNV) in a cohort of 20 patients with prolactinomas (age, mean ± SD 38.6 ± 14.49 years; 12 women). 40% of our patients who underwent surgery were resistant to dopamine agonists. None of our patients had metastatic disease. We identified a somatic *ESR1* (encoding estrogen receptor alpha) mutation (p.y537S) in a post-menopausal woman with a recurrent prolactinoma in DNA obtained from her fourth surgery. No *SF3B1* variants or other pathogenic variants were identified in this cohort. The median CNV events was 46 events (IQR: 1-80) with 64% gene amplification and 36% gene losses. The prolactinoma harboring the $ESR1_{Y537S}$ had 233 CNV events consistent with a highly disrupted genome and much higher than the remaining of our cohort samples. We then sought to investigate if there was circulating cell-free DNA. We were able to identify $ESR1_{Y537S}$ in peripheral blood using droplet digital PCR, indicating high tumor shredding, which is not commonly seen in pituitary adenomas and raises the question of the benign nature of this tumor. $ESR1_{Y537S}$ is a hotspot mutation in metastatic breast cancer. $ESR1_{Y537S}$ confers resistance to classic hormonal treatment in breast cancer by activating the receptor independent of ligand binding. This results in high cell proliferation and confers an advantage over cells expressing wild-type estrogen receptors. Elacestrant, a second-line ER degrader, increases overall progression-free survival in patients with resistant breast cancer and $ESR1_{Y537S}$. Given the lack of response to multimodality therapies, elacestrant was initiated after completion of the third cycle of radiotherapy in this patient with aggressive prolactinoma harboring $ESR1_{Y537S}$. The combination of radiotherapy with this personalized treatment was able to control tumor growth and significantly reduce prolactin levels after years without adequate control.

Conclusion

ESR1 regulates lactotroph differentiation and proliferation. Our data supported a role for $ESR1_{Y537S}$ in the unusually aggressive behavior of this patient's prolactinoma in the postmenopausal setting. Molecular profiling revealing the $ESR1_{Y537S}$ mutation allowed us to use targeted therapy to promote control of a previously resistant prolactinoma.

Effectiveness of myo-inositol in treating infertility in patients with polycystic ovary syndrome

Kamilla Mamadjanova[1], Shakhnoz Mamadjanova[2] & Zulaykho Shamansurova[1,3]
[1]Central Asian University Medical School, Endocrinology, Tashkent, Uzbekistan, [2]Andijan State Medical Institute, Obstetrician and Gynecology, Andijan, Uzbekistan, [3]Institute of Biophysics and Biochemistry at the NUUz, Metabolomics, Tashkent, Uzbekistan

Polycystic ovary syndrome (PCOS) is a highly prevalent and representing the most common endocrine-metabolic disorder in reproductive-aged women. PCOS ishighly correlated with insulin resistance and hyperandrogenism. Myo-inositol (MI) supplementation in women with PCOS has been evaluated over the last years. Many hormonal and reproductive impairments associated with this disorder seem relieved by the supplement.

Material and Methods

The meta-analysis was done using the systematic search performed in MEDLINE, EMBASE, PubMed and Research Gate from the inception until October 20th, 2021. Randomized controlled trials (RCTs) included women diagnosed with PCOS and groups having inositols, metformin and placebo.

Results

Twenty-six RCTs were identified, including data of 1691 patients (806 myoinositol, 311 with placebo, and 509 metformin groups). In patients treated with inositols, the risk of having a regular menstrual cycle was found by 1.79 higher than in the case of placebo. Moreover, the inositols showed noninferiority compared to metformin in this outcome. In the case of BMI (MD = -0.45; CI: -0.89; -0.02), free testosterone (MD = -0,41, CI: -0.69; 0.13), total testosterone (MD = -20.39, CI: -40.12; -0.66), androstenedione (MD = -0.69, CI: -1,16; -0.22) , glucose (MD = -3.14; CI: -5.75; -0.54) levels and AUC insulin (MD = -2081.05, CI: -2745.32; -1416.78) inositol treatment induced greater decrease compared to placebo. Inositol increased sexhormone-binding globulin significantly compared to placebo (MD = 32.06, CI:1.27; 62.85). The primary outcome was normalization of menstrual cycle whereas secondary outcomes were body mass index (BMI), parameters of carbohydrate metabolism and clinical and laboratory hyperandrogenism. Results are reported as risk ratios or mean differences (MDs) with 95%

confidence intervals (CIs). This increased production of androgens is increased by the surplus of LH and by hyperinsulinism. In PCOS, treatment with metformin (MET) ameliorated insulin sensitivity and decreased the androgens levels. Studies shown that MI leads to a decrease in LH and androgen levels, as well as a decrease in insulin resistance. Thus, MI is believed to be able to re-establish ovulatory menstrual cycles (especially in obese women with PCOS).
Conclusion
Polycystic ovarian syndrome is a highly inherited complex polygenic, multifactorial disorder. Insulin resistance increases the production of androgens by the theca cells. Elevated androgen levels play a significant role in menstrual cycle disrturbance and anovulation. These factors then become obstacles in occurrence of pregnancy. Myo-inositol (MI) increases insulin sensitivity, decreases hyperandrogenism and improves the menstrual cycle.

A patient with an adrenal adenoma and pituitary and intracranial meningiomas due to an ARMC5 mutation

Kasiani Papadimitriou[1], Anastasios Tsitsimpis[1], Melpomenì Moustaki[1], Maria Rigana[1], Nikolaos Kalogeris[1], Konstantinos Barkas[2], Konstantinos Nastos[3], Constantine Stratakis[4] & Andromahi Vryonidou[1]
[1]Korgialenio Benakio, Red Cross Hospital, Endocrinology, Diabetes, and Metabolism Department, Athens, Greece, [2]General Hospital 'Agios Panteleimon', Neurosurgery Clinic, Nikaia - Athens, Greece, [3]General Hospital 'Attikon', Third Surgical Clinic, Chaidari - Athens, Greece, [4]Foundation for Research & Technology, Institute of Molecular Biology & Biotechnology, Heraklion, Greece

Introduction
Armadillo-containing repeat protein 5 gene (ARMC5) is a tumor suppressor gene expressed in different human tissues. Inactivating germline and somatic mutations of the gene are involved in the pathogenesis of primary bilateral macronodular adrenocortical hyperplasia (PBMAH). These mutations are mainly met in the familial form of PBMAH and are associated with a more severe Cushing Syndrome, meningiomas and T-cell immune response defects. However, the role of ARMC5 mutations in the pathogenesis of unilateral adrenal cortical adenomas is yet poorly investigated.
Case presentation
A 61 -year- old female was referred to our outpatient clinic due to a left adrenal incidentaloma and an 18F-FDG PET/CT with pituitary and left adrenal uptake. For the last year, she presented progressively worsening fatigue, weakness, headaches, depression and deregulation of arterial blood pressure under her regular treatment. Further diagnostic work up with adrenal CT revealed an inhomogeneous left adrenal lesion, 5,3 X 4,5 cm, with low wash out (absolute 27,8%, relative 20,4%) and pituitary MRI showed pituitary and intracranial lesions suggestive of meningiomas. Hormonal assessment revealed complete pituitary hormone sufficiency and ACTH independent cortisol hypersecretion. Initially the patient underwent a left adrenalectomy with subsequent remission of hypercortisolism, and afterwards on resection of the pituitary tumor. Pathology report was compatible with adrenal adenoma and meningioma, respectively. Genetic screening revealed a rare germline ARMC5 mutation [c.2192C>G (p.Pro731Arg, P731R), heterozygosity]. Post-surgically, the patient is under hormone replacement therapy with hydrocortisone and levothyroxine, and is regularly followed up at our outpatient clinic. Family screening is pending.
Discussion
This a rare case of a patient with ARMC5 mutation presenting with Cushing Syndrome, due to unilateral adrenal adenoma, and pituitary and intracranial meningiomas. Though the relationship between ARMC5 mutations and PBMAH has been established, ARMC5 mutations are considered very rare in unilateral adrenal adenomas. On the other hand, patients with meningiomas presented higher prevalence of adrenal nodules in a recent study. Further research is needed to elucidate the association between meningiomas, adrenal adenomas and ARMC5 mutations.

Metastatic pulmonary neuroendocrine carcinoma associated with AVP deficiency and panhypopituitarism due to a hypothalamic metastasis

Tiberiu Manole[1], Camille Baudry[1], Isabela Banu[1], Adela Voican[1] & Olivier Dupuy[1]
[1]Paris Saint Joseph Hospital, Endocrinology - Diabetology, Paris, France

Introduction
Arginine vasopressin (AVP) disorder, formerly known as diabetes insipidus (DI), is a disease that results in either decreased release and/or secretion of antidiuretic hormone (AVP deficiency or central DI) or a reduced response to it (AVP resistance or nephrogenic DI). Carcinoid tumors are rare malignant neuroendocrine epithelial tumor, 25% occurring in the lungs, making them the second most common site. Atypical carcinoids and the development of metastases are associated with a poor prognosis.
Objectives and Methods
To present a case report of a 59-year-old female with AVP deficiency and panhypopituitarism caused by a metastatic neuroendocrine tumour, with cerebral and bone metastases.
Case presentation
In 2022 the patient presented with a mild polyuro-polydipsic syndrome (4 L/day of water intake and urinary output) and chronic fatigue for which she did a chest CT, revealing a 19 mm right inferior pulmonary lobe mass. Tumor biopsy showed an atypical neuroendocrine carcinoma, with a Ki-67 index of 40% and a positivity for chromogranin A, while the somatostatin receptors were negative. The FDG and DOTATOC scans showed secondary lesions in the mediastinal and inguinal lymph nodes, brain and sternum. The primary lesion was resected and she received chemotherapy and radiotherapy. One year later, she returned to the Emergency Department with increasing polyuro-polydipsic syndrome, with hypernatremia up to 147nmol/l and an episode of a seizure. The MRI showed a progression of the cerebral lesions, as well as a hypothalamic lesion of 9/6 mm compressing the pituitary stalk and she was referred to our clinic.
Results
The water intake and urinary excretion were up to 7 L/day, while the serum osmolality was normal (288 mOsm/kg) and urinary osmolality was at the normal inferior limit (81 mOsm/kg, normal range 50-1400). The blood tests showed panhypopituitarism and a mild hyperprolactinemia. Hydrocortisone, levothyroxine and desmopressin substitution treatments were started. The neurosurgical consultation concluded that the hypothalamic lesion was unresectable. Treatment consisted of systemic chemotherapy resumption and localized radiotherapy for the cerebral metastases. Furthermore, endocrine follow-up is required for hormonal treatment adjustment.
Conclusion
AVP deficiency and metastatic pulmonary neuroendocrine carcinoma are two of the rarest endocrine disorders which can greatly affect patients' quality of life, the latter having a 5-year relative survival rate of 55%. Therefore, prompt diagnosis and treatment are mandatory, as well as close surveillance.

Age-stratified reference ranges for directly measured serum free testosterone in healthy men

Joeri Walravens[1], Gido Snaterse[1], Nick Narinx[2], Leen Antonio[2], Tim Reyns[3], Tom Fiers[3], Jean-Marc Kaufman[1] & Bruno Lapauw[1]
[1]Ghent University Hospital, Department of Endocrinology, Gent, Belgium, [2]Leuven University Hospital, Laboratory of Clinical and Experimental Endocrinology, Leuven, Belgium, [3]Ghent University Hospital, Department of Clinical Chemistry, Gent, Belgium

Introduction
Determination of serum (calculated) free testosterone (FT) in clinical practice has been suggested by several clinical guidelines for the diagnosis of male hypogonadism in men with borderline total T concentrations and in situations with altered sex hormone-binding globulin, as it correlates better with androgen exposure than total T. The gold-standard for the determination of FT levels is considered to be directly measured free testosterone (mFT) using equilibrium dialysis followed by mass spectromety (ED LC-MS/MS). However, no widely accepted reference ranges are available for this clinical parameter. We established mFT reference ranges for healthy men aged 18 to 69 years.
Objective
To establish reference ranges for measured FT in serum of healthy adult men.
Methods
Reference ranges were determined following Clinical & Laboratory Standards Institute guideline C28-A3c per age decade. Serum samples were analyzed from healthy men participating in the SIBLOS/SIBEX and EMAS studies, both population-based cohort studies. Exclusion criteria were medications or conditions that affect sex steroid metabolism or a BMI larger than 35 kg/m2. mFT levels were measured in 867 men using ED LC-MS/MS as previously reported (1). Subsequently, 95% reference ranges were determined using the non-parametric method.

Results

We present 95% mFT age-stratified reference ranges. These reference ranges show an expected, decreasing trend of mFT with aging. Lower limits and median mFT decrease at a remarkably stable rate of, on average, 12% per decade up into the 6th decade of life. However, in the upper limit, a marked decrease of 25% occurs after 39 years, followed by smaller decreases of 6% per decade in older age categories.

Age category (years)	Median mFT (ng/dl)	95% mFT reference range (ng/dl)
25-29 (n=148)	10.3	5.6 - 17.1
30-39 (n=252)	9.7	4.9 - 18.1
40-49 (n=207)	8.0	4.3 - 13.5
50-59 (n=146)	7.0	3.8 - 12.6
60-69 (n=114)	5.9	3.3 - 11.9

Conclusion

We have determined mFT reference ranges in healthy men aged 25 to 69. These reference ranges are a first step to improving the framework for further development and integration of free testosterone measurements and calculations in clinical practice.

Assessing medication adherence and unravelling the reasons for non-adherence among patients with diabetes mellitus

Mukhammadbektosh Khaydarov[1], Timurkhon Tillakhujaev[2], Malika Oblokulova[2], Asadbek Sultonov[2], Zulaykho Shamansurova[2,3] & Zamira Khalimova[4]
[1]Central Asian University - CAU, Toshkent, [2]Central Asian University, Endocrinology, Tashkent, Uzbekistan, [3]Institute Biophysics and Biochemistry at the NUUz, Metabolomics, Tashkent, Uzbekistan, [4]Republican Specialised Scientific Practical Medical Centre of Endocrinology, Endocrinology, Tashkent, Uzbekistan

Introduction

Chronic diseases pose an escalating health burden worldwide, affecting individuals across all age groups and socioeconomic backgrounds. The number of people living with diabetes has nearly quadrupled over the past four decades. The aim of our study was estimation of the level of medication (meds) adherence among DM type 2 patients whose admitted into Republican Specialised Scientific Practical Medical Centre of Endocrinology in Uzbekistan.

Material and methods

Pilot testing were conducted in 120 patients with DM in age between 18 – 75 years old. Type 1 DM – 7%. All people after their agreement and sign consent form, were questioned by using Morisky Medication Adherence Scale (MMAS) after approval from the local Scientific and Ethical Committees. All data was collected using Google template and undergo to statistics.

Results

Data analysis showed that 71% of observed patients were on retirement, 3% living alone, other lives with their family, female patients consisted big part of the group (65%). DM duration >10 years in 65%, between 2 to 10 years in 34%, less than 2 years in 1%. Despite the most of the people followed to healthy habits, 12% among them were smokers and 4.7% were alcohol users, 59% of them have HTN, 40% have CVD, 30% arthritis, 2% no any additional diseases. Only 6% of them achieved good glycemic control, 11% acceptable according to HbA1c level and other were in poor glycemic control. Reason for incompliance to taking prescribed medications were forgetting to take in 28.5%, in 50% careless, in 51% skipped the time to take of medication, 29% stop when fill worse, 46% experienced misunderstanding instruction, 24% stop due to side effects, 38% can change dosage without doctors. Interestingly, 48% of them intentionally stop taking meds, 5% do not take because not understand, 5% afraid to use meds, 8% just forget about Meds, 3% stop after feeling better, 2% due to delivery issues, 6% stop without reasons, 3% stop taking med because of long duration.

Conclusion

Leading cases of not reaching the good glycemic control among people with DM is adherence to prescribed medications due to their careless, misunderstanding, skip the time, stop when feeling worse or better, forgetting, or without any reason. It is necessary educate patients to more tight self-control of adherence to achieve better glycemia in patients with DM.

Improving the inpatient assessment and management of people with diabetes and frailty by the involvement of the diabetes in reach team

Eka Melson[1,2], Kashish Gera[1], Garima Gupta[1], Hnin Lwin[1], Anu Thomas[1], Mohamed Fazil[1], Kevin Thottungal[1], Vishnusankar Umasankar[1], HayMar Tun[1], Meri Davitadze[3], Alison Gallagher[1] & Kath Higgins[1,2]
[1]University Hospitals of Leicester, [2]University of Leicester, United Kingdom, [3]University of Birmingham, United Kingdom

Introduction

Our previous study has shown low rates of inpatient deintensification and high rates of adverse outcomes in people with diabetes and frailty[1]. The diabetes in reach (DiR) team consists of diabetologists working together with diabetes specialist nurses, proactively supporting non-specialists in the inpatient management of diabetes. This could be done either virtually or by face-to-face review in the medical ward. This study assessed the role of the DiR team in improving care for inpatients with diabetes and frailty.

Methods

We included all people with diabetes and clinical frailty score ≥ 6 discharged from our medical unit in the year of 2022. Data including demographics, medications and comorbidities were collected. Inpatient management and outcomes collected include involvement of the DiR team, deintensification rate, inpatient hypoglycaemia (defined by any episode of capillary blood glucose of <4 mmol/l), inpatient mortality and one-month readmission rates. Logistic regressions were conduction to assess for the association between the involvement of DiR with deintensification and other outcomes using StataSE v17.0.

Results

Six hundred and sixty-five people with diabetes and frailty were included in our analysis. 51.9% (n=345/665) were female with a median age of 79 years (71-86). 19% (n=119/625) were deintensified during admission. DiR teams were involved in the care of 26.8% (n=178/665) of the patients. People with inpatient hypoglycaemia were more likely to be reviewed by the DiR team compared to those without hypoglycaemia [aOR: 5.7 (95% CI: 3.7-8.6), $P<0.001$]. In patients who were deintensified, deintensification was done by the parent team in 38.7% (n=46/119) and 61.3% (n=73/119) by the DiR team. Irrespective of hypoglycaemia, being reviewed by the DiR team was associated with increased odds of deintensification compared to those that were not reviewed by the DiR team [aOR: 4.2 (95% CI: 2.6-6.8), $P<0.001$]. No associations were seen between being reviewed by DiR with inpatient mortality and readmission rate.

Conclusion

The majority of inpatient deintensification in people with diabetes and frailty was initiated by the DiR team, compared to the parent team. DiR could play an effective and important role in improving the inpatient deintensification rate in people with diabetes and frailty.

Comparing analytical and glucometric parameters in patients with type 1 diabetes

Pilar Pérez-Reyes[1], Pablo Vera-González[1], Ángel Rebollo-Román[1], Delia Marginean[1] & Verónica Torres-Herrera[2]
[1]Hospital Universitario Reina Sofia, Córdoba, Spain, [2]Facultad Medicina Cordoba, Córdoba, Spain

Aims

We aimed to evaluate the relationship between glycosylated hemoglobin (HbA1c), time-in-range (TIR), Glucose Management Index (GMI) and coefficient of variation (CV) in a cohort of adult patients with type 1 diabetes (T1DM) and flash glucose monitoring (FGM).

Material and methods

Cross-sectional study of patients with T1DM who FGM from Córdoba, Spain. Demographic and analytical data were collected. Glucose metrics and engagement statistics (adjusted for previous 90-day averages) were obtained from LibreView, coinciding temporally with the analytical determination of HbA1c. We defined ‘;stable diabetes‘; in our cohort as CV $<$ 36%, GMI $<$ 7% and TIR $>$ 70%. Statistical analysis was made with SPPS vs 25.

Results

169 patients (55% women, 45% men; mean age of 39.74 11.80 years) were enrolled in the study. The mean duration of diabetes was 19.94 10.63 years. Mean BMI was 26.194.46 kg/m^2. Regarding glycemic data, we found that 53.29% of

patients presented HbA1c below 7%, 55.82% GMI below 7%, 37.42% CV below 36% and 38.03% TIR above 70%. In the correlation analysis we observed a statistically significant positive relationship between HbA1c and GMI (rho = 0.793; $P<0.001$) and between HbA1c and CV (rho = 0.209; $P=0.007$). We also found a significant and negative relationship between HbA1c and TIR (rho = -0.735; $P<0.001$). Therefore, we found that when we measure glucose metrics for the last 90 days, there is a statistically significant linear and direct relationship between laboratory parameters (HbA1c) and glucometric parameters (GMI and CV), and a linear and inverse relationship between HbA1c and TIR.

Conclusion

In our cohort, we found that there's a congruent correlation between laboratory parameters of glycemic control and glucose metrics from FGM, since lower HbA1c levels were associated with stable diabetes according to glucometric data from FGM.

Endocrine toxicity is an independent predictor of survival in lung cancer patients treated with immune checkpoint inhibitors

Sofia Ntouraki[1], Emmanouil Panagiotou[1], Ioannis A. Vathiotis[1], Maria Effrosyni Livanou[1], Athanasios Trimis[1], Andriani Charpidou[1], Konstantinos Syrigos[1] & Melpomeni Peppa[1,2]

[1]Third Department of Medicine, Sotiria General Hospital for Chest Diseases, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece, [2]Second Propaedeutic Department of Internal Medicine, Research Institute and Diabetes Center, Attikon University Hospital, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece

Lung cancer (LC) is a serious health problem worldwide. Survival outcomes have improved over time, due to the widespread adoption of therapeutic agents, including immune checkpoint inhibitors (ICIs). Endocrine immune-related adverse events (irAEs) are common in LC patients treated with ICIs. A retrospective study of LC patients was performed in a tertiary center for cases seen between January 2014 and October 2023. In total, 983 LC patients were included in the study, with a median age of 67 years. 670 patients (68.1%) received treatment with a PD-1 inhibitor, 221 patients (22.5%) with a PD-L1 inhibitor and 92 patients (9.4%) a combined therapy with a PD-1 and a CTLA-4 inhibitor. Endocrine irAEs presented at a median time of 4.1 months and included hypothyroidism (15.6%), hyperthyroidism (4.3%), adrenal insufficiency, (0.4%), hypophysitis, (0.4%), and diabetes mellitus, (0.2%). The median time to onset of thyroid disease showed a statistically significant difference ($P=0.004$), between hypothyroidism (4.87 months, 95% CI: 4.07 - 5.63 months), and hyperthyroidism (2.62 months, 95% CI: 2.10-3.77 months). The incidence of endocrine irAEs was similar between different classes of ICIs. Most (97.6%) endocrine irAEs were mild (grade 1-2) and did not require treatment interruption. In multivariate analysis, the presence of endocrine irAEs was associated with the presence of endocrine comorbidities at diagnosis, the absence of liver metastases, as well as the development of dermatologic irAEs or other irAEs. Median overall survival (OS) was higher in LC patients who experienced an endocrine irAE (31.6 months) compared to those who did not (10.8 months). The survival difference remained statistically significant in the 3-month (HR: 0.42) and 6-month landmark analysis (HR: 0.51). The OS advantage in patients with endocrine irAEs was observed in both NSCLC (HR: 0.36) and SCLC patients (HR: 0.27). Median progression-free survival was also higher (10.7 vs 3.8 months). Additional research is needed to validate the role of endocrine irAEs as an independent predictor of survival outcomes in LC patients.

The association between levels of Follicle stimulating hormone and Glomerular filtration rate in peri- and postmenopausal women

Elena Armeni[1], Nektaria Papanikola[1], Ifigeneia Avgousti[1], George Mavraganis[2], Aikaterini Stefanaki[1], Stavroula A. Paschou[1], Areti Augoulea[1], Iliana Karagkouni[1], Kimon Stamatelopoulos[2] & Irene Lambrinoudaki[1]

[1]National and Kapodistrian University of Athens, 2nd Department of Obstetrics and Gynecology, Aretaieio Hospital, Athens, Greece, [2]National and Kapodistrian University of Athens, Department of Clinical Therapeutics, Athens, Greece

Objective

Kidney function is known to be interrelated with the aging process. On the other hand, a number of studies support a link between the menopausal transition and kidney function, either directly or indirectly, secondary to the effect of the alternating hormone environment or the effect of the accumulated cardiovascular risk factors, respectively. We aimed to evaluate the cross-sectional association between kidney function and sex hormones at the time of the menopausal transition and beyond, in a sample of peri- and postmenopausal women.

Methods

We evaluated retrospectively the data of 217 women, recruited from the 2nd Department of Obstetrics and Gynaecology, Menopause Clinic, Athens, Greece. For the purpose of this study we reviewed electronic patient files, with normal to moderate kidney function (eGFR $>$ 60 mL/min/1.72m^2) corresponding to consultations in the clinic. Women were stratified according to their reproductive status as perimenopausal, so 12 months prior up to 12 months after the final menstrual period (FMP), early postmenopausal (1-5 years after the FMP) and late postmenopausal (>5 years after the FMP). Biochemical data were recorded including sex hormone levels. Kidney function was evaluated using the equation for CKD-EPI 2021.

Results

Women of this sample were aged 53.297.6 years, and were slightly overweight with a body mass index (BMI) of 26.364.12 kg/m^2. The baseline eGFR-EPI value was 94.27.67. Correlation analysis showed that eGFR-EPI values are related to stimulated hormone (FSH, r = -0.198, $P=0.005$) but not with total or free circulating estrogen, testosterone levels, or sex hormone binding globulin (SHBG). The eGFR-EPI values also correlated with menopausal age ($r=-0.177$, $P=0.003$). We evaluated eGFR-EPI values per reproductive status, kidney function decreased linearly with advancing reproductive status, estimated as values of eGFR-EPI (mL/min/1.73m^2): perimenopausal women ($n=81$), 97.813.5 vs early postmenopausal women ($n=74$), 92.115.7 vs late postmenopausal women ($n=100$), 91.712.9 (p for linear trend 0.005). Linear regression analysis showed that values of eGFR were associated with FSH (b-coefficient = -0.150, $P=0.010$) and age (b-coefficient = -0.270, $P<0.001$) with R2 of 9.5%. The model was adjusted for current smoking, homeostasis model assessment of insulin resistance, mean arterial pressure, waist to hip ratio, triglycerides, free estrogen index.

Conclusion

The results of this study highlight an association between the peri- and postmenopausal fluctuation of FSH and the kidney function in women. Further longitudinal studies are required to confirm our findings.

Molecular genetics of unresolved mody (Mody-X)

Mariana Gomes Porras[1], María Soledad Ruiz de Adana Navas[1], María Fontalba Romero[1], Ana Lago Sampedro[1], Cristina Maldonado Araque[1] & Ángel Campos Barros[2]

[1]Regional University Hospital of Málaga, Endocrinology and Nutrition, Málaga, Spain, [2]Institute of medical and molecular genetics (INGEMM), Health Research Institute of the La Paz University Hospital (IdiPAZ), Madrid, Spain

Introduction and Objectives

Although Next Generation Sequencing (NGS) technologies have significantly improved the molecular diagnosis of MODy, there is still a high percentage of cases in which the clinical suspicion remains without confirmatory molecular diagnosis. The main objective was to identify new candidate genes for MODy, by means of targeted NGS of a cohort of adult patients with clinically suspected MODy, in whom variants in the 14 known MODy genes implicated in its etiology were previously excluded.

Subjects and methods

Descriptive study that included 51 adult patients with diabetic debut before the age of 35 years, negative pancreatic autoimmunity, no clinical or analytical data of insulin resistance, negative ultrasensitive C-reactive protein, BMI $<$ 25, and first-degree family history of DM. Genomic DNA samples were sequenced using a proprietary targeted NGS panel to analyze 482 genes associated with dysglycemia (MonDiabV4 panel). Filtering, classification and prioritization of variants was performed with help of VarSeqV2.5 and Alamut Visual Plus V1.9 programs, using confidence and quality criteria, (depth $>$100x; % bp 20x $>$95%), allele frequency $<$1% (gnomAD V2.1.1 controls), impact ('missense', 'nonsense', 'frameshift') and *in silico* prediction of pathogenicity (CADD V1.4, score $>$20).

Results
100% presented heterozygous predicted deleterious variants in more than one gene, with a mean of 3.81.4 variants/case (range 2-6), 11 not previously described. 95.5% were missense, 2.2% frameshift or nonsense, and all were classified as variants of uncertain significance (VUS), using ACMG criteria. They were identified mostly in genes involved in the regulation of insulin secretion, in order of frequency: *CACNA1D, CACNA1B, CACNA1G, CACNA1H, CACNA2D2* and *CACNA2D4* (23.8%), all encoding subunits of voltage-dependent calcium channels expressed in pancreatic β-cells; in *SLC2A2, SLC22A3, SLC27A2, SLC6A1* and *SLC6A13* (14. 3%), encoding transporters of type 2 glucose, organic cations, long-chain fatty acids, and GABA, respectively; or in *VPS13C* (10.7%), *WFS1*(5.9%), *ADCy5* (4.7%), *ADCyAP1* (3.6%) and *ANK1* (1.2%). Deleterious variants were also identified in genes associated with the following pathophysiological mechanisms: reduced β-cell survival (*SIRT1, SERPINB4, THADA*), impaired insulin biosynthesis (*PLCXD3*), insulin exocytosis (*ETV5*), insulin signaling (*ADAMTS9, KLF14, TBC1D4, BMP3*), and pancreatic islet development and differentiation (*RFX6, NOTCH2, GATA6, FOXA2*).
Conclusion
NGS reveals a wide array of new candidate genes for MODy and suggests in most cases, a multifactorial genetic component that differs from DM2 by its earlier clinical presentation and absence of metabolic syndrome and inflammation.

Gemigliptin attenuates TGF-β-induced renal fibrosis by inhibiting the TGF-β/Smad3 signaling pathway through the upregulation of FGF21 expression

Gwonsoo Jung[1]
[1]Daegu-Gyeongbuk Medical Innovation Foundation, New Drug Development Center, Daegu, Korea, Rep. of South

Aim
Fibroblast growth factor 21, a well-known regulator of metabolic disorders, exhibits the potential to prevent renal fibrosis by negatively regulating the transforming growth factor β (TGF-β)/Smad3 signaling pathway. Gemigliptin and dipeptidyl peptidase-4 inhibitors are frequently utilized in the management of patients with type 2 diabetes. However, the protective effects of gemigliptin on renal fibrosis, particularly concerning its potential to upregulate the expression of fibroblast growth factor 21 (FGF21), remains incompletely understood. The purpose of this study was to investigate the gemigliptin's renoprotective effects against TGF-β-induced renal fibrosis by enhancing the expression of fibroblast growth factor 21 in the cultured human proximal tubular epithelial cell line, HK-2.
Methods
HK-2 cells were maintained with keratinocyte-free medium according to the supplier's recommendations, and exposed to the indicated doses of TGF-β, FGF21, and gemigliptin for 24 h. To elucidate the effect of FGF21, knockdown experiments were conducted by transfecting HK-2 cells with small interfering RNA targeting the fibroblast growth factor 21 for 24 h.
Results
Treatment of FGF21 effectively prevented TGF-β-induced renal fibrosis by attenuating TGF-β/Smad3 signaling pathway. Similarly, Gemigliptin showed protective effects against TGF-β-induced renal fibrosis by mitigating TGF-β/Smad3 signaling, which is achieved through the upregulation of FGF21 expression. However, the protective effects of gemigliptin were blocked when FGF21 expression was knockdowned in TGF-β-treated HK-2 Cells.
Conclusion
These results indicate that gemegliptin has the potential to confer protective effects against TGF-β-induced renal fibrosis by elavating FGF21 expression levels in the cultured human proximal tubular epithelial cells.

Is thyroid function associated with polycystic ovary syndrome? a bidirectional mendelian randomization study

Qinnan Zhang[1], Kai Wang[1] & Bingbing Zha[1]
[1]Shanghai Fifth People's Hospital, Fudan University, Department of Endocrinology, shanghai

Objective
Some observational studies have suggested the association between thyroid function and polycystic ovary syndrome (PCOS). However, it remains to be determined whether these associations are causal or not. The aim of this study was to investigate the underlying causal association between different thyroid function status and PCOS.
Methods
Bidirectional Mendelian randomization (MR) analysis was conducted to explore the impact of different thyroid function statuses on PCOS. The study included 10,074 individuals with PCOS and 103,164 controls for the primary analysis, with validation analysis repeated in the FinnGen R9 and EstBB PCOS cohorts. Female-specific thyroid function GWAS data were obtained from European population, including Hyperthyroidism (22,383 cases and 54,288 controls) and Hypothyroidism (27,383 cases and 54,288 controls) from the UK Biobank, and TSH (54,288 cases and 72,167 controls) and FT4 (49,269 cases and 72,167 controls) within the reference range from the ThyroidOmics Consortium. Inverse variance weighting (IVW) was chosen as the principal method, and sensitivity analysis was conducted to test for the presence of horizontal pleiotropy or heterogeneity.
Results
The IVW analysis indicated nominal significance between normal TSH levels and PCOS after adjusted for age and BMI [OR(95%CI) = 0.78(0.62,0.97), $P=0.029$], suggesting that maintaining normal TSH levels might act as a protective factor against the pathogenesis of PCOS. Besides, in order to increase the statistical power, we pooled PCOS GWAS above together by meta-analysis and found PCOS contributed to the occurrence of hyperthyroidism [OR(95%CI) = 1.37(0.73,2.57), $P=0.012$]. However, no causal relationship was found after Bonferroni correction (P-value < 0.0031).
Conclusion
Although the MR analysis didn't indicate genetic causal association between thyroid function and PCOS after Bonferroni correction. Further efforts are needed to interpret the potential causal relationship between thyroid function and PCOS in different age and BMI subgroup.

Keywords: Thyroid Function; Polycystic Ovary Syndrome; Mendelian randomization; Causal association.

Effect of endothelial no synthase gene polymorphism on the course of diabetic nephropathy in patients with type 2 diabetes mellitus

Andriy Nesen[1], Vira Zlatkina[2] & Polina Semenovykh[3]
[1]State Institution 'L.T. Malaya Institute of Therapy of the National Academy of Medical Sciences of Ukraine', Kharkiv, Ukraine, [2]V. N. Karazin Kharkiv National University, Kharkiv, Ukraine, [3]State Institution 'L.T. Malaya Institute of Therapy of the National Academy of Medical Sciences of Ukraine'

The aim of the study was to identify a possible association of the G894T (rs 1799983) polymorphism of the endothelial nitric oxide synthase (eNOS) gene with indicators of renal function and glucose metabolism in patients with type 2 diabetes mellitus (DM) with nephropathy.
Materials and methods
In the course of the study, 126 patients with diabetic nephropathy (DN) were examined. The control group consisted of 20 healthy individuals. After the initial examination, depending on the polymorphic variant rs 1799983 of the eNOS gene, patients with type 2 diabetes were divided into two groups: Group I - patients with DM - carriers of the G/G genotype of the G894T (rs 1799983) polymorphism of the eNOS gene ($n=80$); Group II - patients with DM - carriers of the G/T and T/T genotypes of the G894T (rs 1799983) polymorphism of the eNOS gene ($n=46$). Genotyping of the rs 1799983 polymorphism of the eNOS gene was performed using the Taq-Man® Fast Universal PCR Master Mix and TaqMan® SNP Assay.
Results and discussion
Our studies have shown that in patients with DN, the distribution of genotypes of the G894T polymorphism of the eNOS gene corresponds to the Hardy-Weinberg equilibrium in all studied groups and does not differ significantly from European populations. In the group of patients with DM with DN, the total frequency of G/T and T/T genotypes of the G894T polymorphism of the eNOS gene is 3 times higher than in the control group, which proves the undoubted influence of the T allele on the development of DN in this cohort of patients. Patients with DN - carriers of the mutant T allele (genotypes G/T and T/T) have significantly higher blood glucose and HOMA index ($P<0.05$) than homozygotes (genotype G/G). In patients with DN - carriers of the G/G genotype, the studied polymorphisms have better glomerular filtration rate and lower albuminuria compared to carriers of the G/T and T/T genotypes, $P<0.05$.
Conclusions
Establishing the association of eNOS gene polymorphism with the disease and further assessment of individual genetic risk is important for the development of a differentiated approach to the prevention and treatment of diabetic nephropathy in

patients with type 2 diabetes depending on the hereditary predisposition of a particular patient.

Progression of joint and psychological complications in acromegaly and their association with treatments and disease control

Biagio Cangiano[1,2,3], Caterina Premoli[2], Davide Soranna[1], Giovanni Vitale[†,2], Silvia Grottoli[4], Valeria Cambria[4], Pietro Maffei[5], Francesca Dassie[5], Salvatore Cannavò[6], Marta Ragonese[6], Antonella Zambon[7], Luca Persani[1,2], Letizia Fatti[1] & Massimo Scacchi[3,8]
[1]Istituto Auxologico Italiano IRCCS, Milan, Italy, Division of Endocrine and Metabolic Diseases, Milan, Italy, [2]University of Milan, Department of Medical Biotechnology and Translational Medicine, Milan, Italy, [3]Istituto Auxologico Italiano IRCCS, Division of General Medicine, Ospedale S. Giuseppe, Verbania, Italy, [4]University of Turin, Department of Medical Sciences, Turin, Italy, [5]University of Padua, Padua, Italy, [6]University Hospital of Messina, Endocrine Unit, Messina, Italy, [7]University of Milano-Bicocca, Division of Biostatistics, Epidemiology and Public Health, Department of Statistics and Quantitative Methods, Milan, Italy, [8]University of Milan, Department of Clinical Sciences and Community Health, Milan, Italy

Background
Articular and psychological complications of acromegaly are known to impair patients' quality of life (QoL). The aims of this study are: (1) to look for clinical predictors for the progression of the articular and psychological complications, (2) to evaluate the progression of these complications in relation to the activity of the acromegalic disease, and (3) to evaluate how these complications interact to impair the QoL.
Material and Methods
97 patients with acromegaly were enrolled in this multicentric observational prospective study, excluding those harboring inflammatory rheumatic diseases. At the beginning of the study and after 42 months, patients' history, hormonal and physical exams were recorded, and specific questionnaires studying articular and psychological discomfort (WOMAC, AIMS, VAS), as well as a scale for QoL (AcroQoL), were administered to each patient.
Results
The log-gamma model to look for clinical predictors of psychological or articular disease progression, showed a significant correlation of female gender and a worsening of joint symptoms, as measured by VAS ($P=0{,}0139$), WOMAC pain ($P=0{,}0415$) e AIMS symptoms ($P=0{,}0448$) scales; similarly, previous radiation therapy was associated with a significant worsening of symptoms to AIMS questionnaire ($P=0{,}0084$). When evaluating the progression of both complications in relation to chronic acromegaly treatments, patients treated with dopamine agonists (DA) showed worsening of the AIMS depression scale over time ($P=0.01$). By studying the progression of scores in relation to disease activity, we found a paradoxical effect with worsening of arthropathy symptoms in patients gaining hormonal control and improvement in patients with disease recurrence. Depression scores improved, as expected, upon the achievement of disease remission. Finally, arthropathy and depression were confirmed to be independent factors impairing QoL in acromegaly. However, arthropathy showed a greater impact than depression on the worsening of patients' well-being ($P=0{,}0084$ vs $P=0{,}0500$).
Conclusion
Female sex was shown not only to be a factor associated with worse joint scores, but also a predictor of worsening joint symptoms over time, along with prior radiotherapy. If depression score decreases as expected once remission is achieved, the paradoxical worsening of arthropathy scores suggests a mixed effect of IGF1 on joint symptoms. DA seem to be associated with worsening of depression score over time, even if this effect must be confirmed in controlled trials. Arthropathy shows a greater but independent effect than depression on QoL.

Surgical outcomes in primary hyperparathyroidism: addressing factors predicting persistent or recurrent hyperparathyroidism

Yesmine Merhbene[1], Rihab Laamouri[1], Sabrine Mekni[1], Sawsen Essayeh[1], Karima Khiari[1], Nadia Mchirgui[1], Imen Rojbi[1] & Bennacef Ibtissem[1]
[1]Hospital Charles Nicolle, Tunis, Tunisia

Background
Primary hyperparathyroidism is a common endocrine disorder characterized by hypercalcemia, resulting from excessive secretion of parathyroid hormone. Parathyroidectomy, is considered as the definitive treatment for this condition, leading in most cases to remission and resolution of hypercalcemia. However, some patients experience surgical failure. Persistent hyperparathyroidism is defined as persistence of hypercalcemia after parathyroidectomy or recurrence of hypercalcemia within the first 6 months, whereas recurrent hyperparathyroidism is identified when hypercalcemia recurs after a normocalcemic period lasting more than 6 months.
Aim
This study aims to assess the efficacy of surgery as a definitive treatment for hyperparathyroidism by determining the prevalence of persistent and recurrent hyperparathyroidism as well as predisposing factors.
Methods
A retrospective cohort study spanning from 1976 to 2020 at Charles Nicolles Hospital. Two distinct groups were compared: one comprised of patients who achieved remission post-parathyroidectomy, while the other consisted of individuals experiencing persistent or recurrent hyperparathyroidism. Patient demographics, pre-operative biochemical profiles, were collected. Follow-up data included post-operative biochemical assessments. Descriptive statistics were employed to outline the demographic and clinical characteristics of the study, while statistical analyses aimed to identify factors linked to persistent or recurrent hyperparahyroidism.
Results
Eighty patients were included in our study. A sex ratio of 0.21 was observed. The overall success rate of surgery in treating hyperparathyroidism was substantial: 82.5% of the patients achived remission. Notably, no discernible differences were observed in age, or preoperative levels of calcium, phosphate, and PTH levels between the two groups. Big adenoma sizes were more prone to recurrence; (average size 30 mm in the recurrent group versus 24.7 mm). Patients with hyperplasia or carcinoma exhibited a higher likelihood of recurrence compared to those who had adenomas ($P=0.017$). Conversely, the persistent group demonstrated significantly elevated post-operative PTH levels ($P=0.046$). Moreover, postoperative hypocalcemia emerged as a predictive factor for achieving remission ($P=0.04$).
Conclusion
Our study reveals that surgery is a definitive and effective treatment for hyperparathyroidism. Nevertheless, surgical failure is not an uncommon occurrence, highlighting the need for continued vigilance in managing patients operated for primary hyperparathyroidism. Adenoma's size measurements and anatomopathology results are critical in identifying patients at higher risk of persistent or recurrent hyperparathyroidism. This study provides valuable insights for clinicians to refine their approach in managing those patients ultimately improving long-term prognosis.

Evaluation of 8-oxo-2'-deoxyguanosine as a surrogate marker of NF-κB/NLRP3 axis activation in experimental diabetes mellitus

Usatiuc Lia[1]
[1]Iuliu Haţieganu University of Medicine and Pharmacy, Cluj-Napoca, Romania

NLRP3 (NOD-like receptor family pyrin domain containing 3) inflammasome-induced IL-1β production plays an important role in the pathogenesis of type 1 and type 2 diabetes mellitus (DM). Oxidative stress and inflammation interact with each other in the pathogenesis of DM. Oxidative DNA bases modified by reactive oxygen species (ROS), such as 8-OXO-2'-deoxyguanosine (8-oxoG) are repaired by 8-oxoguanine DNA glycosylase1 (OGG1). It has been previously reported that OGG1-DNA interactions facilitate NF-κB binding to DNA targets. The aim of our study was to investigate the association between serum levels of 8-oxoG, NF-κB and NLRP3 in a rat model of Streptozotocin-induced DM. We also evaluated the effect of NLRP3 activation on insulin resistance by correlating it to the triglyceride to glucose index (TyG).
Material and Methods
Sixty Wistar-Bratislava white male rats were randomly divided into three groups: negative control were injected with citrate buffer, Streptozotocin (SZT) group that received 55 mg/100 g body weight (b.w.) SZT by intraperitoneal administration and SZTMetformin (SZTM) (100 mg Metformin/100g b.w.). For ten days the animals received by gavage water in control and SZT groups, respectively Metformin in the SZTM group. The serum levels of 8-oxoG and NF-κB, IL-1β, IL-18 and Gasdermin levels were determined. Additionally, we monitored the fasting glucose levels for each day during the experiment and we calculated TyG index using the formula TyG = ln [Fasting triglyceride (mg/dl) × fasting glucose (mg/dl)]/2.

Results
8-oxoG, NF-κB, IL1B, IL-18 and Gasdemin D were significantly increased in the STZ group compared to the control group ($P<0.01$). In the SZT group we noticed a statistically significant positive correlation between 8-oxoG, NF-κB, IL-18, IL-1B and Gasdermin. Metformin significantly reduced IL-1B levels and in the SZTM group we found no correlation between 8-oxoG and IL-1B. TyG index presented higher levels in the SZT group and was positively correlated to IL-1B, IL-18 and Gasdermin.
Conclusion
8-oxoG can be used as an indicator of NF-κB/NRLP3 axis activation. Increased levels of TyG index are correlated to NLRP3 activation, indicating its role in the associated insulin resistance development.
Keywords: NLRP3 inflammasome, NF-κB, 8-oxo-2'-deoxyguanosine, Diabetes Mellitus, TyG index

Beware of the imposter! A case report of pseudopseudohypoparathyroidism in Trinidad and Tobago

Ijaz Ogeer[1], Kevin Singh[1], Saajida Hosein[1], Joel Teelucksingh[1] & Neal Bhagwandass[2]
[1]San Fernando General Hospital, Internal Medicine, San Fernando, Trinidad and Tobago, [2]University of the West Indies, Medicine, St. Augustine, Trinidad and Tobago

Background
Hypoparathyroidism is a rare endocrine disorder that is rarely seen in clinical practice. Resistance to parathyroid hormone (PTH) gives rise to specific developmental and biochemical abnormalities allowing for a diagnosis of pseudohypoparathyroidism (PHP) [1]. Uniquely the skeletal defects seen in pseudohypoparathyroidism can occur in the absence of its associated biochemical sequelae, a condition referred to as pseudopseudohypoparathyroism (PPHP). The following case highlights this disorder.
Case
A 60-year-old female presented with generalized seizures. Past history noted diabetes and a cerebrovascular accident. Medications included metformin and once daily insulin. Examination revealed a short stature with height of 153 cm and an increased body mass index of 28.6 kg/m^2 There was brachydactyly of the 4th and 5th metacarpals bilaterally without involvement of the metatarsals. Neurological exam was negative for cognitive impairment. Routine blood investigations yielded normal complete blood count, renal and thyroid function with a markedly elevated low-density lipoprotein cholesterol of 219 mg/dl (reference range < 100). Her calcium, phosphorus and PTH were within range. Radiographs were negative for arthropathy. Antiepileptic therapy, a statin and antiplatelet agents were initiated. Discharge plan included lifestyle modifications and outpatient clinic follow up.
Conclusion
Patients with PPHP have mutations on the paternally inherited allele and have the PHP phenotype alone without hormonal resistance or the severe obesity.[2] Adult short stature is common to both PPH and PPHP due to early closure of the epiphyses of the long bones.[2] Increasing the likelihood of metabolic syndrome and diabetes mellitus. Clinical acumen is required to ascertain the physical findings of PPHP as patients often present with unrelated symptoms or diseases. Upon detection of these signs PTH and calcium measurements must be done so as to not miss the sinister differential of PHP.

LC/MS untargeted lipidomics analysis in women with morbid obesity and type 2 diabetes mellitus: a comprehensive study

Laia Bertran[1], Carmen Aguilar[1], Teresa Auguet[1] & Cristóbal Richart[1]
[1]Universitat Rovira i Virgili

Background and Objectives
Since previously, we performed an untargeted metabolomics analysis in a cohort of morbidly obese (MO) women, in which we observed a different lipid metabolite pattern between metabolically healthy MO (MHMO) individuals and those with associated type 2 diabetes mellitus (T2DM). To validate these findings, now we have performed a complementary study of lipidomics.
Materials and Methods
We assessed a liquid chromatography coupled to a mass spectrometer untargeted lipidomic analysis on serum samples from 209 women, 73 normal-weight (NW) women (control group) and 136 MO women. From those, 65 MHMO and 71 with associated T2DM.
Results
Significantly elevated levels of ceramides, sphingomyelins, diacyl and triacylglycerols, fatty acids, and phosphoethanolamines were observed in MO vs NW. Conversely, significantly decreased levels of acylcarnitines, bile acids, lyso-phosphatidylcholines, phosphatidylcholines (PC), phosphatidylinositols, and phosphoethanolamine PE (O-38:4) were noted. Furthermore, comparing MO women with T2DM vs MHMO, a distinct lipid profile emerged, featuring increased levels of metabolites: deoxycholic acid, diacylglycerol DG (36:2), triacylglycerols, phosphatidylcholines, phosphoethanolamines, phosphatidylinositols, and lyso-phosphatidylinositol LPI (16:0).
Conclusions
Analysing both comparatives, we observed decreased levels of deoxycholic acid, PC (34:3), and PE (O-38:4) in MO women vs NW. Conversely, we found elevated levels of these lipids in MO women with T2DM vs MHMO. These profiles of metabolites could be explored for the research as potential factors of metabolic risk of T2DM in MO women.

Effect of Mediterranean diet on quality of life and disease burden in patients with Hashimoto's thyroiditis

Manal Abushady[1], Nahla Adly[1], Sarah Ibrahim[1] & Sherihan Aboelyazed[1]
[1]Ain Shams University, Internal Medicine, Endocrinology Department, Cairo, Egypt

Background
Hashimoto's thyroiditis is one of the leading causes of hypothyroidism worldwide. Currently the only available treatment is Levothyroxine. Even though symptoms improve with treatment, many patients continue to suffer from a lower quality of life and inability to lose weight. The role of nutritional therapy in managing patients with Hashimoto's disease has been of interest lately.
Aim
The aim of our study was to assess the effects of Mediterranean diet on quality of life in Hashimoto's thyroiditis patients using ThyPRO questionnaire, as well as thyroid autoantibodies and thyroid profile parameters.
Methods
We performed a dietary interventional study on 40 female patients previously diagnosed with Hashimoto's disease over 3 months. The study participants were divided into two groups, Group 1 ($n=17$) were hypothyroid patients on Levothyroxine, while Group 2 ($n=23$) were euthyroid patients and not on levothyroxine. Both groups were started on a modified Mediterranean dietary plan with reduction of goitrogenic foods. Baseline evaluation of anti-thyroid peroxidase antibodies, anti-thyroglobulin antibodies, thyroid profile parameters, body mass index, total cholesterol, triglycerides, HDL, LDL, ESR, and ThyPRO questionnaire (for assessment of disease specific health-related quality of life) was done and reassessed at the end of the study.
Results
In both groups a statistically significant reduction was seen in levels of anti-thyroid peroxidase antibodies, anti-thyroglobulin antibodies, BMI, LDL, total cholesterol and triglycerides ($P<0.01$). Statistically significant improvement in all items of the ThyPRO scale were observed in both groups ($P<0.05$), except for eye symptoms, which were statistically non-significant in both groups. Regarding free T3 and free T4, statistically significant increases in their levels were seen in both groups, however in group 1 the observed changes were statistically more significant. Changes in free T3 and free T4 were (41.2%, $P<0.01$) and (54.32, $P<0.05$) respectively. We also observed statistically highly significant reductions in levels of thyroid stimulating hormone in group 1 (-39.09%, $P<0.01$), however, the changes in group 2 were statistically non-significant.
Conclusion
The disease burden of Hashimoto's disease is not only related to hormone levels, but could also be related to an underlying inflammatory state. A modified Mediterranean diet could have beneficial effects on symptoms burden, quality of life, lipid state, as well as autoantibodies levels and hence can be used as an adjuvant to levothyroxine treatment.

Città della Salute e della Scienza, Turin, Italy, [3]Candiolo Cancer Institute, Fondazione del Piemonte per l'Oncologia (FPO)-IRCCS, Candiolo, Italy, [4]Department of Oncology, Pathology Unit, University of Turin, San Luigi Gonzaga Hospital, Orbassano, Italy, [5]Endocrine, Polypeptide, and Cancer Institute, Veterans Affairs Medical Center, Miami, FL, United States, [6]South Florida VA Foundation for Research and Education, Veterans Affairs Medical Center, Miami, FL, United States, [7]Department of Oncology, Pathology Unit, University of Turin, Turin, Italy, [8]Department of Medicine, Divisions of Medical Oncology and Endocrinology, and Department of Pathology, Miller School of Medicine, University of Miami, Miami, FL; Sylvester Comprehensive Cancer Center, Miller School of Medicine, University of Miami, Miami, FL, United States, [9]Department of Oncology, Radiation Oncology, University of Turin, Turin, Italy

Growth hormone-releasing hormone (GHRH), apart from stimulating GH secretion in the pituitary, exerts many peripheral functions, including stimulation of cell proliferation and survival. In fact, GHRH and GHRH receptors (GHRH-Rs) are expressed in different cancer cell types, where they promote proliferation and survival. Conversely, GHRH antagonists exert antineoplastic activities in several tumors, including lung cancer, one of the leading causes of death by cancer worldwide. Currently, radiotherapy is an important treatment in non-small cell lung cancer (NSCLC) patients, even if lack of tumor control, both locally and/or distantly, is quite common. Although different studies have demonstrated the ability of GHRH antagonists to potentiate the anticancer effect of chemotherapy, the role of these peptides in combination with radiotherapy remains unexplored. Thus, we explored the antitumor role of GHRH antagonists of MIA class, MIA-602 and MIA-690 in combination with radiotherapy, in human A549 and H522 NSCLC cells and primary lung adenocarcinoma cells. Our results revealed that MIA-602 and MIA-690, besides exerting inhibitory effects as single agents, potentiated the cytotoxic and antiproliferative effects of ionizing radiations (IR) in NSCLC and adenocarcinoma cells exposed to single doses of IR (2, 5 or 10 Gy). Furthermore, MIA-690 reduced the expression of GHRH-Rs and insulin-like growth factor (IGF)-I in A549 cells treated with 5 Gy IR. MIA-690 also potentiated the radiotherapy-induced inhibition of colony formation and expression of cell cycle promoters, while upregulating cell cycle inhibitors such as p21 and p27. The proapoptotic function of IR was enhanced by MIA-690, along with modulation of apoptosis effectors and elevation of p53 tumor suppressor protein. Mechanistically, MIA-690 also counteracted the response of A549 cells to IR by inhibiting proliferative, inflammatory, and oxidative pathways, such as PI3K/Akt, STAT3, NF-κB and COX2. Finally, MIA-690 hindered the IR-induced epithelial-mesenchymal transition (EMT) by upregulating mRNA for E-cadherin, while reducing vimentin, metalloproteinase (MMP)-2 and -9 and vascular endothelial growth factor (VEGF). Overall, these findings suggest potential application for GHRH antagonists in combination with radiotherapy for the treatment of NSCLC.

Reversible and late-onset adrenal insufficiency in survivors of COVID19: results from a 24-month longitudinal study

Saroj Sahoo[1,2], Jayakrishnan Menon[1], Nidhi Tripathy[1], Monalisa Nayak[3] & Subhash Yadav[1]
[1]Sanjay Gandhi Postgraduate Institute of Medical Sciences, Endocrinology, Lucknow, India, [2]Mid and South Essex NHS Trust, United Kingdom, Division of Endocrinology, [3]King's College Hospital, London, United Kingdom

Objective
The SARS-CoV-2 requires angiotensin-converting enzyme 2 (ACE2) receptor and transmembrane serine protease 2 (TMPRSS2) for gaining entry inside the cells (1). In humans, ACE2 and TMPRSS2 mRNAs are expressed in several endocrine glands, including the hypothalamus, pituitary, and adrenal cortex (2). Thus, it is possible that patients with COVID19 may have hypothalamic-pituitary-adrenal (HPA) axis dysfunction both during acute COVID19 and/or following recovery from COVID19. We studied the temporal course of hypothalamic-pituitary-adrenal (HPA) dysfunction in patients with corona-virus disease (COVID19).
Methods
After excluding patients receiving glucocorticoids or opiates prior to sampling, and pre-existing pituitary or adrenal disease, 302 patients (median age 54 years [interquartile range 42–64], 76% males, 97 had severe/critical illness) were recruited. HPA axis was evaluated by morning cortisol and adrenocorticotrophic hormone (ACTH) at admission ($n=231$) withing first 48 hours of admission. Adrenal insufficiency (AI) during acute illness was defined using a morning cortisol <83 nmol/l. AI at 12-months follow-up was defined using a peak cortisol <406 nmol/l in the ACTH-stimulation test (APST) ($n=90$). Those with AI at 12-months were further assessed by the APST 6-monthly for recovery of hypoadrenalism.
Results
The median morning cortisol and ACTH during COVID19 were 295 (IQR 136–461) nmol/l and 3.9 (0.8–6.9) pmol/l, respectively. AI was present in 33 (14%) patients; ACTH was elevated in three, and low or inappropriately normal in the rest 30 patients. At 12-months, AI was seen in 13% (12/90) patients and hypothalamic-pituitary in origin in all; five (42%) of them had not met the diagnostic criteria for AI during COVID19. AI diagnosed at admission persisted at 12-months in seven patients and recovered in seven; the remaining 19 patients were lost to follow-up. The presence of AI at 12-months was independent of severity, and steroid use during COVID19. A morning cortisol <138 nmol/l during COVID19 predicted presence of AI at 12-months. All patients showed recovery of HPA axis in the ensuing 12-months.
Conclusion
Central AI was common during acute COVID19 and at 12-months of follow-up. AI can be late-onset, developing after recovery from COVID19 and was transient in nature.

GIP receptor is expressed by human cumulus granulosa cells

Mafalda V. Moreira[1,2,3], Duarte Pignatelli[3,4,5], Raquel Bernardino[1,2], Emídio Vale Fernandes[1,2,6] & Mariana P Monteiro[1,2]
[1]Unit for Multidisciplinary Research in Biomedicine, School of Medicine and Biomedical Sciences (ICBAS), University of Porto, Endocrine and Metabolic Research, Porto, Portugal, [2]Laboratory for Integrative and Translational Research in Population Health (ITR), University of Porto, Porto, Portugal, [3]i3S-Institute for Research and Innovation in Health, University of Porto, Porto, Portugal, [4]Faculty of Medicine of the University of Porto, Endocrinology, Porto, Portugal, [5]Cancer Signaling & Metabolism Group, IPATIMUP- Institute of Molecular Pathology and Immunology of the University of Porto, Porto, Portugal, [6]Centro Materno-Infantil do Norte Dr. Albino Aroso (CMIN), Centro Hospitalar Universitário do Porto (CHUPorto), Gynaecology, Porto, Portugal

Polycystic ovary syndrome (PCOS) is one of the most common endocrinopathies in women of reproductive age and, accounts for 80% of the causes of anovulatory infertility. Despite PCOS being often associated with obesity and insulin-resistance, these are not invariably present. As PCOS aetiology and underlying mechanisms remain unclear, clinical management is limited to target symptoms. Recent evidence suggested the potential of GLP-1 receptor agonists therapies in ameliorating PCOS endocrine and reproductive manifestations, in parallel to inducing weight loss and improving dysglycemia. Moreover, a dual GLP-1/GIP co-agonist drug with even more promising results was just rendered available. Notably, no previous study has been conducted to identify incretin receptors in the human ovary. Herein we aimed to investigate the presence of gastric inhibitory polypeptide (GIP) and glucagon-like-peptide-1 (GLP-1) receptors in human granulosa cells to understand the role of incretin hormones in ovarian physiology and to assess the potential use of incretin-based drugs for the treatment of PCOS-related infertility. For the first time, we were able to identify the presence of GIP receptor transcripts in cumulus cells from patients with and without PCOS undergoing fertility treatments. Additionally, the presence of the GIP receptor was also found on non-luteinized granulosa cells (HGrC1) and granulosa tumour cells (COV434). On the other hand, we were unable to detect the GLP-1 receptor in granulosa cells. Further studies are needed to evaluate whether there are differences in the expression levels of GIP receptors in granulosa cells from overweight/non-overweigh women with PCOS and overweight/non-overweight normo-ovulatory women. Overall, our preliminary findings suggest that GIP may have a significant role in modulating female reproductive function which may provide future targets for pharmacological intervention in reproductive disorders.

Persistent parathyroid hormone elevation post-parathyroidectomy with biological remission: prevalence and predictive factors

Yesmine Merhbene[1], Rihab Laamouri[1], Essayeh Sawsen[1], Sabrine Mekni[1], Karima Khiari[1], Nadia Mchirgui[1], Imen Rojbi[1] & Bennacef Ibtissem[1]
[1]Hospital Charles Nicolle, endocrinology department, Tunis, Tunisia

Background
Primary hyperparathyroidism, is defined by hypercalcemia associated with an elevated or inappropriately normal parathyroid hormone(PTH) levels stemming from hyperfunctioning parathyroid glands. It's a prevalent endocrine disorder. Parathyroidectomy, the surgical excision of affected glands, stands as the definitive treatment, typically resulting in remission and normalization of calcium levels. However, persistent elevation of serum PTH post-parathyroidectomy presents a clinical hurdle, possibly indicating incomplete resolution of the condition or other contributing factors.
Aim
This study aims to ascertain the prevalence of persistent elevated PTH levels among patients achieving remission post-parathyroidectomy and to delineate predisposing factors associated with this persistence.
Methods
Conducted as a retrospective cohort study spanning from 1976 to 2020 at Charles Nicolles Hospital. The research compared two groups: one consisting of patients with persistent elevation of serum PTH levels post-parathyroidectomy, and the other without such elevation, both achieving biological remission. Data sourced from medical records included demographic data, preoperative biochemical profiles, surgical details, and postoperative outcomes. Descriptive statistics were employed to outline the demographic and clinical characteristics of the study cohort, while statistical analyses, including chi-square tests and logistic regression, aimed to identify factors linked to persistent elevation of serum PTH levels.
Results
We included 42 patients with a sex ratio of 0.23. Parathyroid adenoma was the predominant pathology in 76.2% of cases, followed by diffuse hyperplasia in 14.3%, with one case of parathyroid carcinoma detected. Despite achieving normocalcemia postoperatively, 45.2% of patients exhibited persistent elevation of PTH. Notably, no discernible differences were observed in age, creatinine clearance, histological patterns, adenoma size, or preoperative levels of calcium, phosphate, and alkaline phosphatase between patients with persistent PTH elevation and those without. However, serum vitamin D levels were marginally lower in the persistent PTH group. Patients with persistent PTH elevation experienced significantly higher rates of bone complications ($P=0.000$). Additionally, a significant association was noted between higher preoperative PTH levels and persistent hyperparathyroidism ($P=0.005$).
Conclusion
Our study reveals a noteworthy prevalence of persistent elevation in serum parathyroid hormone levels following parathyroidectomy, despite achieving remission. Our findings emphasize the need for continued vigilance in managing primary hyperparathyroidism. Identification of factors associated with persistent PTH elevation, such as higher preoperative PTH levels, underscores the importance of personalized treatment approaches. Further research is warranted to unravel the underlying complications and optimize clinical strategies for managing persistent PTH elevation post-remission.

Diabetes prevalence and impact on stroke outcomes: an analytical study

Houda Ben Soltane[1], Yosra Hasni[2], Mariem Khrouf[1], Ons Haddaji[1], Safa Mehri[1] & Zied Mezgar[1]
[1]farhat hached university hospital, emergency departement, sousse, Tunisia, [2]farhat hached university hospital, endocrinology departement, sousse, Tunisia

Introduction
Rising stroke rates call for a closer look at risk factors such as hypertension, diabetes and obesity. The established association of diabetes mellitus with stroke risk and potential post-stroke complications underscores the need for thorough analysis to effectively mitigate these challenges.
Objective
This review aims to determine the prevalence of diabetes in acute stroke patients and investigate its association with post-stroke outcomes, encompassing both ischemic and haemorrhagic strokes.
Methods
A prospective study spanning 14 months (07.01.22 to 17.10.23) was conducted at the FH - Sousse emergency department. It included individuals aged 18 years and above presenting with abrupt or rapidly progressive focal neurological deficits, or transient ischemic attacks (TIAs) lasting less than one hour, after excluding other potential diagnoses. Both diabetic and non-diabetic patients were included in our study population.
Results
Our study included 150 patients, with a mean age of 66.02 /- 12.59. a male predominance was observed with a sex ratio of 1.54. 85.3% of our patients had associated comorbidities, notably hypertension and diabetes (55.3% and 47.3% of cases respectively). Almost half of our population (40.7%) had a history of a vascular accident, with an ulterior cerebral stroke in 51.9% of the cases and TIA in 9.6%. upon admission, all of our patients benefited from a cerebral CT scan. 44.8% of our patients had a normal CT scan while an angiography was required in 10.6% of the cases. An ischemic stroke was found in 73.4% of our patients, while 16.7% were diagnosed with haemorrhagic stroke and 10% with TIA. The most affected territory was that of the MCA in 57.9% of the cases. 22.7% of our patients were deemed having a severe presentation through clinical and imagery data observation, of whom 6.3% needed IMV, with a total mortality rate of 3.6%. Comparing diabetic and none diabetic patients, the former had significantly more comorbidities ($P<10^{-3}$) in univariate analysis: hypertension (OR = 2.6 IC [1.34-5.109], $P=0.04$) and dyslipidaemia (OR = 4.075, IC [2.029-8.183]; $P<10^{-3}$), with only dyslipidaemia being retained in multivariate analysis (OR = 5.014 IC [2.261-11.118]; $P<10^{-3}$). Diabetics also had a significantly more elevated risk of ischemic stroke in multivariate analysis (OR = 4.607 IC [1.845-11.502]; $P<10^{-3}$), but had no impact on mortality ($P=0.111$).
Conclusion
The study examines diabetes prevalence and its impact on stroke outcomes. It highlights the common occurrence of hypertension and diabetes among stroke patients, emphasizing the need to address these risk factors.

Keywords: diabetes mellitus, stroke, outcome.

Pituitary dysfunction following mild traumatic brain injury in female athletes: neuropsychological and psychological functioning

Lára Ósk Eggertsdóttir Claessen[1], María Jónsdóttir[2], Hafrún Kristjánsdóttir[3], Sigrún Lund[4], Ingunn Unnsteinsdóttir Kristensen[2] & Helga Sigurjónsdóttir[5]
[1]Landspitali the National University Hospital of Iceland, Emergency Medicine, Reykjavík, Iceland, [2]Reykjavík University, Department of Psychology, Reykjavík, Iceland, [3]Reykjavík University, Department of Sport Science, Reykjavík, Iceland, [4]The University of Iceland, School of Engineering and Natural Sciences, Reykjavík, Iceland, [5]Landspitali the National University Hospital of Iceland, Department of Medicine, Reykjavík, Iceland

Background
Pituitary dysfunction (PD), neuropsychological and psychological symptoms, have been reported following mild traumatic brain injury (mTBI). These symptoms may be due to the brain injury itself or PD as hypopituitarism (HP) can have neuropsychological and psychological effects. To the best of our knowledge, this study is the first to report neuropsychological and psychological outcomes in female athletes with PD following sport-related mTBI.
Subjects
Female athletes aged 18 to 45 years currently active in or retired from soccer, team handball, basketball, ice hockey, and martial arts who answered an online questionnaire regarding mTBI history and mental health were included ($n=508$). Of the 308 women who reported one or more mTBI, 166 (53.8%) accepted further participation in an interview where neuropsychological tests were performed. All 166 women were subsequently invited to participate in a medical interview. Of those 151 accepted (90.9%) and 131 (86.7%) of them participated in pituitary hormone screening blood tests (SBT).
Methods
The online questionnaire included a post-concussion symptom scale, and mental health scales evaluating symptoms of anxiety, depression, stress, and quality of life. The neuropsychological tests performed included the Sustained Attention to Response Task (SART) as well as tests measuring executive functioning, visual search, motor and processing speed, divided attention, working memory, and intellectual abilities. The SBT were taken at 0800 hours and included S-IGF1 (age dependant reference range), S-cortisol (values <350 nmol/l were considered abnormal), S-prolactin (reference range 4.79 – 23.3 µg/l), S-TSH (reference range 0.270 – 4.20 mIU/l), S-fT4 (reference range 12 – 22 pmol/l), S-FSH, S-oestrogen, and S-progesterone measurements. If SBT were repeatedly O-RV, detailed endocrinological tests were performed for each axis as indicated.

Results
Following a detailed endocrinological evaluation, 16 women were diagnosed with PD (HP $n=6$, hyperprolactinemia $n=10$) following mTBI. Women with PD had a significantly higher mean SART error score than women with normal pituitary function (PF) (16.7 and 12.8 respectively; $P=0.04$). No other significant differences in neuropsychological outcome were found between the two groups. Moreover, there was no significant difference with regards to mTBI symptoms, anxiety, depression, stress, QOL or insomnia between women with PD and those with normal PF.
Conclusion
Sustained attention or inhibitory performance may be affected in women with PD following mTBI as they had a higher mean SART error score than women with normal PF. No other significant difference in neuropsychological or psychological outcome was demonstrated.

Congenital adrenal hyperplasia (CAH) is a disorder due to mutations of genes coding for adrenal steroidogenesis enzymes, commonly caused by 21α-hydroxylase enzyme deficiency. Severe impairment of 21α-hydroxylase synthesis results in the classic form of CAH (c-CAH) characterized by cortisol and aldosterone deficiency (salt wasting form - SW), or partial enzyme deficiency characterized by cortisol deficiency (simple virilizing form - SV); mild impairment of 21α-hydroxylase synthesis results in the non-classic form of CAH (nc-CAH) potentially characterized by cortisol deficiency. Moreover, CAH is characterized by androgen excess which may promote secondary hypogonadism; furthermore, male patients suffering from CAH may present other andrological disorders including testis hypotrophy, testicular adrenal rest tumours (TARTs) and impaired spermatogenesis. The aim of the current study was to evaluate testis function in males with CAH due to 21α-hydroxylase deficiency. Data were retrieved from GONADIS, a national registry on gonadal status and reproductive and psycho-sexual function in patients affected by pituitary and adrenal disorders. Twenty one male patients aged 18-64 years suffering from CAH on chronic replacement therapy with glucocorticoids were evaluated, including 12/21 patients (57.2%) with c-CAH, 9/21 patients (42.8%) with nc-CAH. Prevalence of testis hypotrophy as well as semen parameters were assessed in the overall cohort of CAH patients and in a subanalysis a comparison between c-CAH vs nc-CAH was performed. The control of disease was defined as serum androstenedione levels within/above the normal range. In the overall cohort of CAH patients, 13/18 (72.2%) reached disease control. Unilateral/bilateral testis hypotrophy was detected in 11/20 (55%) and TARTs in 11/19 (57.9%) of patients; concerning seminal parameters, oligozoospermia was detected in 3/19 (15.8%), azoospermia in 6/19 (31.6%), asthenozoospermia in 4/13 (30.7%), teratozoospermia in 3/13 (23%) and oligo-astheno-teratozoospermia in 3/13 (23%) of patients. In a subanalysis on c-CAH vs nc-CAH patients, significantly lower ACTH ($P=0.04$) and higher testosterone ($P=0.01$) levels were detected in the c-CAH, compared to nc-CAH group; a significantly higher prevalence of TARTs ($P=0.03$), lower total sperm count ($P=0.002$) and sperm concentration ($P=0.04$), and higher prevalence of azoospermia ($P=0.01$), were detected in the c-CAH compared to nc-CAH group. This study demonstrated an overall high prevalence of pathological testis and semen parameters in male patients with CAH. Moreover, a significantly worse semen quality was highlighted in patients with c-CAH, which were also characterized by a significantly higher prevalence of azoospermia and TARTs, therefore suggesting that alterations in semen parameters might be predominantly due to testis damage induced by TARTs.

Background
LIM kinase 1 (LIMK1) plays a pivotal role in dynamic actin remodeling through phosphorylation of cofilin. In turn, the dynamic remodeling of the actin cytoskeleton is involved in exocytosis, thereby contributing to tuned secretion of hormones and neurotransmitters, although the exact role of actin in these processes is still debated.
Results
We report two individuals with de novo variants in LIMK1 with dissimilar clinical phenotypes: one individual exhibited epileptic encephalopathy and developmental delay, the other showed common variable immune deficiency, glucose dysregulation, and episodic sinus tachycardia. Given the intragenic localization of these variants, one impacting the highly conserved kinase domain, the other variant located in the auto-inhibitory LIM domain, we suspected that the phenotypic features could be explained by opposite effects of the *LIMK1* variants on LIMK1-mediated exocytosis dynamics. Indeed, we found significantly decreased actin polymerization in individual 1, contrasting with increased LIMK1 availability, cofilin phosphorylation, and actin polymerization in fibroblasts of individual 2. As compared to wildtype, significantly slower and decreased insulin exocytosis was observed in insulin-secreting cell lines expressing the *LIMK1* variant of individual 1 (harboring the catalytically dead variant), which contrasted with rapid and uncontrolled insulin exocytosis in case of a lack of auto-inhibition for individual 2.
Conclusion
This first report of two individuals with *LIMK1* variants harboring divergent effects on cofilin phosphorylation and actin polymerization, reveals novel and important roles for LIMK1 in tuned exocytosis. These distinct exocytosis defects may underlie the epileptic encephalopathy and glucose dysregulation observed in these individuals.

Weaning patients off long-term low dose prednisolone: an international survey of current endocrine practice

Katharine Lazarus[1,2], Pei Eng[1,3], Kavita Narula[1,2], Sirazum Choudhury[1,2,4], Niamh Martin[1,2], Florian Wernig[1,2], Debbie Papadopoulou[1,2], Tricia Tan[1,2,4], Yasir Elhassan[5,6], Anna Mitchell[7], Helen Simpson[8], Jessica Davis[9], Roisin Evans[9], Kate Single[9] & Karim Meeran[1,2]
[1]Imperial College London, Hammersmith Campus, London, United Kingdom, [2]Imperial College Healthcare NHS Trust, Endocrinology and Diabetes, United Kingdom, [3]NUHS, Endocrinology, Singapore, Singapore, [4], Department of Clinical Biochemistry, London, United Kingdom, [5]Queen Elizabeth Hospital Birmingham, Department of Endocrinology, Birmingham, United Kingdom, [6]University of Birmingham, Birmingham, United Kingdom, [7]Royal Victoria Infirmary, Newcastle upon Tyne, United Kingdom, [8]University College Hospital, Department of Diabetes and Endocrinology, London, United Kingdom, [9]Society for Endocrinology and Bioscientifica, Stoke Gifford, United Kingdom

Background
Prolonged glucocorticoid (GC) use is associated with significant morbidity and mortality, including the development of glucocorticoid-induced adrenal insufficiency (GI-AI). There is currently no consensus regarding testing or weaning of GCs prescribed for non-endocrine conditions.

Aim
To assess the long-term GC weaning practice by endocrinologists in the UK and Southeast Asia.
Methods
An anonymous survey was disseminated to the clinical membership of the Society for Endocrinology (SfE) in May and June 2023, and the ASEAN Federation of Endocrine Societies (AFES) and the Endocrine and Metabolic Society of Singapore (EMSS) in November 2023 and February 2024.
Results
Respondents were asked about their management practice of a patient who no longer requires long-term prednisolone 5 mg daily for asthma, and has an early morning cortisol 98nmol/l. A total of 239 members (SfE 163; AFES/EMSS 76) responded. A Short Synacthen Test (SST) was the choice of 42.2% (SfE 54.0%; AFES/EMSS 30.3%) of respondents, whilst 35.4% (SfE 33.1%; AFES/EMSS 51.1%) wean further before cortisol assessment, and 9.5% (SfE 11.0%; AFES/EMSS 9.2 %) accept this morning cortisol as confirmatory of adrenal insufficiency. A switch from prednisolone to hydrocortisone prior to SST is the practice of 2.3% (SfE 3%; AFES/EMSS 1.3%) of all respondents. GC weaning was the practice of 78.2% (SfE 77.2%; AFES/EMSS 80.3%) of respondents; 27.7% (SfE 29.6%; AFES/EMSS 23.7%) wean down prednisolone, whilst 50.4% (SfE 47.3%; AFES/EMSS 56.6%) switch to hydrocortisone before weaning. Still, 12.6% continue GC replacement without further assessment; 8.0% with hydrocortisone and 4.6% continue 5 mg prednisolone. Most respondents (71.7%: SfE 62.1%; AFES/EMSS 92.1%) did not have a local steroid weaning protocol. Over half (54.8%: SfE 52.4%; AFES/EMSS 47.4%) continue follow-up until prednisolone is weaned off; 39.3% would follow-up three-monthly and 46.2% six-monthly. The commonest perceived causes for weaning failure were relapse of the underlying GC-treated condition (54.7%) and GC withdrawal symptoms (20.1%). Subsequently-confirmed hypothalamic-pituitary-adrenal axis suppression on prednisolone led to a clinical decision by 19.2% of respondents not to pursue further steroid weaning. A lack of evidence-based studies was highlighted as a major challenge (36.8% of respondents). Other challenges included limited follow-up capacity (5.2%), access to Synacthen (5.2%), access to prednisolone 1 mg tablets (2.7%), and difficulty engaging non-endocrinologists to support weaning (6.5%).
Discussion
There remains huge variation in the management of long-term GC weaning. There remains a need to develop an evidence-based approach for safe and effective GC weaning and hypothalamic-pituitary-adrenal axis assessment.

Unexpected diagnosis of a mixed corticomedullary tumor of the adrenal gland in a hypertensive patient with unexplained weight loss

Agnieszka Kuzior[1], Inmaculada Molinero-Marcos[2], Borja Santana-Ojeda[2], Carlos Rios-Gomez[2], Ricardo Jose de Leon-Durango[2], Alba Hernandez-Santana[3], Claudia Arnas-Leon[1,2], Carmen Acosta-Calero[4], Asunción Acosta-Merida[5] & Francisco Javier Martinez Martin[1,2]
[1]Clinica San Roque, Endocrinology & Nutrition, Las Palmas de Gran Canaria, Spain, [2]University Hospital of Gran Canaria Dr. Negrín, Endocrinology & Nutrition, Las Palmas de Gran Canaria, Spain, [3]Parc Taulí University Hospital, Endocrinology & Nutrition, Sabadell, Spain, [4]University Hospital of Gran Canaria Dr. Negrín, Cardiology, Las Palmas de Gran Canaria, Spain, [5]University Hospital of Gran Canaria Dr. Negrín, General and Digestive Surgery, Las Palmas de Gran Canaria, Spain

Introduction and Objective
Pheochromocytomas are usually monocomponent tumors, but very rarely there are also composite pheochromocytomas, with another medullary component (benign or malignant) derived from the neural crest present. Even more rarely there are mixed corticomedullary tumors, with pheochromocytoma plus a cortical adrenal tumor, eventually causing primary aldosteronism or hypercortisolim. Our objective in this communication is to illustrate an infrequent variety of pheochromocytoma, its clinical implications and prognosis, based on a clinical case.
Design & Method
Review of the patient's clinical record and the relevant literature.
Results
A 63-year-old male, previously diagnosed of obesity, type 2 diabetes mellitus, dyslipidemia and essential hypertension was admitted in Cardiology for ACS without ST-segment elevation; angiography revealed no coronary lesions. Four years later the patient was admitted in Internal Medicine for unexplained weight loss (about 20 kg). Blood pressure was well controlled with enalapril, amlodipine, hydrochlorothiazide and bisoprolol; LDL-cholesterol and HbA1C were also adequately controlled. Abdominal CT showed a solid, hyperdense, heterogeneous, indeterminate 4 cm mass in the right adrenal and a 1.7 cm hypodense mass labeled as adenoma in the left one. Biochemical testing for hypercortisolism and primary aldosteronism was negative. Plasma metanephrine/normetanephrine were 1045/546 pg/mL, and a MIBG scan/SPECT-CT showed a single abnormal uptake labeled as pheochromocytoma. After standard preoperative preparation, a robotic right adrenalectomy was performed: recovery was uneventful, and the patient is presently normotensive and asymptomatic with normal plasmatic metanephrines and catecholamines. The final pathology report described a single 40 × 34 × 30 mm mass, labeled as mixed corticomedullay tumor, with 75% pheochromocytoma and 25% cortical adrenal components, without extracapsular extension. There were no signs of malignancy in the cortical component, and the pheochromocytoma component scored 2/20 in the PASS risk scale and 2/10 in the GAPP risk scale (low risk for metastasis in both). Genetic testing is pending. Unfortunately there are no specific risk score scales available for adrenal mixed corticomedullary tumors, but the cortical component should not add to the low risk of malignancy of the medullary component.
Conclusion
Adrenal mixed corticomedullary tumors are extremely rare, owing to the presence of two distinct components of different embryonic lineage; less than 30 cases have been described. Besides hypertension the patients may present hypercortisolism, primary hyperaldosteronism or nonspecific symptoms like weight loss. Awareness of this entity is needed to avoid perioperative hypertensive crises or missing diagnosis such as Cushing's syndrome or primary hyperaldosteronism in addition to pheochromocytoma.

The phenomenon of macro-TSH in a patient on oncoimmunotherapy: a clinical case report

Laura Ebanoidze[1], Ekaterina Pigarova[1], Larisa Dzeranova[1], Larisa Nikankina[1], Galina Kolesnikova[1] & Nadezhda Platonova[1]
[1]Endocrinology research centre, st. Dmitry Ulyanov, 11, Moscow

Introduction
The occurrence of autoimmune adverse events is a frequent complication of oncoimmunotherapy with antibody drugs to PD-1.
Clinical Case
At the age of 33, the patient was diagnosed with melanoma, which was surgically removed. After 3 years, there was a progression with the appearance of liver metastases which were embolized with further initiation of oncoimmunotherapy with nivolumab. As a complication of this treatment the patient developed autoimmune thyroiditis with primary hypothyroidism, and levothyroxine therapy was initiated with gradual dose escalation over several months up to 300 mg per day (2.6 mg per kg of body weight), but without normalization of the thyroid profile: thyroid stimulating hormone (TSH) – 24.68 mU/l (0.35 - 4.94), free T3 – 2.98 pmol/l (2.63-5.9), free T4 – 9.18 pmol/l (10-19). No factors that could potentially alter the bioavailability of levothyroxine were detected. Subsequently, liothyronine was added to levothyroxine therapy and gradually increased from dose of 25 mg in the morning to dose of 25 mg in the morning and 50 mg in the afternoon, which led to normalization of TSH levels while maintaining free thyroxine is in the low normal range. There were no clinical signs of hyperthyroidism in the patient. During the examination at our Centre an inadequate TSH levels were suspected for the given dose of thyroid hormones taken. To address this issue a blood serum test for TSH was performed initially and after precipitation with polyethylene glycol (it allows to remove a high-molecular fraction of immunoreactive TSH from the blood, presumably due to the binding of part of TSH molecules with anti-TSH IgG, by analogy with macroprolactin). The results of the analysis confirmed macro-TSH phenomenon: TSH – 12.8 mU/l (0.25-3.5), bioactive TSH – 2.8 mU/l (0.25-3.5), free T4 – 13.24 mmol/l (9-19), free T3 – 3.04 (2.6-5.7). Thyroid hormone therapy was adjusted as follows: liothyronine was canceled, the dose of levothyroxine was reduced to 225 mg per day.
Conclusion
The phenomenon of macro-TSH may be one of the manifestations of autoimmune complications of oncoimmunotherapy with immune endpoint inhibitors, complicating the interpretation of laboratory tests

Schmidt's syndrome: think about it in males too: A case report

Hasna Ouirar[1], Ikrame Qasdi[1], Caimae zouna[1], Karimi Meryem[1], Hajar Azagouagh[1], Kaoutar Elmoatamid[1], Fatima Toulali[1], Ghizlane Sabbar[1], Kaoutar Rifai[1], Iraqi Hinde[1] & Mohamed Elhassan Gharbi[1]
[1]Ibn Sina University Hospital, Endocrinology and Metabolic Diseases, Rabat, Morocco

Introduction
Autoimmune polyendocrine syndrome type 2 is a rare autosomal dominant life-threatening syndrome. It is defined by the presence of Addison's disease in combination with at least one of the known autoimmune diseases: thyroid autoimmune disease, type 1 diabetes, and hypogonadism. The coexistence of Addison's disease and autoimmune thyroid disease has been known as Schmidt's syndrome. We are detailing the case of a patient who exhibited this syndrome abruptly without a family history.
Case
A 44 years-old male patient with non-known medical history, presented to the emergency department feeling lethargic, with multiple episodes of vomiting and giddiness. On examination patient had cold clammy extremity with signs of dehydration. Hyperpigmentation of face and gums was noted. PR -128/min, hypotensive blood pressure of approximately 75/55 mmHg, hypoglycemia at 0.4g/l, and a microvoltage with a peaked T-wave on the EKG. Laboratory blood tests showed an hyperkalemia of 7.2 mmol/l, hyponatremia of 122 mmol/l and a low cortisol level indicating an Addisonian crisis. Associated with a high TSH level at 83 mui/l and anti TPO was positive suggesting autoimmune thyroiditis. The patient was treated for adrenal insufficiency first followed by thyroid insufficiency. Noteworthy clinical and biological improvement observed.
Discussion
Schmidt's syndrome is a rare disease and difficult to diagnose because the presentation depends on which gland is initially involved. It is more common in middle-aged females and is treatable if diagnosed early. It can be treated with respective substitution therapy. Early detection of the disease and appropriate management may reduce morbidity and mortality significantly in the patients with autoimmune poly glandular syndrome. Therefore, this case report can contribute to the medical literature on Schmidt's syndrome, which can help in early diagnosis and improve patient outcomes.

Background
Despite biochemical control of GH and IGF-I levels patients with acromegaly continue to have marked impairment of their well-being. The acromegalic arthropathy has been identified as a significant contributor to the impaired well-being of these individuals. Few data are available to determine the impact of the arthropathy on function.
Methods
Patients with a diagnosis of acromegaly under follow-up in six tertiary pituitary centres were invited to complete a questionnaire relating to joint pain and distribution; and impact on function and QoL. We present data from (1) 'Disabilities of the Arm, Shoulder and Hand (DASH); (2) Oswestry Disability Index (ODI) to assess the impact of back pain; (3) Knee injury and Osteoarthritis Outcome Score (KOOS); (4) Foot Function Index (FFI); and (5) Health Assessment Questionnaire Disability Index (HAQ-DI). Scores range from 0 (no disability) to 100 (most severe disability) for the DASH, ODI and FFI; in contrast scores for the KOOS subscales are reversed with a score of 100 representing no disability. HAQ-DI values 0 to 1 are considered to represent mild to moderate difficulty, 1 to 2 moderate to severe disability, and 2 to 3 severe to very severe disability.
Results
411 patients completed the questionnaires, median age 60 (range 18-88) yrs, 56.1% female and mean age at diagnosis 43 (range 12-83) yrs, with duration of disease 13 (IQR 5.9-20.9) years. The median DASH score was 10.8 (IQR 0.8–32.8) and for the ODI 12 (IQR 0–32). Values for the KOOS subscales were KOOS-pain (80.6, IQR 58.3–100.0); KOOS-symptoms 80.0 (IQR 57.1–96.4); KOOS-ADL 87.5 (58.8–100.0); KOOS-sport function 75.0 (IQR 35–100.0); and KOOS-QoL 68.8 (IQR 43.8–100.0). The median FFI was 0.0 (IQR 0–32.4). The median HAQ-DI score was 0.25 (IQR 0.0-1.13), however 43 patients had a HAQ-DI score >2 consistent with severe disability and 75 a score of 1-2 in keeping with moderate to severe disability. 253 had inactive and 155 active disease. No difference in any questionnaire score was observed between patients with active and inactive disease. No correlation between any of the questionnaire scores and duration of acromegaly was observed.
Conclusions
Patients with a history of acromegaly demonstrate functional impairment which is greatest in areas which correlate with the most frequently affected joints (such as the knee joint). Moderate to severe disability is present in approximately 25% of individuals.

Increased cardiovascular risk in sheehan syndrome patients on optimal hormonal replacement therapy- a case-control study

Bashir ahmad Laway[1], Mohd Salem Baba[1] & Dr. Abid Rasool[1,1]
[1]sher-i-kasmir institute of medical sciences, Endocrinology, Koshur, India

Objective
Patients with Sheehan syndrome (SS) are predisposed to coronary artery disease (CAD) due to risk factors like abdominal obesity, dyslipidemia and chronic inflammation. In addition to estimate CAD risk enhancers like high sensitive C reactive protein (hsCRP), apolipoprotein B (ApoB) and lipoprotein A [Lp(a)], this study applies Framingham risk score (FRS) and coronary artery calcium (CAC) score to compute a 10-year probability of cardiovascular (CV) events in SS patients.
Design
Case–control study Sixty-three SS patients, on a stable hormonal replacement treatment except for growth hormone and 65 age, body mass index and parity-matched controls.
Measurements
Measurement of serum hsCRP, ApoB and Lp(a) and estimation of CAC with 16-row multislice computed tomography scanner.
Results
The concentrations of hsCRP, ApoB and Lp(a) were significantly higher in SS patients than in controls ($P<.01$). After calculating FRS, 95.2% of SS patients were classified as low risk, 4.8% as intermediate risk and all controls were classified as low risk for probable CV events. CAC was detected in 50.7% SS patients and 7.6% controls ($P=.006$). According to the CAC score, 26.9% SS patients were classified as at risk (CAC $>$ 10) for incident CV events as against 1.6% controls. The mean Multi- Ethnic Study of Atherosclerosis (MESA) score was significantly higher in patients with SS than controls. CAC corelated significantly with fasting blood glucose ($r=.316$), ApoB ($r=.549$), LP(a) ($r=.310$) and FRS ($r=.294$).
Conclusion
Significant number of asymptomatic SS patients have high coronary artery calcium score and are classified at risk for CAD.

Keywords agatston score, coronary artery calcium, Framingham score, panhypopituitarism, Sheehan syndrome

Cardiovascular evaluation of the patients with sleep apnea syndrome and acromegaly: A prospective study on the effects of continuous positive airway pressure (CPAP) therapy

Aysa Hacioglu[1], Zuleyha Karaca[1], Hatice Dogan Kesim[1], Sevda Ismailogullari[2], Muhammed Emre Urhan[1], Asli Sezgin Caglar[1], Nihat Kalay[3], Ugur Karabiyik[3], Serpil Taheri[4], Kursad Unluhizarci[1] & Fahrettin Kelestemur[5]
[1]Erciyes University School of Medicine, Department of Endocrinology, Kayseri, Turkey, [2]Erciyes University School of Medicine, Department of Neurology, Kayseri, Turkey, [3]Erciyes University School of Medicine, Department of Cardiology, Kayseri, Turkey, [4]Erciyes University School of Medicine, Department of Medical Biology, Kayseri, Turkey, [5]Yeditepe University School of Medicine, Department of Endocrinology, Istanbul, Turkey

Background
Patients diagnosed with acromegaly have an increased prevalence of sleep apnea syndrome(SAS). The data are scarce regarding the effects of continuous positive airway pressure(CPAP) use on cardiovascular parameters in these patients. We aimed to prospectively evaluate the cardiovascular effects of CPAP in patients with SAS and acromegaly.
Methods
Adult patients with newly diagnosed acromegaly were performed metabolic (body mass index (BMI), glucose, lipid values) and cardiovascular evaluation studies (24-hour ambulatory blood pressure monitoring, 24-hour ambulatory electrocardiography, carotid intima media thickness(CIMT), echocardiography), and polysomnography at the time of diagnosis. Serum levels of HIF-1 alpha was measured. Quality of life was evaluated by AcroQoL questionnaire. Control group was matched in terms of age, gender and BMIs. Patients were randomly assigned to 'CPAP-using' and 'no-CPAP' groups, and prospectively evaluated one year after remission.
Results
Forty-nine patients(29 female), mean age 42.3010.65 years, and 13 controls were included. Serum LDL, total cholesterol, and HIF-1 alpha levels were lower in the patient group ($P=0.029$, $P=0.006$, and $P=0.021$, respectively). Apnea-hypopnea index (AHI) was higher ($P=0.004$), and the results of cardiovascular evaluation studies were similar except for higher left ventricular posterior wall thickness at end-diastole among the patients ($P=0.006$). Average heart rate during polysomnography was higher in the patients ($P=0.023$). The patients were grouped on the basis of AHI scores (Group-1:AHI <5, Group-2:AHI ≥ 5 and <15, Group-3:AHI ≥ 15). The mean age was significantly higher in Group-3 patients when compared to groups 1 and 2. AcroQoL was lower in Group-3. Glucose values, BMIs, echocardiographic parameters, CIMT, mean blood pressures(MAP), and heart rates, HIF-1 alpha levels were similar across the groups at baseline. 'CPAP-using' ($n=8$) and 'no-CPAP' ($n=8$) groups who achieved acromegaly remission were compared at first year. BMIs remained similar in both groups, but fat mass increased in non-users ($P=0.018$). AHI scores improved only among CPAP users ($P=0.043$). Left ventricular systolic(LVSD) and diastolic diameters(LVDD) were significantly lower in CPAP-users than non-users after one year. Minimum heart rate showed decrease only among CPAP-users ($P=0.042$). CIMTs, MAPs, serum HIF-1 alpha levels, and AcroQoL scores were similar at first year across the groups. HIF-1 alpha levels were positively correlated with LVSD and LVDD at baseline ($P=0.008$, $r_s=0.476$, $P=0.005$ $r_s=0.499$). AcroQoL score was negatively associated with AHI, and positively with average O2 saturations ($P=0.012$, $r_s=-0.381$, $P=<0.001$ $r_s=0.611$).
Conclusion
Use of CPAP in patients with OSAS and acromegaly after remission may lead to better outcomes in terms of cardiac structure and heart rate, but not QoL.

Prevalence of hepatosteatosis in young women with polycystic ovary syndrome (PCOS)

Zaira Benetti[1], Simona Buti[1], Elisabetta Sciarroni[1], Luisa Pignata[1], Emilio Fiore[1], Antonio Salvati[2], Elena Benelli[1], Brunella Bagattini[1] & Massimo Tonacchera[1]
[1]University of Pisa, Department of Endocrinology, Pisa, Italy, [2]University of Pisa, Department of Hepatology, Pisa, Italy

Polycystic ovary syndrome (PCOS) is the most common endocrine disease in women of reproductive age, often characterized by obesity and insulin-resistance. NAFLD (Non-Alcoholic Fatty Liver Disease) is a metabolic disorder characterized by the accumulation of fat in the liver, in absence of alcohol consumption and other possible causes of hepatosteatosis. The association between hepatosteatosis and at least one cardio-metabolic risk factor is defined as MASLD (Metabolic Dysfunction-Associated Steatotic Liver Disease). A high prevalence of NAFLD in PCOS has been observed in several studies. The purpose of this study was to evaluate the prevalence of NAFLD, MASLD and hepatic fibrosis in patients affected by PCOS. In this prospective study 38 consecutive PCOS patients (mean age 23 years, IQR 6) were recruited at the Department of Endocrinology of Pisa. The diagnosis of PCOS was made following the International PCOS Network Guidelines. The diagnosis of NAFLD was based on laboratory assessment of liver function and liver imaging studies, by the use of ultrasound and transient elastography (TE) or Fibroscan, that estimates hepatosteatosis and fibrosis by measuring the Controlled Attenuation Parameter (CAP) and the Liver Stiffness Measure (LSM). Patients were divided in different groups according to their BMI (19% normal weight, 18 overweight and 63% obese) and to the presence of insulin-resistance (36.8% of the women). 31 out of 38 patients (81.6%) had hepatosteatosis at ultrasound; the majority of women (42.1%) exhibiting mild steatosis. The CAP revealed the presence of hepatosteatosis in the 47.2% of patients. The measurement of LSM showed that 72.3% of women had values >5 kPA, indicative of reduced liver elasticity. The 90.3% of the patients were diagnosed by MASLD, primarily due to the overweight. There weren't significant differences in liver stiffness values between insulin-resistant (IR) and non-insulin-resistant (NIR) patients. The BMI was higher in patients with hepatosteatosis and progressively increases according to the severity of the steatosis. A correlation between hyperandrogenism and hepatosteatosis in PCOS we observed: the values of FAI (Free Androgen Index) were significantly higher in patients with steatosis, especially if moderate/severe, and SHBG (Sex Hormone Binding Globulin) levels were significantly lower. The association between hepatosteatosis and SHBG remained significant indepen-dently of insulin-resistance. Furthermore, the levels of 17-OH-progesterone were significantly lower in patients with more sever liver damage. In conclusion, patients with PCOS show an increased prevalence of NAFLD, primarily due to the presence of obesity, insulin-resistance and hyperandrogenism.

Twelve years of experience using teriparatide for severe hypopar-athyroidism in an APS-1 patient: a case report

Tatiana Kokorina[1], Liudmila Rozhinskaya[1] & Zhanna Belaya[1]
[1]Endocrinology Research Centre, Neuroendocrinology and bone disease, Moscow, Russian Federation

Background
Managing hypoparathyroidism in patients with autoimmune polyendocrine syndrome type 1 (APS-1) poses significant therapeutic challenges. The presence of gastrointestinal candidiasis and associated malabsorption complicates treatment and may lead to refractory hypocalcemia. The use of high doses of calcium and active vitamin D metabolites to regulate serum calcium levels frequently results in hypercalciuria, which may cause long-term complications. Consequently, replacement therapy with biologically active fragments of parathyroid hormone (PTH) such as teriparatide and rhPTH (1-84) has been suggested.
Case Report
Patient A. was diagnosed with APS-1 at the age of 10 when she presented with acute adrenal insufficiency and hypocalcemia. Notably, she suffered from cutaneous candidiasis since age 4. Genetic testing identified an R257X mutation in the AIRE gene. Achieving normocalcemia was exceptionally challenging, even with high doses of alfacalcidol (up to 20 μg/day). The patient frequently experienced hypocalcemic seizures, needing repeated calcium IV administrations. By age 24, she had already developed secondary complications such as cataracts and cerebral calcification (Fahr's syndrome). At this point, patient A. began treatment with rhPTH 1-34 (teriparatide). Two daily injections of 20 μg (40 μg/d) were necessary to achieve normocalcemia. However, episodes of hypocalcemia still occurred occasionally. To lessen these calcium level fluctuations, she was transitioned to a continuous subcutaneous rhPTH 1-34 infusion via a pump. Three years following this adjustment, the patient opted to cease pump therapy in favor of conventional treatment with two to three daily injections of teriparatide (40-60 μg/day). At present, at the age of 35, the patient's condition is well-managed with three daily injections of teriparatide (60 μg/day), alfacalcidol (4 μg/day), and calcium (3g/day). Additionally, she receives 20 mg of hydrocortisone for primary adrenal insufficiency and fluconazole for candidiasis. The patient experienced infrequent hypocalcemia episodes (once a year), likely due to low treatment adherence and reductions in teriparatide and vitamin D dosages contrary to medical advice.
Conclusion
Twelve-year continuous teriparatide treatment has successfully maintained normocalcemia without inducing hypercalciuria and significantly reduced

alfacalcidol dose from 20 µg/d to 4 µg/d in the patient with severe hypoparathyroidism. No adverse effects of continuous long-term teriparatide therapy were noted.

Introduction
To prevent ovarian cancer, *BRCA1/2* germline pathogenic variant carriers are recommended to undergo premenopausal risk-reducing salpingo-oophorectomy (RRSO). Premenopausal RRSO leads to immediate surgical menopause, which has been associated with an acute phase of rapid bone loss. However, data on long-term effects is scarce and inconclusive. Therefore, we investigated the long-term impact of premenopausal RRSO on bone mineral density (BMD).
Methods
We conducted a cross-sectional study nested in a nationwide cohort of women at high familial risk of ovarian cancer to assess long-term effects of a premenopausal RRSO compared with a postmenopausal RRSO on BMD. We included 500 women who underwent premenopausal RRSO ($\leq$45 years) with 240 women who underwent postmenopausal RRSO ($\geq$54 years). Participants underwent a Dual Energy X-ray absorptiometry (DXA) scan of the lumbar spine (LS) and femoral neck (FN) to asses BMD. Age differences between the pre- and postmenopausal RRSO groups were accounted for using Z-scores and subgroup analyses restricted to women aged 60-70 at study visit.
Results
Median age at study visit was 58.8 years in the premenopausal RRSO group and 69.0 years in the postmenopausal RRSO group ($P<0.001$), median time since RRSO was 16.1 years (IQR 15.3-21.3). Multivariable regression analyses showed that the Z-scores of both the LS and FN were significantly lower for the premenopausal RRSO group compared with the postmenopausal RRSO group (LS Z-score: 0.5 vs 1.2, $P<0.001$; FN Z-score: 0.1 vs 0.6, $P<0.001$). Furthermore, the relative risk (RR) of having a Z-score $\leq$-1.0 was higher in the premenopausal RRSO group compared with the postmenopausal RRSO group (LS RR: 2.35, 95% CI, 1.26-4.40; FN RR: 1.84, 95% CI, 1.08-3.13). Subgroup analyses in women aged 60-70 at study visit ($n=320$) showed that women in the premenopausal RRSO group had a higher prevalence of low BMD (T-score $\leq$-1.0) compared with the postmenopausal RRSO group (LS 52.0% vs 47.8%; FN 59.5% vs 56.9%; LS or FN 73.0% vs 66.4%), however, in multivariable regression analyses this difference was not statistically significant (LS $P=0.58$; FN $P=0.45$; LS or FN $P=0.35$).
Conclusion
Premenopausal RRSO appears to be associated with reduced BMD Z-scores more than 16 years after RRSO, however, in a subgroup of women of similar age we found no increased risk of low BMD based on T-score $<$-1.0.

Vitamin D and quality of life in patients with hashimoto thyroiditis

Zvezdana Jemuovic[1], Marina Nikolic Djurovic[1], Sandra Pekic Djurdjevic[1], Dragana Miljic[1], Marko Stojanovic[1], Ana Petakov[1], Ljiljana Dimitrijevic Jevremovic[2], Ivana Cekic[1], Ivan Jevtic[1] & Milan Petakov[1]
[1]Clinic for Endocrinology, Diabetes and Diseases of Metabolism, University Clinical Center, Serbia, [2]General Hospital Krusevac, Krusevac, Serbia

Introduction
Hashimoto thyroiditis (HT), chronic autoimmune disease, is related with impaired quality of life (QoL) regardless of euthyroid state. Some studies showed decreased levels of vitamin D in patients with HT which implies there is a relationship between vitamin D deficiency and HT. It remains unclear whether decreased levels of vitamin D are result of autoimmune process or are part of its cause.
Aim
To investigate effect of vitamin D levels on QoL in patients with HT on levothyroxine therapy (LT4).
Methods
Cross-sectional, case control study with 42 HT patients (mean age 47.1413.25) on long levothyroxine replacement and 22 euthyroid healthy controls, matched for age, sex and educational level, were included. HT patients were divided into 2 groups, 25 patients with normal vitamin D levels (nVD) and 22 patients with vitamin D deficiency (dVD). Measurement of TSH, FT4, anti-TPO, anti-Tg, Vitamin D was done. Evaluation of QoL was evaluated by QoL questionnaire - SF36. Fisher's ANOVA analysis was used to compare means between (sub)groups.
Results
HT patients had higher TSH levels in both groups (nVD vs dVD) vs control (3.702.88 vs 2.621.76 vs 1.851.18mIU/l, $P=0.021$) and higher anti-TPO (nVD: 2638.783065.84 vs 2458.832335.37 vs 64.50170.82mIU/l, $P=0.001$). Vitamin D levels were lower in both HT groups (nVD vs dVD) vs control (31.246.96 vs 16.835.12 vs 38,4015.92ng/ml, $P=0.000$). Patients in both nVD and dVD groups reported worse general health – Scale 4 compared vs control (68.2416.59 vs 58.4118.44 vs 73.3615.05, $P=0.014$), physical health – Dimension A (60.2718.46 vs 70.4018.53 vs 73.7317.08, $P=0.042$), mental health – Dimension B (59.2320.47 vs 67.1617.50 vs 73.8617.03, $P=0.036$) and Total SF35 score (60.8620.66 vs 69.7217.54 vs 74.8616.84, $P=0.044$).
Conclusion
Patients with HT and vitamin D deficiency had statistically significant worse quality of life compared to healthy control. Future studies with larger cohorts and in longer observation periods are needed to clarify role of vitamin D in quality of life in patients with Hashimoto thyroiditis.

Clinical presentation of sporadic and familial medullary thyroid carcinoma: is there a real difference?

Valeria Tascini[1], Alessandro Prete[1], Cristina Romei[1], Antonio Matrone[1], Carla Gambale[1], Valeria Bottici[1], Laura Agate[1], Eleonora Molinaro[1] & Rossella Elisei[1]
[1]Pisa, Endocrinology Unit, Pisa, Italy

Introduction
Medullary thyroid carcinoma (MTC) is a rare neoplasm that occurs sporadically in 75% (sMTC) and hereditarily in 25% (fMTC) of cases caused by germinal mutations of the *RET* gene as an autosomal dominant trait. fMTC occurs in the setting of three syndromes: fMTC alone without any other clinical manifestations; and multiple endocrine neoplasia type 2A (MEN2A) and 2B (MEN2B) syndromes. In fMTC, cases are distinguished into index cases (1st clinically detected case) and gene carriers (identified through *RET* screening). According to this screening, gene carriers have usually a more indolent clinical behavior than index cases. The aim of our study is to compare the clinical presentation of patients affected by sMTC with index cases of fMTC.
Methods
We conducted a retrospective observational study of 674 sMTC and 115 fMTC index case patients referred to the Endocrinology Department of University Hospital of Pisa from 1993 to 2023.
Results
Patients with fMTC were younger compared with patients with sMTC (median age 44 vs 55, $P<0.001$), with no difference in gender (males 39% vs 44%, $P=0.3$). The primary tumors of fMTC did not differ in size compared with sMTC (median 1.2 vs 1.4 cm, $P=0.3$). The prevalence of minimal extrathyroidal extension was higher in fMTC compared to sMTC (37.3% vs 19.1%, $P<0.001$). The prevalence of tumor with T stage $>$ 2 was significantly higher in fMTC compared with sMTC (21.6% vs 13%, $P=0.03$). Lymph node metastases were more frequent in patients with fMTC (59% vs 43%, $P=0.002$), predominantly in the central compartment (59% vs 39%, $P=0.005$). However, we did not observe any difference in prevalence of distant metastases (fMTC 11.8% vs sMTC 8.9%, $P=0.37$) and stage IV disease (fMTC 27.5% vs sMTC 28.9%, $P=0.82$) between the two groups.
Conclusions
The clinical presentation of patients with fMTC appears slightly worse than sMTC, although this difference seems not to be clinically significant considering the similar prevalence of distant metastases and stage IV disease. However, the clinical presentation is approximately 10 years earlier in fMTC compared to sMTC.

Primary hyperparathyroidism: the relationship between serum calcium levels and renal function before and after curative surgery

Aija Fridvalde[1,2] & Kristine Geldnere[3,4]
[4]Rīga Stradiņš University, Riga, Latvia, [2]Riga East Clinical University Hospital, Riga, Latvia, [3]University of Latvia, Riga, Latvia, [4]Pauls Stradins Clinical University Hospital, Riga, Latvia

Introduction
The aim of this study was to examine the relationship between serum calcium levels and renal function before and after curative parathyroidectomy (PTX) in patients with primary hyperparathyroidism (PHPT).
Objective and methods
A retrospective evaluation of 48 patient cases, corresponding ICD-10 code E21.0, was carried out, including demographic data and such biochemical markers as serum calcium, creatinine and estimated glomerular filtration rate (eGFR) levels, calculated using MDRD equation.
Results
From 48 participants included in the study 83,3% were female, while 16,7% were male patients. The mean age was that of 61,5 (min 29, max 81, SD 11,8); 14,6% of the patients were below the age of 50. At the time of diagnosis, 52,1% of the patients presented with mild hypercalcemia, 37,5%- moderate, while 6,3%- severe hypercalcemia, but the least- 4,2%- were normocalcemic. The mean calcium levels were those of 2,93 mmol/l (min 2,43, max 3,85, SD 0,31). Altogether 23,1% of the patients had reduced renal function, corresponding to recommended criteria for surgery, already at the time of diagnosis- 10,3% had eGFR that of stage 3a, 12,8%- stage 3b. Further data analysis, using Pearson correlation, revealed association between serum calcium levels and both creatinine and eGFR levels in firstly diagnosed patients – a moderate positive correlation between serum calcium and creatinine levels (r(37)=.597, $P<0,01$) and moderate negative correlation between calcium levels and eGFR (r(37)= -.559, $P<0,01$). Looking at dynamic changes, there was also found a moderate positive correlation between calcium levels in newly diagnosed patients and postoperative creatinine levels, measured at least 6 months up to one year after curative surgery (r(28)=.525, $P<0,01$). In addition, paired T test results showed statistically significant difference (t(25)= -3,6, $P<0,01$) when comparing creatinine levels as measured during the first (M=79,4, SD=28,4) and last (M= 87,2, SD= 32,4) patient assessment, i.e., before and at least six months after the surgery.
Conclusions
This study shows an association between serum calcium levels and such renal function biomarkers as creatinine and/or eGFR, both at the time of diagnosis and after curative surgery, suggesting higher serum calcium as a predictive factor for chronic kidney disease in patients with PHPT even after surgical intervention. While results of this study suggest that PTX didn't halt the deterioration of renal function in PHPT patients, taking in account the small sample size, we would recommend further long-term large-scale controlled studies in order to evaluate surgical effects on renal function.

Psychiatric comorbidities in chronic hypoparathyroidism – a german single-center analysis in 133 patients

Carmina Teresa Fuss[1], Franca Hermes[1], Karen Gronemeyer[1], Ann-Cathrin Koschker[1], Stefan Unterecker[2], Jürgen Deckert[2] & Stefanie Hahner[1]
[1]University Hospital Würzburg, Department of Medicine I, Division of Endocrinology and Diabetology, Würzburg, Germany, [2]University Hospital Würzburg, Department of Psychiatry, Psychosomatics and Psychotherapy, Würzburg, Germany

Introduction
Reduction of quality of life in patients with chronic hypoparathyroidism (HPT) has been reported by several studies. Additionally, self-report data point to a higher prevalence of anxiety disorders in HPT compared to patients after thyroidectomy.
Objectives
To characterize psychiatric diseases in a systematically reviewed cohort of patients with chronic HPT.
Methods
We systematically assessed psychiatric comorbidities in a well-characterized cohort of patients with chronic HPT ($n=133$) using standardized questionnaires (depression: Patient Health Questionnaire (PHQ9), Beck Depression Inventory (BDI2), anxiety: State-Trait Anxiety Inventory (STAI)) and further performed a diagnostic interview using the Mini-DIPS ($n=103$).
Results
Out of the 103 interviewed patients, 69% were female (mean age 5811 years). 92% presented with postoperative HPT. The STAI provides a screening tool to assess both state (X1) and trait (X2) anxiety separately. Scores range from 20-80 with higher scores being positively correlated with higher levels of anxiety. In the STAI X1 18% of patients scored between 40 and 50 and 18% of patients had a score above 50 (mean 4113). Regarding trait anxiety (STAI X2) 21% of patients had values between 40 and 50, whereas 20% scored above 50 points (mean 4012). In contrast, most patients with chronic HPT did not show markedly elevated scores in PHQ9 (81% with scores below 9), as well as BDI2 (71.4% with scores below 13). No significant correlations could be observed between serum calcium, serum phosphate, parathyroid hormone, TSH, 25-OH-Vitamin D levels, disease duration or age and scores of STAI X1, X2 and PHQ9, whereas STAI-X1 and –X2, PHQ9 and BDI-2-scores significantly correlated with HPT symptom severity (all $P<0.001$, Person's r X1: 0.389, X2: 0.321, PHQ9: 0.411, BDI2: 0.478). In the diagnostic interviews, anxiety disorder was found in 42% of patients (agoraphobia $n=18$, specific phobia $n=17$, panic syndrome $n=11$, generalized anxiety disorder $n=12$, social phobia $n=6$).
Conclusion
The performance of systematic screening as well as diagnostic interview for psychiatric disorders in HPT showed a high prevalence of anxiety disorders despite established treatment of HPT. However, the pathophysiology still remains unclear.

Background
Despite biochemical control of GH and IGF-I levels patients with acromegaly continue to have marked impairment of their well-being. The acromegalic arthropathy has been identified as a significant contributor to the impaired well-being of these individuals. We aimed to establish the true prevalence of arthropathy, distribution of joint involvement and use of analgesics for arthropathy in a large series of patients with acromegaly.
Methods
Patients with a diagnosis of acromegaly under follow-up in six tertiary pituitary centres were invited to complete a questionnaire relating to joint pain and distribution; management of their joint problems when present; and impact on function and QoL. We present data from the 'joint pain human figure' describing involved joints; 'joint pain scale'; and 'medication usage' questionnaires.
Results
411 patients completed the questionnaires, median age 60 (range 18-88) yrs, 56.1% female and mean age at diagnosis 43 (range 12-83) yrs. 338 (82.2%) patients reported joint, back or neck pain of >6 weeks duration within the preceding 3 months. The median number of joint sites affected was 4 (range 0-14), and median number of joints affected 5 (range 0–25). The most frequently involved individual joint was the knee ($n=225$; 57.1%), lower back (196; $n=49.7\%$), hip ($n=160$; 40.6%) and shoulder ($n=159$; 40.4%). The most painful joint was reported to occur most frequently within the large joints ($n=218$), compared with the axial skeleton ($n=133$) and small joints ($n=73$). Similar to the involved joints, the single 'most painful' individual joint was reported as the knee ($n=86$; 21.8%), lower back ($n=86$; 21.8%) or hip ($n=55$; 14.0%). On a scale of 0-10, severity of pain occurring during the preceding week was rated at a median of 4 (range 0-10). 52 patients had no pain (13.1%; score 0), 114 mild pain

(28.6%; score 1-3), 178 moderate pain (44.7%; score 4-7) and 54 severe pain (13.6%; score 8-10). 247 (61.4%) patients documented taking regular analgesics for joint pain. 173 used paracetamol, 110 oral non-steroidal anti-inflammatory drugs (NSAIDS), 64 topical NSAIDS, 65 codeine and 47 potent opioids or atypical analgesics (i.e amitriptyline, pregabalin). A single analgesic was used by 110 individuals; and two or more agents by 137. Most individuals taking two or more analgesics took a combination of paracetamol with an oral / topical NSAID.
Conclusion
Patients with a diagnosis of acromegaly have a significant arthropathy burden, frequently involving multiple joints and necessitating use of regular analgesics and anti-inflammatory agents.

Graves' orbitopathy: 40 years after diagnosis of graves' disease

Ons Maaoui[1], Sawsen Essayeh[1], Sabrine Mekni[1], Rihab Laamouri[1], Nadia Mchirgui[1], Karima Khiari[1], Imen Rojbi[1] & Ibtissem Ben Nacef[1]
[1]Charles Nicolle Hospital, Endocrinology

Introduction
Graves' orbitopathy (GO) is an autoimmune inflammation of the orbital tissues and it's the most frequent extrathyroidal complication of Graves' disease (GD). It typically develops concomitantly with GD, but, it can also precede it or occurs secondarily. We report the case of a patient who presented with GO 40 years after the diagnosis of GD.
Case report
A 74-year-old patient with history of arterial hypertension, type 2 diabetes, total thyroidectomy 40 years ago for GD, was hospitalized in our department for severe GO. The ophthalmological examination of the right eye showed visual acuity of 3/10 with conjunctival hyperemia, and the left eye showed exophthalmos with eyelid innoclusion, conjunctival hyperemia, limited ocular motricity, inferior corneal opacity and superficial punctate keratitis. An orbital MRI was performed, showing a dysthyroid orbitopathy with inflammatory thickening and fatty infiltration of the oculomotor muscles, responsible for bilateral grade 3 exophthalmos and no signs of optic neuritis. The patient was put on general measures and intravenous corticosteroid therapy. The clinical outcome was favorable with regression of inflammation's signs and improvement of visual acuity.
Conclusion
This case underlines the variable and often unpredictable nature of GO, and highlights the importance of vigilance for late-onset complications of GD and the need for ongoing monitoring even in patients with long-standing disease management.

Safety of continous subcutaneous insulin infusion therapy in adults with type 1 diabetes during hospitalization

Eduardo Torrecillas del Castillo[1], Ignacio Jiménez Varo[1], Mercedes Peinado Ruiz[1], Pablo Rodríguez de Vera[1], Isabel Serrano Olmedo[1] & María Asunción Martínez Brocca[1]
[1]hospital universitario virgen macarena, Sevilla, Spain

Aim
The use of continuous subcutaneous insulin infusion (CSII) systems in type 1 diabetic patients (DM1) is progressively increasing, leading to an increase in cases in which its maintenance during hospitalization is considered. The objective of the study is to analyze the safety of glycemic control with CSII therapy during hospitalization in DM1 adults.
Material and Methods
Retrospective observational study on a cohort of DM1 people hospitalized the last five years who maintained CSII therapy, at the Virgen Macarena University Hospital (Sevilla). We evaluated the differences in glycemic control between the hospitalization period, the month before and the month after hospitalization using the variables: "HbA1C" and percentages of glucometric ranges of the patient's "ambulatory glucose profile" (AGP). To avoid information bias, we performed a subanalysis according to type of CSII therapy and glycemic monitoring method.
Results
24 patients were analyzed: 62.5% women, average age 48.8 years. HbA1C 7.33%. Days of admission hospitalizated without CSII 11.68%. Most frequent reason for disconnection: surgery (7) and need for IV insulin infusion (3). Classification according to type of CSII and glucometry source: 640 + capillary controls (20.8%), 640 + integrated system (16.7%), 640 + flash glucose monitoring (45.8%), 670 (9.3 %) and 780 (8.3%). The overall analysis did not show serious complications associated with CSII treatment (severe hypoglycemia, diabetic ketoacidosis, severe isolated hyperglycemia). When subanalyzing the glucometric data in the subset of patients with interstitial glucose monitoring systems ($n=12$), limiting by the days of admission and the month before and the month after it, no significant differences were recorded in the AGP variables: <54 mg/dl: 1.29%, standard deviation (SD) 2.18 (during admission); 0.57%, SD 0.94 (previous); 1.04, SD 1.05 (later). $P=0.193$. 55-69 mg/dl: 3.44%, SD 3.75 (during admission); 2.02%, SD 2.56 (previous); 3.42%, SD 2.85 (later). $P=0.1$ 70-180 mg/dl: 55.94%, SD 16.35 (during admission); 57.90%, SD 20.34 (previous); 55.78%, SD 20.89 (later). $P=0.87$. 181-250 mg/dl: 32.79%, SD 13.40 (during admission); 30.09%, SD 15.07 (previous); 29.78%, SD 14.86 (later). $P=0.779$. >251 mg/dl: 6.53%, SD 8.44 (during admission); 9.41%, SD 9.94 (previous); 9.98%, SD 12.39 (later). $P=0.387$.
Conclusion
With adequate protocolization and supervision, maintaining CSII therapy during hospitalization is safe and allows glycemic control similar to the previous one.

Technological upgrade improves glycemic control and sleep quality in adults with type 1 diabetes

eleonora ciocca[1], federica carigi[1], francesco conti[1], chiara giuliani[1] & jonida haxhi[1]
[1]Sapienza University of Rome, Roma, Italy

Introduction
Type 1 diabetes results from autoimmune destruction of pancreatic beta cells and requires lifetime insulin treatment. Poor glycemic control may worsen sleep quality in people with diabetes and poor sleep quality may worsen glycemic control by increasing insulin resistance, which could further lead to an overall worsening of the quality of life in diabetes. Technology use in diabetes improves glycemic control and in pediatric populations, it has been shown to improve quality of life and sleep in patients and their caregivers.
Materials and methods
We investigated the changes in sleep quality (Pittsburgh Sleep Quality Index questionnaire) and wellbeing (WHO 5 item questionnaire) in 19 adult people with diabetes (age 4714 years, 79% women) who transitioned from a less advanced to a more advanced technology. Eleven patients transitioned form multiple daily injections (MDI) to automated insulin delivery (AID), three from sensor augmented pump (SAP) to AID and five from MDI to SAP.
Results
PSQI score improved significantly 3 months after the technological upgrade compared to baseline (5.22.8 vs 6.63.7, $P=0.04$), along with a significant improvement in time in range (TIR 73%11% vs 54%20%, $P=0.00064$), time above range (TAR250 6%6% vs 15%11%, $P=0.009$; TAR180-250 18%8% vs 30%15%, $P=0.001$) and HbA1c (7.1%1.1% vs 7.9%1.3%, $P=0.004$). No significant differences were observed in the wellbeing score, time below range (already low at baseline) body weight, blood pressure, renal function or lipid profile.
Conclusions
Technological upgrade results in better glycemic control (lower TAR and higher TIR) and better self-reported sleep quality in adults with T1D.

Calcaneal quantitative ultrasound as a screening tool in patients with acromegaly

Andrea Casabella[1], Claudia Campana[2], Federica Nista[2], Angelo Milioto[2], Diego Ferone[2], Sabrina Paolino[1,3] & Federico Gatto[4]
[1]IRCCS Ospedale Policlinico San Martino, Genova, Italy, [2]University of Genova, Endocrinology Unit, Department of Internal Medicine and Medical Specialties, School of Medical and Pharmaceutical Sciences, Genova, Italy, [3]University of Genova, Laboratory of Experimental Rheumatology and Academic Division of Clinical Rheumatology, Department of Internal Medicine and Specialties, Genova, Italy, [4]IRCCS Ospedale Policlinico San Martino, Endocrinology Unit, Genova, Italy

Introduction
Patients with acromegaly have an increased fracture risk, particularly vertebral fractures. Growth hormone (GH) excess, and the related increase of IGF-1 levels, have been shown to impair bone microarchitecture more than bone density. Therefore, the assessment of trabecular bone score (TBS) has been recommended beside standard dual-energy X-ray absorptiometry (DXA). The calcaneal quantitative ultrasound (QUS) is less expensive and more accessible compared to DXA, and has been studied in multiple setting as a screening tool for bone status. The aim of this study was to investigate the ability of calcaneal QUS to screen for bone impairment in patients with acromegaly.
Material and Methods
Bone Mineral Density (BMD, g/cm^2), lumbar spine T-score (L1-L4), total hip, femoral neck as well as relative skeletal muscle mass index (RSMI) in whole body composition were calculated using a DXA scan [Lunar full-Prodigy (GE Lunar, Madison, WI, USA). Trabecular bone score (TBS) [TBS Insight Medipas Group v 3.0] was derived for each spine DXA examination. Calcaneal QUS (Osteosys BeeTLe, Caresmed) was analyzed and the relative T-score calculated. Fracture Risk Assessment Tool (FRAX), both conventional and modified by TBS, was calculated for each patient. Patient clinical data, including disease control and bone turnover markers, were collected.
Results
Thirty-two patients with acromegaly (44% females), with mean age 5911 years, were included in the study. Median age-adjusted IGF-1 $\times$ upper limit of normality ($\times$ULN) was 0.84 (IQR 0.36-1.32), with the majority of patients (68.8%) having a controlled disease (IGF-1 $\leq$ 1$\times$ULN). QUS T-score showed a strong positive correlation with DXA T-scores at all sites (rho 0.608-0.795, $P<0.001$), and a moderate correlation with TBS (rho 0.356, $P=0.04$). The ROC curve analysis showed that the QUS T-score was able to predict the presence of osteopenia with high sensibility (AUC$=0.810$, $P<0.02$). Consistently, a negative correlation was observed between QUS T-score and the FRAX computed for both major osteoporotic fractures and hip fractures (rho$=$ - 0.664 and -0.662, respectively, $P<$ 0.001). Similarly, QUS T-score showed a negative correlation with the FRAX modified by TBS (rho$=$ -0.686 and -0.700, respectively, $P<$ 0.001). Interestingly, QUS T-score showed a positive correlation with RSMI (rho 0.421, $P=0.016$).
Conclusion
Calcaneal QUS could be a useful tool to screen patients with acromegaly for the presence of osteopenia and fracture risk, selecting patients for DXA evaluation. Moreover, low QUS T-score is also associated with an impairment of bone microarchitecture and the presence of sarcopenia.

The prevalence of joint replacement surgery in patients with acromegaly

Sophie Hebden[1], Megan Heague[1], Julie Lynch[2], Nawaz Z Safdar[2], David McLaren[2,3], Alberto Stefano Tresoldi[4,5,6], Kirstie Lithgow[4,5,6], Sandrine Urwyler[4,5,6], Chetna Varsani[7], Shahzad Akbar[8], Katie McLoughlin[9], Katarzyna Adeniji[9], Tara Kearney[9], Thozhukat Sathyapalan[8], Claire Higham[10], William Drake[7], Niki Karavitaki[4,5,6], Robert D Murray[2,3] & Nikolaos Kyriakakis[2]

Background
Patients with acromegaly experience early onset arthropathy characterised by initial joint space widening due to cartilage hyperplasia, with later degenerative changes characterised by joint space narrowing, sclerosis and osteophyte formation. To date no specific treatment is available for the arthropathy these patients experience, with management being limited to analgesics, anti-inflammatory agents, physiotherapy, joint injections, and potentially joint replacement surgery in the latter stages. We evaluated the prevalence of joint replacement surgery in a large population of patients with acromegaly.
Methods
Patients with a diagnosis of acromegaly under follow-up in six tertiary pituitary centres were invited to complete a questionnaire relating to joint pain and distribution; and impact on function and QoL. As part of the 'Medication Use' questionnaire, patients were asked to complete data relating joint replacement surgery.
Results
411 patients completed the questionnaires, median age 60 (range 18-88) yrs, 56.1% female and mean age at diagnosis 43 (range 12-83) yrs, with duration of disease 13 (IQR 5.9-20.9) years. Of the cohort 70 (17.4%) patients had undergone joint replacement, equating to a total of 130 episodes of joint replacement surgery. The median number of joints replaced was 2 (range 1–6). The most frequent joints replaced were the hip in 49 patients (70 joint replacements), knee in 30 (42 joint replacements), and shoulder in 9 (15 joint replacements). The median age at the time of joint replacement surgery was 59.0 (IQR 51.8-70.0) years. The median age in those with joint replacement at the time of questionnaire completion was 65.9 (IQR 56.4-73.0) years and 58 (IQR 47.9-68) years in those without joint replacement. Patients with joint replacements had a greater number of painful joints than those without joint replacements (5, IQR 3-7 Vs 3, IQR 1-6; $P=0.002$). There was no difference in the proportion of patients with active acromegaly between those who had and had not had joint replacement (38.8% Vs. 35.7%; $P=0.73$), however duration of disease was longer (17.0, IQR 8.2-24.3 Vs. 13.0, IQR 5.9-20.9; $P=0.024$) years. In addition to replacement joints, 70 patients had undergone other surgical joint interventions to the knees ($n=22$), spine ($n=16$), wrist ($n=12$), hallux ($n=9$), shoulder ($n=6$), elbow ($n=6$), ankle/foot ($n=4$) and hip ($n=3$).
Conclusions
Patients with a history of acromegaly have a significant risk of requiring joint surgery or replacement with correlates with higher number of joints affected, age and duration of disease.

Comparison of hydrocortisone and prednisolone in managing adrenal insufficiency– HYPER-AID study interim results from a tertiary care centre

Masato Ahsan[1,2], Amy Morrison[1,2], Natasha Fowkes[1,2], Shailesh Gohil[1,2], Miles J Levy[1,2], Karim Meeran[3] & Narendra Reddy[1,2]
[1]Leicester Royal Infirmary, Leicester, United Kingdom, [2]University of Leicester, United Kingdom, [3]Imperial College London, United Kingdom

Background
Adrenal insufficiency (AI) requires life-long glucocorticoid substitution therapy (1), and bears significant risks of infection, cardiovascular (CV) & metabolic disease burden. Historically Hydrocortisone (HC) has been the mainstay of treatment. Prednisolone is a once-daily alternative due to a longer half-life (up to 3.2 hrs). Currently, there is no discernible evidence supporting the superiority of either medication (2).
Objective
To explore the impact of HC and Prednisolone on bone health, cardiovascular risk, glycaemia, and overall well-being among AI patients.
Methods
The retrospective observational study was carried out in University Hospitals of Leicester as per the established protocol for 'Hydrocortisone versus Prednisolone for the Treatment of Adrenal Insufficiency Disease' (HYPER-AID Study), IRAS ID: 234243. AI patients receiving stable HC replacement for at least 4 months were enrolled. Baseline anthropometric data, CV risk, and metabolic biochemistry data were collected prior to swapping of HC to once-daily low-dose Prednisolone ($<$5 mg/day), with a follow-up visit scheduled after a minimum period of four months.
Results
Out of 25 patients initially enrolled, 17 completed the study. 10/17 were male, mean age: 60.7 yrs, mean weight: 82.89 15.6 kg, mean duration of follow-up: 13 months. HC dosage varied from 20 to 30 mg/day, which was replaced with 3 to 5 mg of Prednisolone. There was no significant change in BMI (28.47 to 28.24 kg/m2), mean waist circumference, from 101.7 cm to 100.2 cm and HbA1C from 5.98% to 5.94%. No significant alterations were noted in blood pressure, heart rate, full blood count, bone profile, lipid profiles, serum electrolytes, renal function, liver functions and hormonal profiles. No adrenal crisis episodes, fractures or side effects were reported whilst on Prednisolone and all 17 patients wished to continue on Prednisolone due to ease-of-use and general wellbeing reasons.
Conclusion
Prednisolone as a replacement therapy in AI patients appears to be a safe alternative to HC, given no significant changes noted in bone, metabolic and anthropometric markers following the swap. Patient preference for Prednisolone over HC is noted due to ease-of-use of once-daily administration. The interim analysis indicates non-

inferiority of Prednisolone compared to HC. However, additional research involving larger cohorts is necessary to validate these results.

DOI: 10.1530/endoabs.99.P595

Unravelling mitotane resistance in adrenocortical carcinoma: exploring alterations in lipid metabolism

Mariam Hassany[1,2], Kate Warde[2,3], Sarah Feely[2], Giulia Cantini[1], Arianna Propato[1], Luca Galtarossa[1], Michaela Luconi[1] & Michael Dennedy[2]

[1]University of Florence, Department of Experimental and Clinical Biomedical Sciences 'Mario Serio', Florence, Italy, [2]University of Galway, Discipline of Pharmacology and Therapeutics, Galway, Ireland, [3]Huntsman Cancer Institute, Salt Lake City, United States

Management of ACC is difficult. Diagnosis usually occurs at an advanced disease stage. Resection of localised disease offers a potential cure, but recurrence is common (75-85% of cases). For the treatment of unresectable/metastatic disease, mitotane is the only approved drug, alongside M-EDP chemotherapy. Mitotane has a narrow therapeutic window and is poorly tolerated. Additionally, ACC is a heterogenous disease regarding phenotype, genotype, disease progression and resistance to mitotane/chemotherapy. Better pre-clinical disease models are necessary to reflect ACC heterogeneity and offer insight into the mechanisms of treatment resistance. Investigating two ACC cell lines, mitotane sensitive H295R and mitotane-resistant MUC-1 demonstrated differing lipid droplet content whereby H295R cells predominantly store cholesteryl esters, while MUC-1 cells stored predominantly triacylglycerol, with an overall similar lipid droplet number in each cell line. Lipid storage may reflect the metabolic needs of each ACC cell line, thus we considered the metabolic and steroidogenic profiles of both cell lines. Seahorse XFe (Agilent) analysis demonstrated that MUC-1 cells rely significantly more on mitochondrial oxidative phosphorylation (OXPHOS) when compared to H295R: in MUC-1, OXPHOS contribution to the cell energy metabolism was 29,62 %, while in H295R 20,97 % ($P<0.01$). MUC-1 cells demonstrate significantly lower levels of androstenedione and cortisol when compared to H295R cells ($P<0.0001$). Additionally, MUC-1 cells express significantly lower levels of the steroidogenic enzyme, StaR, compared to H295R cells ($P<0.0001$) with no appreciable expression of CYP11B1 or CYP11B2 in MUC-1 cells, reflecting a difference in mitochondrial function between both cell lines. Overall, these results complement our previous findings in relation to TAG storage in MUC-1 cells and suggest that these cells use fatty acids derived from TAG lipolysis to fuel mitochondrial respiration through β-oxidation. Recent evidence shows that aggressive cancer cells can rely both on glycolysis and OXPHOS, and that the replenishment of the tricarboxylic acid cycle (TCA) intermediates can support many aspects tumor progression, including drug resistance. Therefore, we propose further investigation to better understand and overcome treatment-resistance in ACC.

Unexpectedly high levels of 25-hydroxycholecalciferol in a patient with waldenström macroglobulinemia

Claudia Arnas-Leon[1,2], Agnieszka Kuzior[2], Alba Hernandez-Lazaro[3], Ricardo Jose de Leon-Durango[1], Carlos Rios-Gomez[1], Borja Santana-Ojeda[1], Inmaculada Molinero-Marcos[1], Jennifer Maria Perez-Rivero[4], Cintia Rodriguez-Hernandez[5] & Francisco Javier Martinez Martin[1,2]

[1]University Hospital of Gran Canaria Dr. Negrín, Endocrinology & Nutrition, Las Palmas de Gran Canaria, Spain, [2]Clinica San Roque, Endocrinology & Nutrition, Las Palmas de Gran Canaria, Spain, [3]Parc Taulí University Hospital, Endocrinology & Nutrition, Sabadell, Spain, [4]Centro Salud Escaleritas, Family & Community Medicine, Las Palmas de Gran Canaria, Spain, [5]Health center Arucas, Family & Community Medicine, Arucas, Spain

Introduction and Objectives

Vitamin D deficiency is highly prevalent. Both physicians and the population are increasingly aware of this fact, and the demand for determinations of vitamin D has escalated. The vitamin D status of the patients is most commonly assessed by the measurement of 25-hydroxycholecalciferol using an automated immunoassay. However, immunoassays are prone to interferences by circulating immunoglobulins such as rheumatoid factor, or more rarely by paraproteins in patients with multiple myeloma or monoclonal gammopathy. We hereby present the novel case of a patient with Waldenström macroglobulinemia who presented artifactually high levels of 25-hydroxycholecalciferol in successive routine clinical measurements, in order to raise awareness of this potentially dangerous laboratory error.

Methods

Review of the patient's clinical records and of the relevant literature

Results

A 66-year-old had been diagnosed with Waldenström macroglobulinemia in 2013 and was treated with rituximab. He was referred to our Endocrinology Clinic in October 2023 because in all five routine measurements of 25-hydroxycholecalciferol performed by immunoassay since April 2021 up to October 2023 the result was >154.2 ng/mL (normal range 30.0 - 84.2 ng/mL) over the maximum measurable range and potentially toxic. The patient denied taking any supplement of vitamin D or multivitamins, had little solar exposure and did not consume cod liver. The measurements of calcium (over 20 determinations in a10-year follow-up), phosphate and intact PTH were repeatedly normal. The patient had no history of renal lithiasis, but an abdominal CT scan from 2018 showed cholelithiasis, which had caused no symptoms. There were no symptoms of hypercalcemia or vitamin D toxicity, consistently with the normocalcemia of the subject. The proteinogram showed a monoclonal paraprotein (IgM kappa light chain), 16.4 g/l. Rheumatoid factor was negative. We suspected paraprotein interference in the 25-hydroxycholecalciferol immunoassay and in November 2023 ordered a liquid chromatography- tandem mass spectrography (LC-MS/MS, reference method) yielding a result of 23.0 ng/mL of 25-hydroxycholecalciferol (low-normal) while our routine immunoassay again returned >154.2 ng/mL from the same venous sample.

Conclusion

The reference method confirmed an artifactual elevation of 25-hydroxycholecalciferol and discarded toxic levels, with the Waldenström paraprotein as the most likely culprit. While there are a few reports of similar interferences in patients with multiple myeloma or monoclonal gammopathy, or high levels of rheumatoid factor, this is a novel result in Waldenström macroglobulinemia. Physicians, especially endocrinologists, should be aware of this fact In order to avoid unnecessary diagnostic and therapeutic procedures.

Changing landscape of comorbidities in acromegaly: a single-center experience

Polat Ercan[1], Büşra Fırlatan[1], Suleyman Nahit Sendur[2], Seda Hanife Oguz[2], Selcuk Dagdelen[2] & Tomris Erbas[2]

[1]Hacettepe University School of Medicine, Department of Internal Medicine, Ankara, Turkey, [2]Hacettepe University School of Medicine, Division of Endocrinology and Metabolism, Ankara, Turkey

Purpose

Acromegalic patients carry a high burden of cardiovascular, metabolic, and neoplastic diseases, but there are limited studies focusing on morphological and functional changes in the kidneys.

Methods

The data of acromegalic patients followed over a 43-year period at our center were examined for the development of chronic kidney disease (CKD), renal cysts, and urological cancers.

Results

A total of 394 patients (202M/192F, mean age at diagnosis: 41.112.3 years, median duration of disease: 17-years) were included in the study. The median GH and IGF-1 levels at diagnosis were 12.1 ng/mL and 891.6 ng/mL, respectively. The majority (77.1%) of the patients had a pituitary macroadenoma, with a median diameter of 15 mm (range: 2-51 mm). At least one renal cyst was observed in 41% of the patients (size: 2-90 mm), with 47.4% located bilaterally. In the multiple regression model (MRM) analyzing the development of renal cysts, advanced age (OR:1.04, $P<0.001$), nephrolithiasis (OR:2.45, $P=0.018$), liver cyst (OR: 2.65, $P=0.008$), and multiple neoplasia (OR:1.91, $P=0.045$) were defined as independent risk factors. A 1 mEq/l increase in serum potassium level at diagnosis correlated with a 57.1% lower risk of renal cyst development (OR:0.429, $P=0.028$). CKD and nephrolithiasis were detected in 16.1% and 15.1% of the patients, respectively. Advanced age (OR:1.052, $P=0.005$), male gender (OR:3.575, $P<0.001$), and hypertension (OR:2.786, $P=0.007$) were determined as independent risk factors for CKD. In patients with and without CKD or renal cysts, levels of GH and IGF-1 at baseline, during follow-up, and at the last visit were comparable. Among the 65 (16.5%) acromegalic patients followed with a cancer diagnosis, urological cancers were detected in 8 cases (7M/1F). Following thyroid cancer urological cancers were the second most common in our series, including 3 renal cell carcinomas (RCC), 2 ureteral cancers, 2 bladder cancers, and 1 renal PEComa. The median age of patients with

urological cancers was 68 (42-77) years, and the duration of acromegaly was 22.5 (10-37) years. In all three cases with RCC, there were also second primaries including papillary thyroid cancer, pancreatic cancer, and rectal cancer.
Conclusion
Our findings suggest that renal cysts are more prevalent in acromegalic patients compared to the general population, possibly indicating tubular dysfunction and morphological changes in the kidneys associated with chronic exposure to high levels of GH and IGF-1. The occurrence of urological cancers as the second most frequent type of cancer highlights the need for surveillance of acromegalic patients in this regard.

Differentiation of intra-tumoral necrosis between clusters 1 and 2 pheochromocytoma

Lise Ronger[1], Rachel Desailloud[1], Saint Fabien[2], Renard Cedric[3] & Abdallah Al-Salameh[1]
[1]Chu Amiens-Picardie, Endocrinology, Amiens, France, [2]Chu Amiens-Picardie, Urology, Amiens, France, [3]Chu Amiens-Picardie, Radiology, Amiens, France

Introduction
Pheochromocytoma is a catecholamine-secreting neuroendocrine tumor arising from the chromaffin cells of the adrenal medulla. It is rare and considered benign, but can be life-threatening in the event of catecholaminergic discharge. Tumors differ in genotype, mechanism of tumorigenesis and type of secretion. On imaging, it is often characterized by central intra-tumor necrosis; there is very little data in the literature on the genesis and pathophysiological role of the latter. As a result, necrosis is never measured at the time of diagnosis. In this study, we therefore wanted to investigate potential correlations between the extent of intra-tumor necrosis and the various hormonal secretions in pheochromocytomas.
Methods
We retrospectively identified all major patients operated on at Amiens University Hospital between 2005 and 2022 for adrenal pheochromocytoma confirmed by pathological examination and for whom diagnostic imaging (CT or MRI) and hormone assays were found in the database. The volume of intra-tumor necrosis was measured manually by a specialist radiologist at Amiens University Hospital.
Results
The analysis of this study is based on a total of 49 patients included between 2005 and 2022, 25 of whom were allocated to the group with necrosis and 24 to the group without necrosis after radiological assessment of intra-tumour necrosis. The mean age at the time of adrenalectomy was 53.4 15.2 years. MRI was preferred for the study of intra-tumour necrosis when it had been performed (9 patients). After multivariate analysis, there was a significant difference between the two subgroups in terms of tumour volume, female sex and intensity of urinary metanephrine secretion.
Conclusion
At present, our study appears to the only one to examine the clinico-biological impact of intra-tumoral necrosis in pheochromocytomas. Significant factors have emerged which may guide clinical practice, particularly with regard to the role of MRI in the choice of diagnostic imaging.

Key-words: Pheochromocytoma, intra-tumour necrosis, metanephrines, clusters 1 and 2.

Changes in lipid profile in patients with type 2 diabetes labeled as metformin-intolerant rechallenged with extended release metformin

Alba Hernandez-Lazaro[1], Ricardo de Leon-Durango[2], Borja Santana-Ojeda[2], Inmaculada Molinero-Marcos[2], Agnieszka Kuzior[3], Claudia Arnas-Leon[2,3], Jennifer Maria Perez-Rivero[4], Esperanza Perdomo-Herrera[5], Alba Lucia Tocino-Hernandez[6] & Francisco Javier Martinez Martin[2,3]
[1]Parc Tauli University Hospital, Endocrinology & Nutrition, Sabadell, Spain, [2]University Hospital of Gran Canaria Dr. Negrín, Endocrinology & Nutrition, Las Palmas de Gran Canaria, Spain, [3]Clinica San Roque, Endocrinology & Nutrition, Las Palmas de Gran Canaria, Spain, [4]Centro Salud Escaleritas, Family & Community Medicine, Las Palmas de Gran Canaria, Spain, [5]Centro de Salud de Playa Blanca, Family & Community Medicine, Playa Blanca, Spain, [6]Centro de Salud Los Gladiolos, Family & Community Medicine, Santa Cruz de Tenerife, Spain

Introduction and Objectives
Since 2005, the NICE guidelines on T2DM recommend extended-release metformin (XRM) in patients with gastrointestinal disturbances induced by conventional metformin, as the tolerance of XRM is clearly superior, improving patient compliance, satisfaction and outcomes. In Spain XRM is recently available, but only in a fixed combination with sitagliptin. As yet, data on the efficacy, tolerability and impact on lipid profile of this combination are not available. We undertook to study if treatment with XRM/sitagliptin can improve the lipid profile in patients with T2DM previously labeled as metformin-intolerant and treated with a DPP4 inhibitor (DPP4i)
Patients and Methods
Consecutive patients with T2DM, HbA1c >7% and GFR (CKD-EPI) >45 mL/min/1.73m^2 labelled as metformin-intolerant due to gastrointestinal symptoms, and treated with a DPP4i (with or without additional antidiabetic medication) were switched to the 50 mg sitagliptin plus 1000 mg XRM combination, taking 1 pill daily in the first month and afterwards 2 pills if the tolerance was good. Additional antidiabetic medication, if any, was unchanged; however, the patients received lifestyle advice, and antihypertensive and cholesterol-lowering medications were adjusted according to current ESC-ESH-EAS recommendations. Tolerability data were obtained by questionnaire in the follow-up visit. Data are given as meansd. The calculations were done by intention-to-treat. Comparisons were made by the paired t-test. All Included patients granted informed consent.
Results
Changes in lipid profile were studied in 70 patients (45 women, age 548 years, with 7.83.0 years since the diagnosis of T2DM), of which 51 (73%) tolerated 2 tablets of XRM/sitagliptin (1000/50 mg); 8 (11%) tolerated 1 tablet and 11 (16%) did not tolerate any. The reductions in fasting plasma glucose were 36 mg/dl with 1 pill and 44 mg/dl with 2 pills, and in HbA1c were 0.6% with 1 pill and 0.9% with 2 pills (all $P<0.01$). After 3-4 months of treatment, total cholesterol was reduced from 21733 to 19731 mg/dl ($P<0.001$); triglycerides from 19048 to 15846 mg/dl ($P<0.01$); LDL-cholesterol from 13029 to 10826 mg/dl ($P<0.001$), and HDL-cholesterol rose from 50 15 to 57 16 mg/dl ($P<0.01$).
Conclusion
A large majority of the patients with T2DM labelled as metformin-intolerant did tolerate XRM/sitagliptin, and their lipid profile significantly improved. The study intervention only added XRM as an antidiabetic drug, but in many of the patients there were additional interventions in lifestyle, antihypertensive and cholesterol-lowering drugs. Therefore, the changes in the lipid profile must be considered as multifactorial.

Different clinical presentations of cases with 11-beta-hydroxylase (11β-OHD) deficiency

Ons Maaoui[1], Sabrine Mekni[1], Rihab Laamouri[1], Sawsen Essayeh[1], Nadia Mchirgui[1], Karima Khiari[1], Imen Rojbi[1] & Ibtissem Ben Nacef[1]
[1]Charles Nicolle Hospital, Endocrinology, Tunisia

Introduction
Congenital adrenal hyperplasia (CAH) due to 11-beta-hydroxylase (11β-OHD) deficiency is, in order of frequency, the second most common form after 21 hydroxylase deficiency. We report the cases of patients with 11β-OHD followed in our department.
Patient 1
The patient was referred to our department at the age of 13. The history of the disease dates back to the age of 3, when the child presented pubic and axillary hair and a large penis. Examination revealed a 5-cm penis and empty bursae. The child also presented with hypertension and hypokalemia. Pelvic ultrasound revealed female internal genitalia and the karyotype was 46XX. The genetic study confirmed the diagnosis. The child was raised as a boy. At the age of puberty, he underwent two surgical procedures, one for bilateral breast hypertrophy and the second to correct a communication between the vagina and urethra. Genetic investigation revealed two healthy homozygous sisters and one heterozygous sister for the p.G379V mutation of CYP11B1.
Patient 2
Patient aged 16 years (karyotype 46, XY) was diagnosed with 11β-OHD at the age of 2. The patient had a staturoponderal and pubertal advance at the onset. His clinical presentation was characterized by resistant and unstable hypertension. He was hospitalized thrice for hypertensive emergencies. Due to his hypertension, he developed dilated hypokinetic cardiomyopathy, grade 3 hypertensive retinopathy, and hypertensive nephropathy.
Patient 3
The patient was referred to our department at the age of 16 years. She came from a consanguineous marriage, followed for an 11 B-OHD since the age of 17 months with a 46-XX karyotype. The diagnosis was established during the exploration of sexual ambiguity with genitography showing a 20 mm long vaginal cavity ending in the vertical portion of the urethra which was of the male type with major

hypospadia. Pelvic ultrasound revealed female internal genitalia. The patient underwent clitoral anastomosis resection and vaginoplasty. At the age of 5, hypertension was diagnosed and at the age of 14, she developed hirsutism with elevated testosterone level of 3.66 ng/ml despite treatment with hydrocortisone. Moderate adrenal hyperplasia was diagnosed on CT scan, leading to left adrenalectomy. Histological findings confirmed diffuse nodular hyperplasia. The postoperative testosterone control was 1.16 ng/ml.
Conclusion
We presented patients diagnosed with classic 11β-OHD with different clinical presentations. This particular disorder is relatively understudied. Our results highlight the need for further research to improve our understanding of the relationship between specific genetic features, clinical presentation and long-term course of this disorder.

A rare case of concurrent pituitary adenoma with granulomata

Yashaswini Choudhary[1], Adhithya Sankar[1], Federico Roncaroli[1,1] & Waseem Majeed[2]
[1]Salford Royal, United Kingdom, [2]Salford Royal, Salford, United Kingdom

Case presentation
A 60-year-old gentleman presented with altered vison. Past medical history included ulcerative colitis, henoch-schonlein purpura (HSP) and Graves' disease. Family history included a brother that underwent surgery for a pituitary macroadenoma. Pituitary MRI identified a 27 × 16 × 20 mm macroadenoma with chiasmal compression. Perimetry demonstrated bitemporal hemianopia. Clinical assessment showed no stigmata of endocrinopathy. Pituitary function tests were normal apart from hypogonadotrophic hypogonadism and testosterone replacement was initiated. The patient underwent trans-sphenoidal surgery. Post-operative pituitary MRI showed near total resection with minimal residuum and the patient remains well with stable pituitary function. Surprisingly, histology revealed a densely granulated (silent) corticotroph pituitary neuroendocrine tumour containing giant cell non-necrotising granulomas. Additional stains for associated infective organisms were negative. Histological samples did not contain normal pituitary tissue and therefore a diagnosis of granulomatous hypophysitis (GRH) could not be confirmed. Investigations for vasculitis, connective tissue diseases, sarcoidosis and IgG4 disease were negative and a whole-body CT ruled out systemic inflammation. Dual pathology within a pituitary is extremely rare and has only been reported in a few case reports and series. Interestingly, typical clinical and radiological features associated with hypophysitis were absent in this patient. In this patient, a background of inflammatory and autoimmune disorders raised the possibility of a systemic inflammatory disorder. Indeed, GRH in patients with Crohn's disease has previously been described. Interestingly, Force *et al*., report that hypophysitis remission was achieved with anti-TNF-α therapy, suggesting a shared underlying pathophysiological mechanism (1). However, ulcerative colitis is typically diagnosed in the absence of granuloma, therefore a shared inflammatory mechanism may be less likely in our case. It is also postulated that GRH may be triggered by autoantibodies against non-secretory pituitary proteins, leading to local immunological mechanisms within pituitary adenomas may drive granulomata formation, independent of systemic signals (2). This rare presentation of dual pathologies highlights the difficult nature of diagnosis and investigation of pituitary lesions. Attention is needed to identify such cases as separate treatments may be required. In this patient, we hypothesise that secondary granuloma may have developed in relation to local intra-adenoma mechanisms, with an alternative hypothesis of systemic inflammation related to inflammatory bowel disease

Corticosterone induces adiposity and insulin resistance in a dose dependent manner in a murine model of adrenal insufficiency

Mhairi Paul[1], Boglarka Nagy[1], Natalie Z.M. Homer[1], Robert Semple[1], Roland Stimson[1] & Mark Nixon[1]
[1]Centre for Cardiovascular Science, University of Edinburgh, Edinburgh, United Kingdom

Adrenal insufficiency, characterised by inadequate cortisol production, significantly impacts quality of life and overall health. Current treatment primarily involves hydrocortisone replacement. However, dosing challenges and risk of adverse cardiovascular complications persist with this therapy. Consequently, there is a pressing need for safer glucocorticoid replacement options to mitigate the cardiometabolic toxicity, while effectively managing adrenal insufficiency. Preliminary evidence suggests another endogenous glucocorticoid, corticosterone, does not induce the same metabolic effects in adipose tissue as cortisol, and so may be a viable option as a safer, alternative replacement therapy. While animal models of glucocorticoid excess suggest high-dose corticosterone induces cardiometabolic dysregulation, its effect at lower doses, especially in adrenal insufficiency, remains unclear. Therefore, the aim of this study was to investigate the dose-dependent effects of corticosterone in a mouse model of adrenal insufficiency. Adult male C57Bl/6J mice (8 weeks old) were adrenalectomised and administered corticosterone in drinking water (25, 50, or 100 μg/mL) or vehicle (1% v/v ethanol) for 4 weeks ($n=7$-10 per group). Energy expenditure was assessed by indirect calorimetry using the Promethion Core (Sable Systems) after 3 weeks. Body composition was measured by TD-NMR (Bruker MiniSpec) between 3-4 weeks of treatment. At week 4, insulin sensitivity was assessed by an insulin tolerance test. Mice were fasted for 6 hours (0800-1400) before insulin bolus (0.75U/kg; IP) and quantification of glucose levels over 2h. Fasting blood was used to quantify insulin levels (ELISA, Millipore). Mice were culled by decapitation, and blood and tissues harvested for downstream analysis. Circulating and tissue corticosterone levels were quantified by liquid chromatography- tandem mass spectrometry. While corticosterone did not induce changes in body weight, body composition was significantly altered, with corticosterone increasing fat-mass and decreasing lean-mass in a dose-dependent manner. This increase in adiposity occurred independently of changes in energy expenditure, food intake, or physical activity. Corticosterone impaired insulin tolerance in a dose-dependent manner, in parallel with reducing the glucose disposal rate (K_{ITT}). Moreover, corticosterone dose-dependently increased fasting insulin levels, and increased the HOMA-IR index of insulin resistance. Circulating and adipose corticosterone levels were only significantly increased with the highest dose (100μg/ml vs Vehicle). However, Pearson correlation analysis identified significant correlation between adipose corticosterone and indices of metabolic regulation. This study demonstrates that even relatively low-dose corticosterone can induce metabolic dysfunction in adrenal insufficiency. Further work is needed to determine the relative 'risk' by comparing corticosterone and cortisol, and to identify the underlying mechanisms behind potential differences.

Evaluation of the quality of life in moroccan patients diagnosed with hypoparathyroidism

Essafi Mohammed Amine[1], Handa Samira[1], Aynaou Hayat[1] & Salhi Houda[1]
[1]Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition. Hassan II University Hospital Center, Fez, Morocco

Background and aims
Hypoparathyroidism (HPt) is a rare endocrine disorder often of post-surgical origin, resulting in hypocalcaemia. Several complications have been described including impairment of quality of life (QoL). Our study aims to evaluate the effect of hypoparathyroidism on the Qol of patients diagnosed with HPt.
Methods
A cross-sectional study was conducted in the Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition of the Hassan II University Hospital of Fez. We included in our study all patients followed for chronic HPt. Well-being was assessed using the WHO 5 index, and QoL was assessed by the SF-36 questionnaire in its validated Arabic version. Data were entered into Excel and analysed using SPSS 26. Multiple linear regression was utilized to ascertain the variables linked to the QoL in individuals diagnosed with HPt.
Results
A total of 143 patients with HPt were included in the study, 86.7% of whom were female. The mean age of the patients was 44.6 17.3 years. 89.9% were of post-surgical origin. The assessment of well-being by the WHO 5 index showed a low score (<50), meaning poor well-being in 44.8%. Regarding the QoL, the assessment showed low scores in the areas of general health (41.7), limitations due to physical condition (40.5), vitality (41.4) and limitations due to psychological condition (42.6). The multiple linear regression model revealed a noteworthy association between low SF36 score and advanced age ($\beta = -5.91$ $P<0.001$), surgical origin ($\beta = 8.71$ $P<0.001$), low education level ($\beta = -10.1$ $P<0.001$), and poor compliance with medication ($\beta = -11.3$ $P<0.001$). However, the relationship between impaired QoL and achievement of normocalcemia was non-significant ($P=0.69$)

Conclusion
Our work objective that patients with HPt have a reduced and multifactorial QoL. Despite normocalcaemia. It is hypothesized that parathyroid hormone directly influences QOL. These results could serve as a basis for future research.

Title: investigating molecular mimicry between SARS-CoV-2 antigens and pancreatic islet antigens in type 1 diabetes pathogenesis using near-sequence similarity

Emmanuel Beltazar[1], Edoardo Beltazar[1], Owais Siddique[2], Tayyibah Patel[2], Honey Panchal[1] & Pravenaa Sivakumar[1]
[1]University College London, UCL Division of Medicine, United Kingdom, [2]University College London, United Kingdom

Background
Type 1 diabetes mellitus (T1DM) involves the autoimmune destruction of pancreatic islet beta cells, with recent research implicating a role for viral infections in its onset. The rise in T1D cases during the COVID-19 pandemic has sparked investigations into potential causes. Molecular mimicry between SARS-CoV-2 antigens and pancreatic islet antigens has been suggested as a plausible mechanism, yet no attempts have been made to explore this phenomenon as comparing functional protein structure remains challenging. To address this, we used pcDelta, a near-coincidence statistic originally developed for evaluating T-cell receptor (TCR) clonotype skewing following antigen exposure. Through the application of pcDelta to two sets of TCR sequences, we quantified near-sequence similarity, with higher pcDelta values indicating greater sequence similarity. The presence of similar TCR sequences suggests similar target antigens and is thus a surrogate for the degree of molecular mimicry.
Methods
CDR3 sequences of the beta chain of TCR specific to various viral antigens were sourced from the VDJ database, a meticulously curated repository of TCR sequences with annotated antigen specificities. Concurrently, islet antigen-specific CDR3 were extracted from a comprehensive review consolidating TCR clonotypes isolated from individuals diagnosed with T1D, cross-validated across multiple studies. Using pcDelta, we quantified near-sequence similarity at the amino acid level between TCR specific to islet pancreatic antigens and viral antigens. To account for different number of epitope-specific TCRs, subsampling was performed and a pcDelta value calculated for each sample.
Results
The analysis of TCR specific to Islet antigens and SARS-CoV-2 revealed a pcDelta value of (4.1310^-5), significantly exceeding the pcDelta values observed between Islet TCRs and influenza A (2.4210^-5) and HIV-1 (2.19*10^-5). This indicates a higher degree of near-sequence similarity between pancreatic islet and SARS-CoV-2 TCRs compared to other viral antigens (P-value <0.001).
Conclusion
The significant elevation in pcDelta values between SARS-CoV-2 and islet antigens TCR compared to other viral antigens indicates increased near sequence similarity between the two TCR groups. This suggests the TCRs might be targeting antigens that might be structurally similar, implying molecular mimicry between SARS-CoV-2 and islet antigens. However, the reliance on existing data sources for TCR sequences may introduce biases or incomplete representation of the T1D landscape. In addition, the study simplifies TCR binding dynamics, although the assumption has been widely used in the literature. Future investigations could employ structural modelling or functional assays to elucidate the impact of molecular mimicry in T1D and consolidate the validity of the approach.

Vitamin D status and steatohepatitis in obese diabetic and non-diabetic patients

Laura Taban (Cotoi)[1], Stoian Dana[2], Timar Bogdan[2], daniela-georgiana amzar[2], Borlea Andreea[2], Calin Adela[2], Motofelea Alexandru[2] & Laguerre Nadege[3]
[1]Centre Hospitalier de Luxembourg, Luxembourg, Luxembourg, [2]Victor Babeş University of Medicine and Pharmacy, Timişoara, Romania, [3]Metz-Thionville Hospital Mercy, Ars-Laquenexy, France

Background and Aims
The presence of steatohepatitis in obese patients can be multifactorial. The current study tries to determine the differences between diabetic and non-diabetic patients regarding the presence of steatohepatitis. We evaluated sequential liver samples and collected the times of bariatric surgery to assess the presence of NASH in patients with obesity, in the circuit of bariatric surgery.
Methods
We performed a retrospective study of 49 patients presenting high-grade obesity in the circuit of bariatric surgery, with liver biopsy. The patients underwent bariatric surgery at a single center in France and were followed for 2 years. The liver biopsies were performed intraoperatively on all 49 patients before the bariatric surgery. The primary endpoint of the study was to evaluate the relationships between steatohepatitis/liver fibrosis and the presence of diabetes and to evaluate the current relationships between the biochemical work-ups. Special importance was accorded to the correlations between vitamin D levels and the presence of hepatic steatosis, due to the antifibrogenic pattern in the liver, as shown in many important papers in the field.
Results
Significant correlations were found between the presence of liver fibrosis and the presence of diabetes ($P=0.022$), but not regarding the antidiabetic treatment. An important correlation was found between the vitamin D levels and the presence of liver fibrosis, as well as with the levels of A1C hemoglobin and LDL cholesterol levels.
Conclusion
Vitamin D deficiency presents a strong correlation with hepatic steatosis in individuals with morbid obesity. Correcting vitamin D deficiency may present a beneficial role in treating hepatic steatosis, diabetes, and cardiovascular risk in patients with morbid obesity.

Medical gender detransition is mainly associated with psychological factors

Mariana Gomes Porras[1], Mónica Tomé García[1], María Cruz Almaraz Almaraz[1], Guadalupe Cano Oncala[2] & Isabel Esteva de Antonio[1]
[1]Regional University Hospital of Málaga, Endocrinology and Nutrition, Málaga, Spain, [2]Regional University Hospital of Málaga, Psychology, Málaga, Spain

Background
Medical gender transition is a personal and complex process that can have irreversible health consequences. Detransition is the process of stopping and/or reversing partially or totally and temporarily or permanently the social, legal and/or medical changes achieved during gender transition. The current prevalence of detransition is unknown, most likely underestimated.
Aim
To determine the prevalence and describe the sociodemographic and health characteristics and factors associated with medical detransition in persons over 14 years of age with Gender Incongruence under follow-up in the Transsexual Care Unit (TCU) of a Spanish reference hospital from 1999 to February 7, 2024.
Material and methods
Cross-sectional descriptive study that included 18 transsexual people who stopped cross-sex hormone therapy (CHT). Data were obtained by review of medical records and semi-structured telephone interviews directed to those with loss to follow-up. Qualitative data were expressed as absolute value and percentage and quantitative data as range (minimum-maximum).
Results
The prevalence of medical gender detransition was 0.75% (18/2396). 14 cases (77.7%) started follow-up in the TCU in the last 6 years (2018-2024). Detransition occurred after 1-300 months from the start of medical gender transition. 11 cases (61.1%) were partial detransitions (maintained the legal and social changes) while 7 (41.2%) were total. All partial detransitions were secondary or without identity desistance while total detransitions were primary or with identity desistance. To date, 88.8% have maintained the decision to detransition, so they were considered permanent. 50% were transsexual men with onset of the identity feeling at 4-30 years of age and first visit to the TCU at 14-43 years of age. 72.2% without family support and 100% had previous psychomorbidity. 3 cases had sex reassignment surgery (SRS). 3 and 2 cases required hormone replacement therapy and non-genital reversal surgery, respectively. The psychological factor was present in 13 cases (predominantly non-binary gender identity followed by satisfaction with the changes already achieved) followed by medical (7 cases), cultural (3 cases) and social (3 cases) factors.
*c*Conclusions
Detransition is a complex process that requires assessment in specialized multidiscipslinary teams. In our series, all the detransitions presented previous psychomorbidity and 76.5% associated psychological factors. We recommend prioritizing psychosocial and identity assessment before beginning the medical transition. There is a need for health guidelines on gender detransition.

Implication of serotonin in the physiopathology of aldosterone-producing adenoma

Celine Duparc[1], Margot D'Agostino[1], Antoine-Guy Lopez[2], Sylvie Renouf[1], Gilles Manceau[3], Tchao Meatchi[4], Laurence Amar[5], Estelle Louiset[1] & Hervé Lefebvre[2]
[1]Univ Rouen Normandie, Inserm, Normandie Univ, NorDic UMR 1239, Rouen, France; [2]Univ Rouen Normandie, Inserm, Normandie Univ, NorDic UMR 1239, CHU Rouen, Department of Endocrinology, Diabetes and Metabolic Diseases, ROUEN, France; [3]Department of digestive Surgery, Assistance Publique Hôpitaux de Paris, Georges Pompidou University Hospital, University Paris Cité, PARIS, France; [4]Service d'anatomie pathologique, Assistance Publique-Hôpitaux de Paris (AP-HP) Centre, Georges Pompidou University Hospital, University Paris Cité; [5]Université Paris Cité, Inserm, PARCC, Equipe Labellisée par la Ligue contre le Cancer, PARIS, France

In the human adrenal gland, serotonin (5-HT), released by subcapsular mast cells strongly stimulates aldosterone production via activation of the type 4 serotonin receptor (5-HT4R). Consistently, plasma aldosterone levels increase after administration of 5-HT4R agonists like cisapride to healthy volunteers. Previous studies performed in aldosterone producing adenomas (APA) have shown an increase in mast cells density and an overexpression of *HTR4* gene, encoding 5-HT4R, in APA tissues in comparison to normal adrenal. Moreover, administration of cisapride to patients with APA induced an exaggerated plasma aldosterone response. These results suggested that 5-HT could play a role in the pathophysiology of APA. The aim of our study was to examine expression of genes and proteins involved in aldosterone production and actors of the serotonergic pathway in a series of adenomas removed from patients with primary aldosteronism. We have also investigated the *in vitro* effect of various 5-HT4R ligands on aldosterone production by tissue explants or cultured cells derived from adenoma tissues obtained at surgery. Among the 72 tissues studied, 65% were identified as classical APAs, according to classification of the new international histopathology consensus for unilateral Primary aldosteronism. The presence of 5-HT was detected by immunohistochemistry in 75% of the classical adenomas. 5-HT was principally detected in adenoma tissues, in mast cells but also in steroidogenic cells. 5-HT4R immunostaining was widely distributed in most APA tissues, a pattern which was not exclusively noticed in AS-positive adenomas. Expression of the gene encoding the 5-HT-synthesizing enzyme tryptophan hydroxylase was similar in APA and normal adrenals. *HTR4* overexpression was more pronounced in classical than non-classical APAs and *HTR4* mRNA levels were positively correlated to those of *CYP11B2* mRNA encoding AS. Administration of 5-HT to normal adrenocortical or APA cells in culture stimulated *CYP11B2* gene expression and aldosterone production. In addition, in cultured APA cells, BIMU-8 and prucalopride, two 5-HT4R agonists, stimulated aldosterone synthesis in a dose-dependent manner with a higher efficiency than that observed in normal adrenocortical cells. Moreover, BIMU-8, strongly increased aldosterone production by perifused APA explants, an effect which was blocked by administration of GR-113808, a 5-HT4R antagonist. Administration of 48/80 compound, a mast cell degranulator, to perifused APA explants induced a 5-HT release immediately followed by an increase in aldosterone levels. These data indicate that the 5-HT signalling pathway, which is enhanced in APAs, exerts an autocrine/paracrine stimulatory action on aldosterone synthesis and may thus participate in the pathophysiology of primary aldosteronism.

Gender-affirming hormone therapy and its impact on myocardial mass and cardiac function: a prospective magnetic resonance study on transgender men and women

Carola Deischinger[1], Dorota Slukova[1], Jürgen Harreiter[1], Stephan Nopp[2], Ivica Just[3], Martin Krssak[3], Siegfried Trattnig[3], Lana Kosi-Trebotic[1], Ulrike Kaufmann[4] & Alexandra Kautzky-Willer[1]
[1]Medical University of Vienna, Endocrinology and Metabolism, Vienna, Austria; [2]Medical University of Vienna, Hematology and Hemostaseology, Vienna, Austria; [3]Medical University of Vienna, High field MR Centre of Excellence, Department of Biomedical Imaging and Image guided Therapy, Vienna, Austria; [4]Medical University of Vienna, Department of Obstetrics and Gynaecology, Vienna, Austria

Background
The differences in cardiac parameters such as myocardial mass, left ventricular ejection fraction (LVEF), cardiac output, and brain natriuretic peptide (NT-proBNP) levels between cisgender men and women are well-established. However, no evidence exists regarding changes in myocardial mass or cardiac function parameters in transgender individuals undergoing gender-affirming hormone therapy (GAHT).
Patients and method
A prospective study enrolling 20 transgender men (TM) and 15 transgender women (TW) was conducted at the Medical University of Vienna from 2019 to 2022. A 3-Tesla electrocardiogram-gated magnetic resonance imaging was used to measure myocardial mass, LVEF and other cardiac function parameters before GAHT and at six-month follow-up. Myocardial lipid content was quantified using magnetic resonance spectroscopy.
Results
In TM, myocardial mass increased significantly after six months of GAHT from in mean ($\pm$SD) 48 ($\pm$8) g/m^2; at baseline to 54 ($\pm$7) g/m^2; at follow-up ($P=0.011$). TW showed a non-significant decrease of 4 ($\pm$14) g/m^2; in myocardial mass. In both groups, no significant changes were noted in LVEF, stroke volume, cardiac output, or peak filling rate. Neither testosterone (TM: $r=$-0.127, $P=0.679$; TW: $r=$-0.127, $P=0.679$) nor estrogen levels (TM: $r=$-0.154, $P=0.616$; TW: $r=$-0.154, $P=0.616$) were related to myocardial mass at follow-up in either group. However, testosterone levels in TM correlated with cardiac output index ($r=0.396$, $P=0.019$), and in TW, with myocardial lipid content ($r=0.579$, $P=0.007$). Notably, NT-proBNP levels in TM were significantly reduced at follow-up (from in median (IQR) 41 (26-57) pg/ml to 19 (12-34) pg/ml). Myocardial lipid content decreased in transgender men but remained similar in transgender women at follow-up.
Conclusions
Myocardial mass increased while NT-proBNP levels decreased significantly in TM after six months of GAHT. However, no significant changes in cardiac function were noted in both TW and TM. Long-term studies are needed to better understand the cardiac effects of GAHT.

Assessing atherosclerotic risk: carotid intima-media thickness in non-functional adrenal incidentalomas

Sabrina Ayari, Nadia Khessairi, Cherchir Faten, Elyes Kamoun, Oueslati Ibtissem & Chihaoui Melika
RABTA Hospital, Tunis, Tunisia

Introduction
Carotid intima-media thickness (CIMT) is a simple and non-invasive method used to detect atherosclerosis. This measure could predict future cardiovascular events. Some studies have showed an increased cardiovascular in non functional adrenal incidentalomas (NFAI). The aim of this case control study was to determine the relationship between NFAI and CIMT.
Methods
This case control study included 40 NFAI patients (16 men, 24 women, mean age 52.9$\pm$11.2 years) and 40 individuals (17 men, 23 women, mean age 56.8$\pm$8 years) in the control group matched for age, sex, and weight. NFAI diagnosis was established according to current guidelines. Patients with mild autonomous cortisol secretion, chronic kidney disease, liver failure or under hypolipidemic drugs, combined contraceptive pills, alcohol or depression were excluded of this study. All participants underwent physical examination (waist circumference (WC), blood pressure), adrenal imaging, and biochemical evaluation including CRP-hs and baseline cortisol. All participants underwent the measurement of CIMT.
Results
The NFAI group had significantly higher CIMT (0,62mm (0.57-0.65) vs 0.46mm (0.39-0.55), $P<10^{-3}$). CIMT was positively correlated to CRP-hs ($r=0.323$, $P=0.045$), baseline cortisol ($r=0.484$, $P=0.002$) and age ($r=0.433$, $P=0.005$) in NFAI patients. No correlation was found between CIMT and systolic blood pressure, fasting blood glucose, size of the adrenal tumor, and lipid levels.
Conclusion
NFAI may in fact produce small amounts of GCs that, in consequence, may cause morphological and functional changes in vessels. Given the increased risk of subclinical atherosclerosis in NFAI patients, a more vigilant follow-up is necessary.

Pheochromocytoma associated with pregnancy. Diagnostic difficulties and management

Zahra Ismail, moustapha ibrahim Fod, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
University Hospital Center Mohamed VI, Departement of Endocrinology, Diabetes and Metabolic Disease, Marrakech

Introduction
Pheochromocytoma is a rare cause of hypertension in pregnancy. Its prevalence ranges from 0.2% to 0.002% of cases of hypertension in pregnancy. Early diagnosis and appropriate management can reduce mortality and morbidity. Were report a case of pheochromocytoma diagnosed during pregnancy.
Observation
34-year-old diabetic patient, 29 weeks pregnant. Admitted for hypertensive peaks up to 170 mmHg of systolic, initially mistaken for pre-eclampsia. Given the 4-year history of hypertension associated with headaches and palpitations, endocrine hypertension was suspected. Urinary metanephrines were measured, and were very high (41 times upper limit for normethanephrine and 27 times for metanephrine). Abdominal MRI without gadolinium injection revealed a heterogeneous tumor above the left kidney measuring 7 cm, suggesting a pheochromocytoma. As the patient was already in her third trimester, surgery was postponed and the patient was put on alpha blockers and calcium channel blockers. Her blood pressure normalized under medical treatment. The patient had intrauterine fetal demise at 33 weeks and underwent adrenalectomy in the post partum.
Discussion
Pheochromocytoma is most common between the fourth and fifth decades of life, in both men and women. The diagnosis of pheochromocytoma in pregnant women is often difficult, and the presence of hypertension can be misleading. Persistent or paroxysmal hypertension is the most common sign of this disease. Headaches occur in up to 90% of symptomatic patients. Hypertension in pregnancy should be investigated early to differentiate pre-eclampsia from other causes. Urinary cathecolamines and metanephrines and MRI are used for diagnosis. Medical treatment with an alpha-blocker should be started as soon as the disease is diagnosed, and continued for at least 10 to 14 days before surgery. Surgery is the definitive treatment for pheochromocytoma, but the timing is controversial. Decisive criteria are gestational age, accessibility of the tumor, presence or absence of fetal distress, and the patient's response to medical treatment. If the pregnant woman is in her 24th week of gestation or more, surgical removal is postponed until or after delivery. Despite its low prevalence, pheochromocytoma during pregnancy increases maternal and fetal morbidity and mortality.

Familial glucocorticoid deficiency type 2 – a case report

Nicoleta Chelaru[1], Cristina Cretu[1], Mariana Cabac[2] & Cristina Cristea[1]
[1]Saint Spiridon County Hospital, Endocrinology, Iasi, Romania; [2]Spitalul Orăşenesc Târgu Neamţ, Endocrinology, Romania

Background
Mutations in the ACTH receptor (MC2R) gene or in its melanocortin accessory protein (MRAP) gene disrupt receptor expression, signaling, and constitutive activity of the MC2R, leading to familial glucocorticoid deficiency (FGD) type 1 and type 2 respectively. FGD is a life-threatening, rare autosomal recessive disorder characterized by impaired cortisol synthesis and classically preserved mineralocorticoid production. There have also been described other mutations that disrupt the signaling pathways of ACTH. The clinical picture of FGD varies depending on the age of onset, the underlying genetic cause, and the severity of the deficiency and may include: recurrent hypoglycemia, seizures, hyperpigmentation, severe, recurrent infections and other symptoms linked to cortisol deficiency.
Case report
Our patient is a slightly hyperpigmented girl with no significant natal or family history and a normal psychomotor development in the first year of life. At the age of two she presented epileptic crisis, ataxia, neuropsychological delay and an autism spectrum disorder, attributed at first to a mutation in the MTOR gene, corresponding to Smith-Kingsmore phenotype. At 3 y 10 mo evaluation, she displayed a tall stature and primary hypothyroidism, therefore levothyroxine substitution was initiated. It was on the age of 6 when a second genetic study identified a homozygous mutation in the MRAP gene c.106+2dup consistent with FGD type 2. Laboratory tests showed undetectable cortisol, very high ACTH level, normal renin and aldosterone levels. Consequently, glucocorticoid substitution was initiated, then she was referred to our clinic for further follow up. It is noteworthy that she has a history of a viral meningo-encephalitis and cerebral parasitosis aspect on the MRI.
Discussions
MRAP defects have been associated with a more severe clinical picture and an early onset of the disease. Our patient's diagnosis at the age of 6 is remarkable, considering that the median age at diagnosis is typically less than 1 year. Interestingly the thyroid function substitution did not precipitate an adrenal crisis. Literature data report several cases of patients with FGD and primary hypothyroidism, but we haven't found any strong association. Another interesting fact is that tall stature associated with FGD is attributed to MC2R gene defects, and not to MRAP mutations, probably due to the early diagnosis of the latter and the lack of the prolonged effect of ACTH excess on the growth plate. We consider that early diagnosis would have improved our patient's outcome in terms of infections and seizures that could have been precipitated by cortisol deficiency.

Identification of lipid profiles and fatty acid abundances associated with histopathology and subtypes of primary aldosteronism

Yuhong Yang[1], Yuqing Liu[1], Haifeng Zhou[2], Maoting Gao[1], Yutong Yan[1], Guodong Ma[1], Min Wang[1], Meiling Bao[3], Tao Yang[1] & Min Sun[1]
[1]The First Affiliated Hospital of Nanjing Medical University, Department of Endocrinology, Nanjing, China; [2]The First Affiliated Hospital of Nanjing Medical University, Department of Interventional Radiology, Nanjing, China; [3]The First Affiliated Hospital of Nanjing Medical University, Department of Pathology, Nanjing, China

Background
Primary aldosteronism (PA) is mainly caused by unilateral (unilateral PA) or bilateral aldosterone-producing lesions of adrenals (bilateral PA). Accumulating findings suggest distinct metabolic profiles between patients with unilateral and bilateral PA. However, the link between the metabolic features and histopathologic findings of adrenals from patients with PA remains largely unknown.
Objective
To characterize metabolic profiles with a focus on the lipid parameters, adiposity and fatty acid alterations in patients with PA with distinct histopathologic findings and subtypes.
Methods
Patient data were retrospectively collected from a single center and analyzed in 76 patients with bilateral PA and 105 with unilateral PA who were categorized into 71 of classical and 34 of nonclassical histopathology according to HISTALDO consensus. Fatty acid abundances in peripheral serum and adrenal specimens were measured by gas chromatography/mass spectrometry and liquid chromatography-tandem mass spectrometry, respectively, with human adrenocortical HAC15 cells as an *in vitro* functional validation model.
Findings
Patients of classical histopathology displayed the highest baseline serum omentin-1 levels (classical vs nonclassical vs bilateral PA: 36.13[19.95–191.45] vs 19.63[13.67–37.33] vs 13.46[9.90–29.31] ng/ml, $P < 0.001$), and the lowest leptin levels (classical vs nonclassical vs bilateral PA: 6.40[2.88–10.68] vs 13.43[4.63–21.32] vs 10.06[5.17–18.46] ng/ml, $P = 0.005$). Compared with the nonclassical group, patients of classical histopathology showed lower BMIs (25.17 ± 3.58 vs 27.03 ± 3.06 kg/m^2, $P = 0.031$) and smaller visceral adipose tissue areas (120.69[74.79-171.16] vs 155.29[127.81-197.46] cm^2, $P = 0.020$). No differences in lipid profiles and adiposity were detected between the nonclassical and bilateral PA groups. In contrast, patients of classical histopathology displayed the highest peripheral serum polyunsaturated fatty acids (PUFAs) especially ω6-PUFAs concentrations relative to the other two groups. Linear discriminant analysis demonstrated fatty acid signatures classified patients with distinct histopathology and subtypes with an accuracy of 98.7%. Combing with the findings of fatty acid abundance comparisons in aldosterone-producing adenomas vs paired adjacent cortex that identified four distinct PUFAs, C20:4 n-6 (arachidonic acid, ARA) in peripheral serum and adrenals showed a strong association with histopathology and subtypes of PA. Functional experiments demonstrated ARA decreases HAC15 cell viability via reactive oxygen species-induced apoptosis and promotes aldosterone synthase expression and aldosterone production via calcium signaling.
Interpretation
Patients with unilateral PA of classical histopathology display the least severe lipid profiles and adiposity, while showing the highest peripheral serum PUFA levels which is likely associated with their *in situ* productions in adrenal lesions, with ARA as a potential biomarker for aldosterone-producing lesions of PA.

Audit of clinical outcomes from our nurse-led adrenal nodule clinic in a London hospital

Agathoklis Efthymiadis, Dannah Pua, Sangita Sharma, Andrew Solomon, Elaine Hui, Shivashankar Seechurn, Mushtaqur Rahman, Asjid Qureshi, Ian Seetho & Mahesh Deore
Northwick Park Hospital, Diabetes & Endocrinology, London, United Kingdom

Introduction
There is an increased number of referrals to endocrinology for adrenal nodules found on imaging. This is due to increased use and advancement in imaging modalities. Adrenal nurse-led clinics are cost-effective and safe. We established an adrenal nodule nurse-led clinic at Northwick Park Hospital in September 2022.
Methods
Retrospective data collection and analysis of patients reviewed at the clinic between September 2022-2023.
Results
Twenty-Nine patients (M = 12/F = 17) were seen. Twenty (69%) patients had left-sided adrenal nodules, five (17%) patients had right-sided adrenal nodules and four (14%) patients had bilateral adrenal nodules. Mean nodule size was 1.9 cm (range = 1.0-8.8, SD = 1.6). Four (14%) adrenal nodules were $\geq$ 4 cm. Waiting time from initial referral to clinic review was 41.5 days (SD = 29.9). Fourteen (48%) patients had hypertension, thirteen (45%) had diabetes and none had hypokalaemia. Non-functioning benign adrenal adenoma was diagnosed in seventeen (59%) of patients, primary hyperaldosteronism in three (10%), mild autonomous cortisol secretion in two (7%), myelolipoma in one (4%), Cushing's syndrome in one (4%) patient, while five (16%) patients still remain under investigation. All patients were subsequently reviewed at the endocrinology consultant-led clinic. Eleven (38%) patients were discussed at the local endocrine multidisciplinary meeting. Ten patients (34%) were directly discharged after their first consultant-led consultation, whilst three (10%) were referred to a tertiary centre for further endocrine investigations. The remaining patients were followed-up locally and four (14%) were discharged after a second consultant appointment, whilst the rest required further endocrine testing.
Discussion and conclusions
We compared our performance to the literature. The number of patients referred to our adrenal nurse-led clinic each year, the size of adrenal lesion and the final diagnosis was comparable to other centres. The timeframe from referral to clinic appointment was shorter in our clinic compared with another centre in the UK (41 days vs 3.6 months). The shorter time to testing may reduce anxiety in patients. All patients in our clinic were subsequently reviewed at a consultant-led clinic before they were discharged, whilst in other centres patients are directly discharged from the nurse-led clinic. This audit shows the importance of a local adrenal nurse-led practice that is appropriate for assessment of patients with benign adrenal nodules, facilitating early patient review, endocrine dynamic testing and prompt discharge of patients with adrenal incidentalomas, that enables reduced clinic visits and faster access to testing, using a standardised algorithm in line with the European Society of Endocrinology guidelines.

Presentation and management of adrenal masses in a large tertiary care centre: a longitudinal study

Onnicha Suntornlohanakul[1,2], Sumedha Mandal[3], Pratyusha Saha[3], Emre Saygili[1,4], Miriam Asia[5], Wiebke Arlt[1,6,7], Yasir Elhassan[1,3,5], Alessandro Prete[1,3,5,8] & Cristina Ronchi[1,3,5]
[1]Institute of Metabolism and Systems Research, University of Birmingham, Birmingham, United Kingdom; [2]Endocrinology and Metabolism Unit, Division of Internal Medicine, Faculty of Medicine, Prince of Songkla University, Songkhla, Thailand; [3]Centre for Endocrinology, Diabetes and Metabolism, Birmingham Health Partners, Birmingham, United Kingdom; [4]Division of Endocrinology and Metabolism, Department of Internal Medicine, Faculty of Medicine, Canakkale Onsekiz Mart University, Canakkale, Turkey; [5]Department of Endocrinology, Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom; [6]Medical Research Council Laboratory of Medical Sciences, London, United Kingdom; [7]Institute of Clinical Sciences, Imperial College London, London, United Kingdom; [8]NIHR Birmingham Biomedical Research Centre, University of Birmingham and University Hospitals Birmingham NHS Foundation Trust, Birmingham, United Kingdom

Background
Adrenal masses are detected in 5-7% of adults. The European guidelines on managing adrenal incidentalomas published in 2016[1] have standardised the management of these patients. However, evidence of the guidelines' impact on clinical care is still lacking.
Methods
We conducted a retrospective, comprehensive review of clinical presentation, radiological characteristics, final diagnosis, and outcome of a large cohort of patients with adrenal masses referred to our tertiary centre (Queen Elizabeth Hospital Birmingham, UK) between 1998 and 2022. We performed a sub-analysis comparing the characteristics and outcomes before and after implementing the 2016 guidelines.
Results
We included 1397 patients (55.7% women; median age 60 years, [interquartile range, IQR, 49-70]). Incidental discovery was the most frequent mode of presentation (67.9%). Overall, 14.7% of patients had bilateral masses, and 32.8% had masses $\geq$ 4 cm (median 2.9 cm, [IQR 1.9-4.7]). Unenhanced computed tomography (CT) Hounsfield Units (HU) were available for 763 patients; of these, 32.9% had heterogeneous tumours or HU > 20. 44.3% of patients had hormonally inactive adrenal masses. After standardised workup, the most common diagnoses were adrenocortical adenoma (ACA, 56.0%), phaeochromocytoma (12.7%), adrenocortical carcinoma (10.6%), and metastases from an extra-adrenal malignancy (5.7%). Eventually, 65% of patients referred for indeterminate masses were diagnosed as having benign lesions, while 18% remained indeterminate. At multivariable regression analysis, the significant predictors in discriminating malignant from benign lesions were HU > 20 or heterogeneous mass (odds ratio, OR, 28.40, 95%confidence interval, 95%CI [5.87-137.56]), followed by increased serum androgens (OR 27.67, 95%CI [4.05-189.00]), mass detection during cancer surveillance (OR 11.34, 95%CI [3.32-38.70]), size $\geq$ 4 cm (OR 6.11, 95%CI [2.22-16.86]) and male sex (OR 3.06, 95%CI [1.12-8.34]). After implementing the guidelines, there was no significant difference comparing patients seen before (n = 386) and after 2016 (n = 990) in the use of additional imaging in the entire cohort or among patients with indeterminate radiological appearance (HU > 20 or heterogeneous density or size $\geq$ 4 cm). Nevertheless, the proportion of patients with non-functioning benign adrenal masses that underwent multiple follow-up visits significantly decreased from 89.6% to 70.2%, while the discharge rate after the initial workup increased from 4.4 to 25.3% (P < 0.001).
Conclusion
From our extensive review of patients with adrenal masses including a high proportion of large and heterogenous lesions, ACAs remained the commonest aetiology. Implementing the European 2016 guidelines positively impacted clinical practice, reducing the number of follow-up visits, and increasing the discharge rate of benign, non-functioning masses.

Dyslipidemia unveiled in non functional adrenal incidentalomas

Sabrina Ayari, Nadia Khessairi, Sahar Abidi, Elyes Kamoun, Oueslati Ibtissem & Chihaoui Melika
Rabta Hospital, Tunis, Tunisia

Background
Non functional adrenal incidentalomas (NFAI) constitute the majority of adrenal tumors. This entity is a result of advances in imaging techniques and their prevalent use in clinical practice. Among the associated metabolic effects of NFAI, dyslipidemia emerges as a key factor, stimulating growing interest in understanding the link between these two entities.
Methods
This case control study included 40 NFAI patients (16 men, 24 women, mean age 52.9 $\pm$ 11.2 years) and 40 individuals (17 men, 23 women, mean age 56.8 $\pm$ 8 years) in the control group matched for age, sex, and weight. NFAI diagnosis was established according to current guidelines. Patients with mild autonomous cortisol secretion, chronic kidney disease, liver failure or under hypolipidemic drugs, combined contraceptive pills, alcohol or depression, were excluded of this study. All participants underwent adrenal imaging, biochemical evaluation including triglyceride (TG), high-density lipoprotein cholesterol (HDL-C), cholesterol total (CT), Low-density lipoprotein cholesterol (LDL-C). Dyslipidemia was defined according to the National Cholesterol Education Program (NCEP) ATP III.
Results
The prevalence of dyslipidemia was 52,5% in NFAI patients compared to 57.5% in the control group. HypoHDLemia represented the most common type of dyslipidemia in both groups, 35%and 33% respectively. Hypercholesterolemia and hypertriglyceredemia were diagnosed respectively in 20% and 18% of NFAI patients vs 25% and 18% in control group.

Conclusion
Our study didn't show a higher prevalence of dyslipedemia in NFAI patients. However, management of dyslipidemia in NFAI should be considered for primary and secondary prevention of cardiovascular risk.

Predicting postoperative hypocortisolism in patients with non-aldosterone-producing adrenocortical adenoma: a retrospective single centre study

Ilaria Bonaventura[1], Alessandra Tomaselli[1], Francesco Angelini[1], Davide Ferrari[1], Dario De Alcubierre[1], Valeria Hasenmajer[1], Emilia Sbardella[1], Alessia Cozzolino[1], Alessandro Paganini[2], Andrea Isidori[1], Marianna Minnetti[1] & Riccardo Pofi[3]
[1]Sapienza University of Rome, Experimental Medicine; [2]Sapienza University of Rome, Department of General Surgery, Surgical Specialties and Organ Transplantation "Paride Stefanini"; [3]University of Oxford, Department of Endocrinology, Oxford Centre for Diabetes, Endocrinology and Metabolism and NIHR Oxford Biomedical Research Centre

Background
Limited information exists on postoperative hypocortisolism and hypothalamus-pituitary-adrenal axis recovery in patients with adrenal incidentaloma following unilateral adrenalectomy. We evaluated frequency of postoperative hypocortisolism and predictors for recovery in non-aldosterone- producing adrenocortical adenoma patients after unilateral adrenalectomy.
Methods
A retrospective analysis of 32 adrenal incidentaloma patients originally included in the ITACA trial (NCT04127552) with confirmed non-aldosterone- producing adrenocortical adenoma undergoing unilateral adrenalectomy from September 2019 to April 2023 was conducted. Preoperative assessments included adrenal MRI, anthropometrics, evaluation of comorbidities, adrenal function assessed via ACTH, urinary free cortisol, and 1 mg dexamethasone suppression test. ACTH and serum cortisol or Short Synacthen test were performed within 6 days, 6-week, 6-month, and a year after surgery.
Results
Six days postoperative, 18.8% of patients had normal adrenal function. Among those with postoperative hypocortisolism, 53.8% recovered by 6-week. Patients with earlier adrenal recovery (6-week) had lower preoperative 1 mg dexamethasone suppression test (median 1 mg dexamethasone suppression test 76.2 [61.8-111.0] nmol/l vs 260.0 [113.0-288.5] nmol/l, $P<0.001$). Univariate analysis showed preoperative 1 mg dexamethasone suppression test negatively related with baseline ACTH levels ($r=-0.376$; $P=0.041$) and negatively associated with the 6-week baseline ($r=-0.395$, $P=0.034$) and 30-minute cortisol levels during Short Synacthen test ($r=-0.534$, $P=0.023$). Logistic regression analysis demonstrated preoperative 1 mg dexamethasone suppression test as the only biochemical predictor for 6-week adrenal recovery: ROC curve identified a 1 mg dexamethasone suppression test threshold of 131 nmol/l predicting 6-week recovery with 89.5% sensitivity and 72.7% specificity (AUC 0.87; 95%CI 66.9-98.7, $P<0.001$). Other preoperative assessments (tumor size, ACTH levels and anthropometrics) were not associated with postoperative hypothalamus-pituitary-adrenal axis function, but the presence of diabetes was associated with a lower probability of recovery (OR = 24.55, $P=0.036$). ACTH levels increased postoperatively in all patients but did not predict hypothalamus-pituitary-adrenal axis recovery.
Conclusions
The preoperative 1 mg dexamethasone suppression test cortisol value and presence of diabetes are the only relevant predictor of hypothalamus-pituitary-adrenal axis recovery in patients with non-aldosterone- producing adrenocortical adenoma undergoing surgery, regardless other clinical and biochemical variables. Notably, pre and postoperative ACTH levels did not predict hypothalamus-pituitary-adrenal axis recovery. These findings point towards the potential for saving resources by optimizing their allocation during follow-up assessments for patients with non-aldosterone producing adrenocortical adenoma undergoing unilateral adrenalectomy.

[1]Hospital das Clínicas, University of São Paulo School of Medicine, Division of Endocrinology, São Paulo, Brazil; [2]Hospital das Clínicas, University of São Paulo School of Medicine, Division of Urology, São Paulo, Brazil; [3]Cancer Institute of São Paulo State (ICESP), Interventional Radiology, São Paulo, Brazil; [4]Hospital das Clínicas, University of São Paulo School of Medicine, Radiology Institute (InRad), São Paulo, Brazil; [5]Hospital das Clínicas, University of São Paulo School of Medicine, Laboratory of Hormones and Molecular Genetics LIM/42, Division of Endocrinology and Metabolism, São Paulo, Brazil; [6]Cancer Institute of São Paulo State (ICESP), University of Sao Paulo Medical School, Division of Endocrine Oncology, São Paulo, Brazil

Introduction
Masses in adrenal topography have been diagnosed frequently due to more available access to radiological imaging. Adrenal incidentalomas occur around 5% to 7% of patients undergoing abdominal imaging mainly over 50 years of age. The HCFMUSP is a complex tertiary center, a national reference to adrenal disorders and since 2006 around 300 adrenalectomies were performed; 8% of them corresponded to undetermined masses in adrenal topography.
Objective
We retrospectively analyzed imaging features and the definitive diagnosis of undetermined masses located in adrenal gland topography identified by abdominal CT or MRI from 2006 to 2023 ($n=49$).
Methods
All patients were undergoing an extensive hormonal evaluation, according to the European and American Society of Endocrinology guidelines. Two expert radiologists reviewed all images. Forty-nine patients were included and underwent unilateral adrenalectomy, to elucidate the etiology of the lesion on adrenal topography. Masses diagnosed as adrenocortical carcinoma were excluded from this analysis.
Results
Thirty-four (69.3%) were female. The general mean age was 48.3 years old (range 18-82yo). Abdominal or lumbar pain was the leading cause for the imaging study (42.8%), and 34.6% were identified as adrenal incidentalomas during the approach to urinary tract infection, nephrolithiasis, or pulmonary disease. None of these patients had any clinical signs of adrenal hormonal hyperfunction, neither abnormal hormonal secretion. Twenty-five patients (51%) presented a mass on the left side, and only two cases presented bilateral adrenal masses. The mean size was 8.54 cm (1.3-18 cm), with non-adrenal-neoplasia standing out for a larger average size of 11 cm (7.2-15 cm). The mean Hounsfield Units (HU) on non-contrasted CT scans were 25 HU (0-50 HU). There was no significant difference in HU concerning the size of the lesion, although non-adrenal neoplasias showed a slightly higher average, reaching 30.4 HU (3-48 HU). The etiologies were: non-adrenal cancer (15 cases) (30.6%), ganglioneuroma (9 cases) (18.3%), adrenal cysts (6 cases) (12.2%), adrenal hemorrhage (4 cases) (8.1%), infectious disease (4 cases) (8.1%), schwannoma (3cases) (6.1%), lymphangioma (2 cases) (4%), pseudocyst (2 cases) (4%), prostate cancer metastasis (1 case) (2%), arteriovenous malformation (1 case) (2%), myelolipoma (1 case) (2%), acute splenitis (1 case) (2%).
Conclusion
In this large cohort, undetermined masses in adrenal topography were more prevalent in females, with non-adrenal cancer being the most frequent cause, particularly highlighting leiomyosarcoma. Ganglioneuroma was the most frequently diagnosed benign tumor.

Milan, Italy; [7]Unit of Endocrinology, Department of Biotechnology and Translational Medicine, Ospedale Niguarda Cà Granda, University of Milan, Milan, Italy

Background
A recent cross-sectional study showed that both comorbidities and mortality in patients with adrenal incidentaloma (AI) are tied to sex. However, only few longitudinal studies evaluating the development of arterial hypertension, hyperglycemia, dyslipidemia and bone impairment in patients with AI are available. The aim of this study is to analyze the impact of sex in the development of these comorbidities during long-term follow-up.
Patients and Methods
We retrospectively evaluated 189 patients (120 females, 69 males) with AI, from four referral centers in Italy and Croatia. Clinical characteristics and hormonal data were collected at baseline and at last follow-up visit (LFUV). To compare each characteristic at baseline and at LFUV, we used the Wilcoxon test for continuous variables and the McNemar test for categorical variables. Differences between groups were analyzed with the Mann-Whitney test for continuous variables and the Chi-square test for categorical variables.
Results
Median follow-up was 52 (IQR 25-86) months. At LFUV, in both sexes arterial hypertension was more frequently reported than at baseline (females: 77.8% vs 65.8%, $P=0.002$; males: 69.1% vs 58.0%, $P=0.035$), as well as hyperglycemia (females: 39.6% vs 28.8%, $P<0.001$; males 54.0% vs 36.2%, $P<0.001$). Patients were stratified in two groups by cortisol after 1 mg-dexamethasone: 99 (62 females, 37 males) with non-functional adrenal tumors [NFAT] and 89 (57 females, 32 males) with tumors with mild autonomous cortisol secretion [MACS]. In the NFAT group, at baseline, we did not observe any difference in clinical characteristics and comorbidities between males and females. At LFUV, the NFAT group showed a higher frequency of hyperglycemia in males than in females (57.6% vs 33.9%, $p=0.03$). In the MACS group, at baseline, females were younger (60, IQR 55-69 vs 67.5, IQR 61-73, years; $p=0.01$) and presented higher rates of bone impairment (89.3% vs 54.5%, $p=0.02$) than males. At LFUV, in the MACS group, the median age remained lower (66, IQR 61-73 vs 73.5, IQR 65-78, years; $p=0.02$) and bone impairment more frequent (88.9% vs 58.8%, $p=0.01$) in females than males. Moreover, females presented a higher frequency of visceral adiposity (95% vs 60%, $p=0.01$)
Conclusions
Patients with AI frequently develop arterial hypertension and glycemic alterations and should be periodically checked for these comorbidities, regardless sex. Bone impairment was frequently reported in females with MACS, suggesting a sex-specific effect of cortisol on bones.

DOI: 10.1530/endoabs.99.EP195

Metabolic impact of dual-release hydrocortisone in patients with congenital adrenal syndrome: a retrospective study

Pierluigi Mazzeo, Filippo Ceccato, Giacomo Voltan, Irene Tizianel, Alessandro Mondin, Martina Lazzara, Alessandro Bavaresco & Mattia Barbot
Endocrine Disease Unit, Department of Medicine - DIMED, University-Hospital of Padova, Padua, Italy

Background
Congenital adrenal hyperplasia (CAH) is an autosomal recessive disorder characterized by impaired cortisol secretion and androgen excess. The mainstay of CAH treatment is glucocorticoid (GC) replacement, necessary to avoid adrenal crisis and manage androgen excess. The delicate balance between GC under/overtreatment is crucial to prevent metabolic and cardiovascular complications. Dual-release hydrocortisone (Plenadren®) is once-daily modified-release formulation of hydrocortisone (HC) approved for adrenal insufficiency. Data on its use in CAH are scarce. The aim of this study is to evaluate clinical, metabolic and hormonal characteristics of patients with CAH switched from conventional GC treatment to Plenadren.
Patients and method
Retrospective study on 29 patients followed at our Unit (M/F:17/12) with CAH; 18/29 patients were switched to Plenadren (median age 33 years, IQR 24-40). Clinical, metabolic and hormonal data were evaluated at baseline and during follow-up (at 6 months and last available visit) and compared with patients (11/29) who continued conventional GCs.
Results
There were no statistical differences between the two cohorts of patients at baseline. During follow-up, patients switched to Plenadren showed a worsening of ACTH control [123(23-307) vs 193(142-713) ng/l, $P=0.09$] despite an overall increase of daily HC equivalent dose (13 vs 20 mg/day); other parameters of disease control such as 17-OH progesterone [200 (19-433) vs 254 (99-426) nmol/l, $P=0.58$] and total testosterone levels in male [12.8 (9.0-19.1) vs 13 (10.0-16.6) nmol/l $P=0.99$] remained stable, as well as metabolic parameters like HOMA index [2.5 (1.25-2.9) vs 0.8 (0.7-2.5), $P=0.20$] and total cholesterol [178 (142-206) vs 147 (122-157) mg/dl, $P=0.11$]. However, comparing with patients on conventional GCs regimen, total cholesterol levels improved [147 (122-157) vs 200 (169-208) mg/dl, $P=0,03$], but disease control was poorer [ACTH 193 (142-713) vs 50 (19-105) ng/l, $P=0.015$ and 17-OH progesterone 254 (99-426) vs 24 (7-123) nmol/l, $P=0.004$]. Unsatisfactory disease control was the main reason for discontinuation (12/18 patients), after a median time of 29 months (6-49), but no adrenal crisis was recorded during follow-up.
Conclusions
Although dual-release HC can mimic the circadian rhythm of cortisol secretion, it provides suboptimal hormone control in CAH. The once-daily administration in the morning has a fall of cortisol level at bedtime, not avoiding the overnight ACTH-driven androgen excess. However, Plenadren is a safe treatment and tends to improve the metabolic profile compared to conventional GCs; thus it could be a reasonable choice in older CAH patients or post-menopausal women, in whom reducing cardiovascular risk factor and adrenal insufficiency are the main aims over obtaining a strict control of adrenal androgens.

Introduction
Tumor-derived material, particularly micro-RNAs, have been identified in the bloodstream and hold promise as molecular markers for diagnosing and monitoring adrenocortical incidentalomas (AIs).
Purpose
We examined selected circulating microRNAs (miR-483-5p, miR-210, miR-335, miR-22-3p), identified from microRNA profiling studies, as markers of malignancy or cortisol hypersecretion in a cohort of patients with AIs and controls in a clinical setting.
Methods
Blood samples were collected from a total of 67 patients with AIs, comprising 50 cases of adrenocortical adenomas (ACA) and 17 cases of adrenocortical carcinoma (ACC). Within the ACC group, samples were obtained either preoperatively or upon the detection of local recurrence or distant metastases in 11 cases, whereas the other 6 were collected from patients who had remained disease-free for over 3 years. Out of the 55 AI patients evaluated preoperatively, 26 had non-functioning tumors (NFAIs), 21 exhibited mild autonomous cortisol secretion (MACS) and 8 had Cushing syndrome (CS). A control group of 15 participants was enrolled for comparative analysis. Quantitative real-time polymerase chain reaction was employed to analyze microRNA expression in serum samples. Cel-miR-39-3p served as the reference gene for data normalization, and the expression levels were determined using the dCT method.
Results
Circulating miR-483-5p and miR-210 levels were considerably elevated in the group of preoperative/advanced ACC compared with ACA ($P<0.001$, $p=0.02$ respectively) and controls ($P=0.03$, ns, respectively). Interestingly, circulating miR-483-5p levels were also significantly elevated in preoperative/advanced ACC compared to disease-free ACC patients ($P=0.04$). MiR-483-5p levels demonstrated the highest sensitivity (81.8%) and specificity (92%) for distinguishing preoperative/advanced ACC from ACA (AUC=0.894, 95% CI: 0.793–0.994, $P<0.001$), while miR-335 levels did not reach sufficient diagnostic accuracy. MiR-22-3p levels effectively discriminated patients with CS from those with NFAIs (AUC=0.784, 95% CI: 0.626–0.941, $P=0.017$) reaching sensitivity up to 100% along with specificity 61.5%. MiR-22-3p levels presented a

statistically significant positive correlation with 24-hour urinary free cortisol ($rs=0.504$, $p=0.02$), as well as a significant negative correlation with adrenocorticotropic hormone ($rs=-0.351$, $p=0.01$).
Conclusion
Our study suggests that specific microRNAs could serve as valuable noninvasive biomarkers for diagnosing and monitoring AIs, complementing current diagnostic tools.

Adrenal phenotype in multiple endocrine neoplasia type 1

Arianna Cremaschi[1], Roberta Mungari[1], Alessandra Mangone[1,2], Giulia Del Sindaco[1,2], Elisa Sala[1], Giulia Carosi[1], Veronica Lotito[1,2], Emanuele Ferrante[1] & Giovanna Mantovani[1,2]
[1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Endocrinology Unit, Milano, Italy; [2]University of Milan, Department of Medical Sciences and Community Health

Background
Adrenal involvement in multiple endocrine neoplasia type 1 (MEN1) has been reported, its prevalence varying from 9 to 73%. The aim of this study was to characterize the adrenal phenotype and the prevalence and clinical significance of cortisol hypersecretion in a cohort of MEN1 patients.
Methods
We retrospectively analyzed data of 36 adult patients with germline menin mutation (20 females; mean age 50 ± 17.4 years) in regular follow-up at our Endocrinology Unit between 2000 and 2023. All study participants underwent periodical MRI abdominal imaging and evaluation of adrenal glands. If adrenal lesions were present hormonal evaluation was carried out and included: 1 mg dexamethasone overnight suppression test (DST), urinary free cortisol (UFC) levels and salivary cortisol levels assessed on 3 consecutive nights; aldosterone, renin levels and urinary metanephrines were assessed when hypertension was present. Patients were also screened for hypercortisolism-related comorbidities (cardiovascular events, hypertension, glucose and lipid metabolism, osteoporosis).
Results
13 patients (36%) had radiological evidence of adrenal lesions: 4 had hyperplasia (30.7%, 3 females) of which 2 unilateral and 2 bilateral, 4 had bilateral macronodular hyperplasia (30.7%, 3 males) and 5 had unilateral nodular lesions (38.5%, 4 males). The mean diameter of lesions was 15.7 ± 6 mm. One patient with macronodular bilateral hyperplasia had adrenal hemorrhage. Of these 13 patients, 9 (69.2%) had at least one test suggestive for hypercortisolism. 6 had serum cortisol levels after 1 mg DST ≥1.8 µg/l (mean 3.12 ± 1 µg/l), 4 had elevated UFC levels (median 1.3 IQR 1.1-1.4 ULN) and 1 had 2/3 elevated salivary cortisol levels. Median ACTH levels were 11.6 IQR 7.2-18.8 ng/l. Only one patient had both unsuppressed cortisol levels after 1 mgDST and elevated UFC on multiple occasions, thus medical therapy with metyrapone was started. One patient underwent surgical adrenalectomy. Of the 9 patients 4 had hyperplasia, 2 had macronodular hyperplasia and 3 had unilateral nodules. None had clinical signs of overt Cushing syndrome. We compared the prevalence of hypercortisolism-associated comorbidities between patients with possible cortisol autonomous secretion and without and found no significant difference (cardiovascular events 0 vs 1; hypertension 2 vs 2; mean BMI 24.6 ± 2.6 vs 27.9 ± 7.2 kg/m^2; diabetes 3 vs 1; IFG 0 vs 4; dyslipidemia 1 vs 1, osteoporosis 3 vs 1). No patients had hyperaldosteronism or pheochromocytoma.
Conclusion
Our data, with the limitation of a small series, suggest that there is a high frequency of biochemical evidence of hypercortisolism, however this does not seem to be associated with clinical signs or with increased frequency of typically related comorbidities.

Background
Adrenal endothelial tumors are mainly represented by adrenal cavernous hemangiomas (ACHs) and adrenal cystic lymphangiomas (ACLs). They are rare incidental findings, with about 160 cases of both ACHs and ACLS reported in the literature. They are usually unilateral, benign, non-functioning, and asymptomatic, although abdominal pain and life-threatening retroperitoneal hemorrhage may occur if tumor size increases. Radiological features often overlap with malignant adrenal tumors, therefore ruling out malignancy becomes mandatory. We analyzed clinical, radiological, and histopathological data to identify specific characteristics of adrenal endothelial tumors.
Methods
We conducted a retrospective review of patients admitted to our Department between 2007 and 2022 with ACHs or ACLs confirmed by histopathology. All clinical and radiological data were collected retrospectively from electronic health records.
Results
A total of 20 patients underwent elective adrenalectomy and were diagnosed with adrenal hemangiomas ($n=10$), adrenal cystic lymphangiomas ($n=7$), or undefined/combined adrenal cystic lesions ($n=3$). Six patients had no available information about preoperative workup. More than half of the cases were incidentally discovered ($n=13$) and only 2 cases were identified correctly by preoperative imaging studies. Mean age at the diagnosis was 53 years. Sex was evenly distributed (females $n=9$, males $n=11$). All tumors were unilateral. Mean preoperative tumor size was 45 mm. An upward trend in tumor size was observed in 7 cases. All tumors showed CT density values on the non-contrast series >10 Hounsfield Units (HU). Calcifications were found in 5 patients. Functional evaluation was performed in 13 patients, whereas 6 patients had no available information about hormone secretion. Hormonal studies revealed non-functioning adrenal masses in 9 cases and autonomous cortisol secretion in 2 patients, assessed by 1 mg dexamethasone suppression test. Elevated urinary metanephrines were found in 2 cases.
Conclusions
ACHs and ACLs represent a diagnostic dilemma in clinical practice due to their rarity and their misleading imaging features. Because of the heterogeneous clinical and radiological pictures, treatment should be targeted to the patient's characteristics.

Appropriateness of patient selection for inpatient short synacthen testing in a tertiary hospital

Lyeann Tan[1], Vijay Ramadoss[1], Ada Teo[1], Kavita Narula[2], Katharine Lazarus[2], Doddabele Srinivasa Deepak[1], Li Zhen Ong[1], Karim Meeran[2], Chin Meng Khoo[1] & Pei Chia Eng[1]
[1]National University Health Systems, Endocrinology, Singapore, Singapore; [2]Imperial College London, Hammersmith Campus, United Kingdom

Background
The Short Synacthen test (SST) is commonly used in clinical practice to evaluate adrenal function. Appropriate patient selection for SST is needed to ensure accurate interpretation of the results and to mitigate increased healthcare costs associated with unnecessary testing and inappropriate glucocorticoid (GC) steroid replacement. This study aimed to investigate the indications of inpatient SSTs over a one-year period, to determine the accuracy of testing.
Method
We reviewed all relevant clinical information of all the inpatient SSTs performed between 28th February 2022 and 28th February 2023 at our institution. An SST test was considered appropriate if patients presented with symptoms suggestive of adrenal insufficiency (AI), and inappropriate if no clear indication was provided or the patient's clinical history and presenting features did not suggest AI.
Results
457 patients, with a median age of 67 years (IQR 56 to 76.5 years) underwent 485 inpatient SSTs. The common indications for SSTs were: postural hypotension

(36.70%), hyponatremia (17.1%), hypotension (16.3%) and previous or current exogenous GC use (8.1%). Of those who underwent SSTs for postural hypotension, 89.9% were symptomatic and 10.1% were asymptomatic. Of those who presented with hyponatremia, 6% had symptoms suggestive of AI and an initial presenting sodium of 127 nmol/l (IQR 124 nmol/l - 130 nmol/l). 27.9% of the patients who had hypotension had ongoing infection; 30.4% had persistent low blood pressure suggestive of AI and 33.0% had a transient hypotensive episode. 4.5% of the SSTs were carried out due to subjective feelings of giddiness and lethargy and 5.6% of SST had no documented indications. Of the 485 inpatient SSTs, 74/485 (15.3%) did not have a prior morning cortisol. 228/485 (47.0%) of SSTs did not have a measured paired baseline ACTH. Nearly half (49%) of the SSTs were performed in patients who did not have features suggestive of AI. 28 SSTs were repeated due to incorrect initial tests. Of those who underwent SSTs for suspected features of AI, 65.4% had a normal SST result. Similarly, in those who underwent SST where there was no indication for AI, 62.5% had a normal result.

Conclusion

A majority of the inpatient SSTs were inappropriately indicated. Our study demonstrates that presenting features for SST testing do not reliably predict SST outcomes in our cohort. Common errors identified insufficient pre-test cortisol testing and lack of concomitant ACTH measurement. We advocate judicious patient selection for SST testing to avoid inappropriate use of SST and subsequent life-long need for GC replacement.

The effect of adrenalectomy on metabolic parameters in patients with primary aldosteronism

Karin Zibar Tomšić[1], Mirjana Đukić[2], Mirsala Solak[1] & Darko Kaštelan[1]
[1]University Hospital Centre Zagreb, Department of Endocrinology, Zagreb, Croatia; [2]General Hospital Sisak, Department of Endocrinology, Sisak, Croatia

Background

A few studies have shown that aldosterone has negative impact on metabolic parameters.

Objectives

The aim of the study was to evaluate metabolic parameters in patients with primary aldosteronism (PA) before and one year after adrenalectomy.

Methods

In this retrospective study, we examined 51 patients (median age 50 years, IQR 43–55; 55% male) who underwent adrenalectomy for PA between 2016 and 2022. Patients with diabetes mellitus, dyslipidemia, and autonomous cortisol secretion were excluded. We assessed differences in glucose ($n=24$), lipid profiles ($n=32$), body weight ($n=47$), and the defined daily dosage (DDD) of antihypertensives ($n=51$). Clinical remission of PA was defined according to PASO criteria.

Results

Complete clinical remission was attained by 45% of patients, while 51% achieved partial clinical remission, and 4% experienced no clinical remission. A year after surgery, there was a significant reduction in the median defined daily dosage (DDD) of antihypertensives compared to pre-surgery levels (4.5 vs 1.3, $P<0.001$). Similarly, the median fasting glucose level also showed marked improvement after surgery (5.1 mmol/l vs 4.9 mmol/l ; $P=0.035$). Conversely, no significant differences were observed in total cholesterol and triglyceride levels ($P=0.754$) and body weight ($P=0.724$) before and after surgery.

Conclusion

Adrenalectomy in patients with PA resulted in significant improvements in metabolic parameters, including reduced use of antihypertensive medications and improved fasting glucose levels one year after surgery. These results emphasise the potential metabolic benefits of adrenalectomy in the treatment of primary aldosteronism.

Remission rate of primary aldosteronism after unilateral adrenalectomy

Mirjana Đukić[1], Karin Zibar Tomšić[2], Nikola Knežević[2,3] & Darko Kaštelan[2,3]
[1]General Hospital Sisak, Department of Endocrinology, Sisak, Croatia; [2]University Hospital Centre Zagreb, Department of Endocrinology, Zagreb, Croatia; [3]School of Medicine, University of Zagreb, Zagreb, Croatia

Background

The existing consensus for patients with primary aldosteronism (PA) after unilateral adrenalectomy recommends annual follow-up to rule out persistence or recurrence of the disease.

Objectives

The aim of the study was to assess the remission rate in patients with PA ≥ 1 year after adrenalectomy.

Methods

Of the 41 patients who underwent adrenalectomy for PA between 2016 and 2021, 24 had available follow-up data and were included in the study. To diagnose unilateral disease we used lateralization index ≥ 4 or contralateral suppression index ≤ 0.37. Biochemical and clinical remission of PA was defined according to PASO criteria.

Results

The median age of participants was 50 years (IR 42-56), 50% were women. The median follow-up time after surgery was 5 years (IR 3-5). Aldosterone concentration before and after surgery was 998 pmol/l (IR 583-1284) and 240 pmol/l (IR 194-369), $P<0.001$. Plasma renin activity before surgery was 0.15 µg/l/h (IR 0.1-0.38) whereas after surgery it was 1.5 µg/l/h (IR 0.9-5.7), $P<0.001$. Finaly, median potassium level after surgery was significantly higher compared to the level before surgery (4.3 mmol/l vs 2.9 mmol/l ; $P<0.001$). At the time of data collection, 92% of patients were in complete biochemical remission, whereas 8% were in partial biochemical remission. Regarding clinical remission, the respective rates of patients who were in complete and partial remission were 54% and 38%. Only 8% of patients did not achieve clinical remission of the disease after unilateral adrenalectomy. Both patients who were in partial biochemical remission achieved complete clinical remission.

Conclusion

Our results showed that with a lateralization index ≥ 4 or contralateral suppression index ≤ 0.37, long-term, complete or partial, biochemical remission of PA was achieved in all patients after unilateral adrenalectomy. Furthermore, long-term, complete or partical, clinical remission, was achieved in 92% patients.

Reninoma: a rare cause of hypertension in pregnancy

Deirdre Green, Liam Plant & Domhnall O'Halloran
Cork University Hospital, Cork, Ireland

A reninoma is a tumour of the afferent arteriolar juxtaglomerular cells that secretes the enzyme renin, leading to hyperactivation of the renin-angiotensin-aldosterone system. It is a cause of pathological secondary hyperaldosteronism that results in severe hypertension and hypokalaemia. Fewer than 200 cases have been described, seven of which were associated with pregnancy. We present the case of a 29-year-old woman referred with hypertension and hypokalaemia at 10 weeks' gestation of a dichorionic twin pregnancy. She was treated with Labetolol 600 mg four times daily, Methyldopa 1g three times daily and Nifedipine LA 60 mg twice daily to maintain a blood pressure of approximately 130/90mmHg. Her medical history included hypertension, diagnosed aged 19. She had one previous uncomplicated singleton pregnancy. There was no family history of hypertension or endocrinopathy. Recumbent plasma renin concentration was elevated at 67.7 ng/l (3-6 ng/l), and plasma aldosterone was elevated at 1425 pmol/l (<440 pmol/l). Tests for hypercortisolism and catecholamine excess were negative. Echocardiography revealed borderline concentric left ventricular hypertrophy and no coarctation of the aorta. Urine protein:creatinine ratio was elevated at 53.4 mg/mmol (<45 mg/mmol). A 2.4 cm solid, right renal lesion was identified on ultrasound. Further characterisation with magnetic resonance imaging demonstrated a heterogenous high signal area that indented the renal sinus fat and extended into the medullary area of the kidney. A biopsy of the lesion was arranged, and histopathology confirmed a juxtaglomerular cell tumour. No evidence of pre-eclampsia was seen. The patient proceeded for a right total nephrectomy at 16 weeks' gestation. Macroscopically the lesion was a well circumscribed, haemorrhagic, tan-coloured mass lesion measuring $3.2\times2.5\times2.6$ cm. The tumour was microscopically characterised by diffuse proliferation of tumour cells with moderate amounts of eosinophilic cytoplasm and vesicular nuclei. The tumour cells were positive for CD34, SMA, and vimentin and negative for CD117. Electron microscopy of the tumour showed rhomboid shaped granules characteristic of renin in tumour cells. The remainder of the kidney was unremarkable. The postoperative course was complicated by hypotension, and anti-hypertensive medications were discontinued. Supine plasma renin level measurement 7 weeks postoperatively was normal at 10.3 ng/l (<16 ng/l), 15% of the original value. Two infants were born via elective Caesarean section at $33+4$ weeks gestation. Reninoma is a very rare and potentially curable form of hypertension, particularly in women of childbearing age. Plasma renin concentration was three times greater than the expected value for this stage of

pregnancy. Management in pregnancy is challenging and involvement of the multi-disciplinary team is vital.

Biochemical diagnosis of pheochromocytoma/paraganglioma in children and adolescents

Kristin Potthoff[1], Tamara Prodanov[2], Lara Knigge[1], Sara Talvacchio[2], Angela Hübner[3], Stefan Bornstein[1], Jacques Lenders[4], Mirko Peitzsch[5], Karel Pacak[2], Graeme Eisenhofer[1] & Christina Pamporaki[1]
[1]University Hospital Carl Gustav Carus at the TU Dresden, Department of Medicine III, Dresden, Germany; [2]National Institutes of Health (NIH), Eunice Kennedy Shriver, National Institute of Child Health and Human Development, Bethesda, United States; [3]University Hospital Carl Gustav Carus at the TU Dresden, Department of Pediatrics, Dresden, Germany; [4]Radboud University Medical Center, Department of Internal Medicine, Nijmegen, Netherlands; [5]University Hospital Carl Gustav Carus at the TU Dresden, Institute of Clinical Chemistry and Laboratory Medicine, Dresden, Germany

Introduction
Currently, it is unclear whether plasma free or 24-hour urinary metanephrines are preferable for diagnosis of pheochromocytoma/paraganglioma (PPGL) in children.
Objectives
To investigate whether measurements of plasma free or 24-hour urinary fractionated metanephrines is a reliable test for screening for PPGL in children.
Methods
This retrospective study included data from 60 children with and 78 without PPGL. Data included sex, age (5-18 years), plasma concentrations of free metanephrines, and genetic test results. For a subset group of 87 children tested for PPGL, concentrations of 24-hour urinary metanephrines were also available. For patients with PPGL, data also included tumor location, size, tumor catecholamine phenotype, and presence of recurrent and/or metastatic disease.
Results
Among children with PPGL, the plasma panel presented with larger fold-normetanephrine increases above the upper cut-offs (8-fold vs 3-fold, $P < 0.001$) compared to the urinary metabolites. The plasma panel showed a diagnostic sensitivity and specificity of 100% and 93% respectively compared to 94% and 88% for the urinary panel. Measurements of plasma free metabolites offered similar diagnostic performance (AUC:0.987, 95%CI:0.969-1.00) to 24-hour urinary fractionated metanephrines (AUC:0.972, 95%CI:0.942-1.00). Sub-analysis of intra-individual temporal measurements of metabolites showed that subsequent increases larger than 35% in plasma normetanephrine over time can signal early stage development of a noradrenergic PPGL.
Conclusions
Plasma free and 24-hour urinary fractionated metanephrines are both reliable screening tests for PPGL in children and adolescents. The plasma panel may be useful for early detection of noradrenergic PPGL relevant for children tested within surveillance programs due to hereditary risk of noradrenergic tumors.

Clinical utility of S-GRAS prognostic system in adrenocortical carcinomas: confirmatory results from a single-centre institutional registry

Erik Bényei[1], Judit Tőke[1,2], Gergely Huszty[3], Katalin Borka[4], Zoltán Sápi[5], Zsuzsanna Jakab[1], Gergely Kiss[6], Ildiko Kalina[6], Péter Resimann[1], Andrea Uhlyarik[1], Péter Igaz[1,2,7] & Miklós Tóth[1,2]
[1]Semmelweis University, Faculty of Medicine, Department of Internal Medicine and Oncology, Budapest, Hungary; [2]Healthcare Provider of European Reference Network on Rare Endocrine Conditions; [3]Semmelweis University, Department of Surgery, Transplantation and Gastroenterology, Budapest, Hungary; [4]Semmelweis University, Department of Pathology, Forensic and Insurance Medicine, Budapest, Hungary; [5]Semmelweis University, Faculty of Medicine, Department of Pathology and Experimental Cancer Research, Budapest, Hungary; [6]Semmelweis University, Faculty of Medicine, Medical Imaging Centre, Budapest, Hungary; [7]Semmelweis University, Department of Endocrinology, Budapest, Hungary

Introduction
Adrenocortical carcinoma (ACC) is a rare tumor known for its diverse biological behaviour and generally poor prognosis. Recently, the S-GRAS scoring system has emerged as an accurate prognostic model, incorporating the most frequently used clinicopathological parameters: ENSAT stage, grade, resection status, age at diagnosis, and tumor symptoms. So far, this system's efficacy has only been validated in extensive multicenter studies, proposing it as a reliable tool for predicting outcomes in ACC patients (Elhassan, 2022).
Aims
We aimed to comprehensively outline the clinicopathological characteristics of patients treated with ACC in our tertiary referral centre. We then aimed to analyse the prognostic value of the computed S-GRAS scores and compare them to prior results on patient outcomes from previous studies. Through this comprehensive demonstration, we aimed to confirm the robustness and applicability of the S-GRAS prognostic system in a single-center study.
Methods
From our ACC patient cohort of 86 patients, we analyzed data of those patients who had fully available data to calculate S-GRAS scores. 54 patients fulfilled this inclusion criteria; all were treated at our centre between January 1, 2000, and August 31, 2022. Mann-Whitney U test was used to compare patient cohort distributions, and survival correlations were analysed using Kaplan-Meier curves with log-rank tests and univariate Cox regression analyses.
Results
The distribution of our patient cohort by S-GRAS score did not differ significantly from the cohort of Elhassan *et al*. (2022). Among the studied characteristics in our analysis, hormone secretion (RR = 2.8, $P = 0.002$), higher ENSAT stages (III and IV) (RR = 9.5 $P = 0.033$ and RR = 13.5, $P = 0.011$), R1 and R2 resection states (RR = 3.0, $P = 0.002$ and RR = 4.7, $P = 0.007$), and a Ki67 index above 20% (RR = 2.7, $P = 0.026$) were associated with an increased risk of mortality. Higher S-GRAS scores (4-5 points and 6-9 points) were found to have a significant negative impact on overall survival (RR = 9.0, $P = 0.005$ and RR = 10.9, $P = 0.002$). The calculated hazard ratios corresponded well to those reported in the analyses of prior multicentre studies.
Conclusion
Preoperative hormone secretion, higher ENSAT stages, R1/R2 resection states, and a Ki67 index above 20%, were associated with an increased risk of mortality. The S-GRAS scoring system emerged as a powerful tool for prognosis, as confirmed by our single-center study with consistent results from a relatively modest patient cohort. Our findings reaffirm the reliability and applicability of the S-GRAS system in diverse clinical settings, even in limited size cohorts.

Psychometric parameters and quality of life in patients with adrenal tumours

Elisavet Charikleia Tasouli, Chrysoula Mytareli, Evangelia Andreadaki, Foteini Thanasoula, Vasiliki Siampanopoulou, Athina Karabela, Petros Papalexis, Alexandros Lafioniatis & Anna Angelousi
Unit of Endocrinology, First Department of Internal Medicine, Laikon General Hospital, National and Kapodistrian University of Athens, Athens, Greece

Introduction
Neuropsychiatric disorders are common and well-studied in patients with overt hypercortisolism. However, data regarding patients with adrenal incidentalomas (AIs) are limited. The aim of our study is to assess the psychometric and quality of life status in individuals with benign adrenal tumours.
Methods
Eighty-two patients diagnosed with AIs, encompassing 53 females and 29 males, with a total mean age of 64 years and 52controls (without AI in computed tomography scan) were included. Functional profile was based on a complete hormonal work-up including serum levels of cortisol at baseline at 8:00 am and post-1 mg overnight dexamethasone suppression test (ODST), adrenocorticotropic hormone (ACTH) levels, plasma renin activity and aldosterone levels, adrenal androgens and catecholamines levels. Psychometric analysis and quality of live status were evaluated based on established generic questionnaires, such as the European Quality of Life (EuroQoL-5D-5L) and the Depression, Anxiety, Stress Scale (DASS-21). Oncological patients were excluded.
Results
Based on the ODST cortisol levels, patients were categorized into three distinct groups: Group 1 was consisted of patients with non-functional AIs (NFAIs) exhibiting ODST cortisol levels below 1,8 μg/dl ($n = 42$), group 2 included patients with possible autonomous cortisol secretion (PACS) with cortisol levels ranging between 1.8-3 μg/dl ($n = 23$) and group 3 included patients with

autonomous cortisol secretion (ACS) with cortisol levels above 3µg/dl ($n=14$). Statistical analysis revealed a statistically significant difference in the overall DASS scores among the three groups (p-value <0.0001). Post-hoc tests revealed specific group differences, with ACS patients presenting higher total DASS score compared to NFAIs (28.5 ± 13.3 vs 10.4 ± 8.5, $P<0.001$) and compared to PACS patients (28.5 ± 13.3 vs 20.65 ± 8,63, $P=0.048$). Significant difference was also shown between NFAIs and PACS (10.98 ± 8.4 vs 20.65 ± 8.63, $P=0.04$). Controls presented lower DASS score compared to NFAIs (4.93 ± 7.37 vs 10.98 ± 8.4, $P=0.046$). These findings were corroborated by the validated EuroQoL domain reflecting compromised anxiety and depression.

Conclusion

The results of our study showed that individuals with AIs even those without overt Cushing syndrome (PACS and NFAI) might exhibit mental impairment or psychological consequences, highlighting the significance of screening for these disorders besides the well-studied metabolic abnormalities.

In vitro differentiation of mouse pluripotent stem cells into glucocorticoid-producing adrenocortical cells

Ioannis Oikonomakos[1,2], Yasmine Neirijnck[2], Melina Tedesco[2], Fariba Jian Motamedi[2], Serge Nef[3], Stefan Bornstein[1,4], Charlotte Steenblock[1] & Andreas Schedl[2]

[1]University Hospital Carl Gustav Carus Dresden, Department of Internal Medicine III, Dresden, Germany; [2]Institute Of Biology Valrose - iBV, Nice, France; [3]University of Geneva, Department of Genetic Medicine and Development, Geneva, Switzerland; [4]King's College London, Faculty of Life Sciences & Medicine, United Kingdom

The adrenal cortex, a pivotal endocrine regulator governing body homeostasis, metabolism, and stress response through steroid hormone synthesis, presents formidable challenges for effective replacement in disorders like adrenal insufficiency and congenital adrenal hyperplasia. The limitations of current hormone replacement strategies stem from the intricate dynamics of hormonal release. This study harnesses insights derived from the analysis of a recently published single-cell atlas of the mouse to establish a robust differentiation protocol for mouse embryonic stem cells (mESCs) into adrenocortical-like cells. Key findings reveal the expression of critical adrenal progenitor markers (*Gata4, Wt1, Nr5a1, Mc2r*) during the differentiation of the cells. Furthermore, we identified Tenascin and Fibronectin as pivotal extracellular matrix proteins influencing adrenocortical development. Notably, culturing cells on Fibronectin during differentiation enhanced the expression of NR5A1, the master regulator of steroidogenesis. In parrarel, we saw that by employing 3D aggregates in microwell culture induced the expression of essential steroidogenic enzymes, including the adrenocortical-specific enzymes *Cyp21a1* and *Cyp11b1*. Importantly, these aggregates demonstrated the production and secretion of glucocorticoids, validating specific differentiation towards the adrenocortical lineage. Crucially, no gonad-specific steroids were detected in the medium, affirming the specificity of the differentiation protocol. This study provides insights into the extracellular matrix supporting adrenocortical development and outlines a step-wise protocol for differentiating mouse ES cells into glucocorticoid-producing adrenocortical cells. The directed differentiation of pluripotent stem cells offers a promising avenue for innovative cell replacement therapies, holding potential for a lasting cure in patients with adrenal disorders.

Chronotype and sleep parameters are different in patients with primary adrenal insufficiency compared to controls

Lakshmi Kalathinkunnath[1], Jozsef Arato[1], Hannes Beiglböck[2], Michael Krebs[2], Fani Sentinella Jerbic[1], Till Roenneberg[3], Alexandra Kautzky-Willer[2], Helmut Leder[1], Kristin Tessmar-Raible[1] & Peter Wolf[2]

[1]University of Vienna, Wien, Austria; [2]Medical University of Vienna, Wien, Austria; [3]Ludwig Maximilian University of Munich, München, Germany

Background

Human chronotypes can be defined as the natural preference for specific wake and sleep times, as measured by the start and end of sleep on days without temporal restrictions. They are a consequence of the circadian clock individual periods. Cortisol is a key mediator for the rhythmic expression of circadian signals in almost all tissues. Physiological timing of cortisol levels is strictly regulated by the hypothalamic-pituitary-adrenal (HPA) axis. Diseases affecting HPA signaling might therefore have important consequences on the individual's chronotype. We therefore investigated patients with primary adrenal insufficiency with stable hydrocortisone replacement therapy.

Methods

In this exploratory pilot study, 20 patients with autoimmune adrenilitis and 40 control subjects of comparable age (54.53 ± 18.42 vs 48.56 ± 15.5 years) and sex (14f/6m vs 32f/8m) were assessed for their chronotypes using the Munich Chronotype Questionnaire for at least four times. They were also requested to constantly wear an actimetry device for 12 weeks, that monitored their sleep, temperature and light reception in this time frame. F-tests were applied to test for variability in sleep parameters and chronotypes between patients and controls, and a one-way ANOVA was applied to test for significant difference between means of sleep onset of the two cohorts.

Results

We observed high variability in sleep onset (F statistic $=1.876$, $P<0.001$) and sleep duration (F statistic $=2.496$, $P<0.001$) for patients in comparison to controls. The mean value for sleep onset were also observed to be earlier for patients (mean = 131.708 minutes) in comparison to controls (mean = 155.803 minutes) (confirmed with one way ANOVA, statistic $=29.842$, $P<0.001$). Chronotypes of patients showed high variability in comparison to controls (F statistic $=2.192$, $P=0.008$). In addition, the patient population also seemed to show a numerically later sleep onset on the weekends, which is not compensated by increased duration of sleep on the next day.

Discussion

The changes in chronotype and sleep onset in patients with primary adrenal insufficiency are likely caused by glucocorticoid replacement and possibly additional hormonal alterations. Improved awareness of their sleep variability and more controlled sleep/wake schedules, as well as illumination can likely improve the patients' life quality. Possibly associated clinically relevant effects on cardiovascular risk factors remains to be investigated in future experiments.

Description of the x-linked adrenoleukodystrophy cohort from the csur unit of adult metabolic disorders at virgen del rocio university hospital (seville)

Lucía González Gracia, Elena Dios Fuentes, Rosa Benítez Ávila, Bothayna Oulad Ahmed, Alfonso Soto Moreno & Eva Venegas Moreno

Virgen del Rocío University Hospital, Sevilla, Spain

Introduction and Objective

X-linked adrenoleukodystrophy (X-ALD) is a rare disease caused by a mutation in the ABCD1 gene (Xq28). It is characterized by the absence of very long-chain fatty acids (VLCFAs) degradation, leading to their accumulation primarily in the central and peripheral nervous system, adrenal cortex, and gonads. It presents a variable clinical spectrum and prognosis. The aim of our study is to describe the characteristics of all X-ALD patients under follow-up at the Adult Inborn Errors of Metabolism Unit at Virgen del Rocio University Hospital (Seville).

Methods

Retrospective observational study. The following variables were collected: gender, current age and age at diagnosis, symptoms, age of symptom onset, and treatment (dietary, pharmacological, hematopoietic cell transplantation [HCT], and gene therapy). Quantitative variables are expressed as median [p25-p75], and qualitative variables as n(%).

Results

21 patients. 10 (47.6%) were males. Patients had a median age of 39.2 [23.9-53.8] years and were diagnosed at a median age of 7.1 [21.3-50.13] years. The most frequent mutation was c.971G > A (p.Arg324His). Regarding males, 7 (70%) were diagnosed as index cases, and 8 (80%) were symptomatic, with a median onset of symptoms at 14.5 [4-50.5] years: 60% adrenal insufficiency, 30% cerebral involvement, 30% myeloneuropathy, and 10% gonadal insufficiency. Concerning females, 10 out of 11 (90.9%) were diagnosed due to having an affected family member, and 4 (36.3%) had symptoms, with a median onset at 45 [41.5-56] years: 27.2% myeloneuropathy, 9.1% premature ovarian failure, and 0% adrenal insufficiency. 81% had elevated VLCFAs at diagnosis (90% of males and 72.7% of females): C22 52 [28-65] µmol/l, C24 59 [41-67] µmol/l, C26 1.51 [0.86-2.12] µmol/l, C24/C22 1.24 [0.95-1.45], and C26/C22 0.029 [0.016-0.063]. Regarding treatment, 8 (38.1%) follow a saturated fat-restricted diet, 4 (19%) take Lorenzo's oil, 6 (28.4%) hydrocortisone, 5 (23.8%) fludrocortisone, and 1 (4.8%) testosterone. One male underwent HCT, and another received gene therapy, with clinical stability of cerebral lesions in both patients. There was 1 death of a male during follow-up.

Conclusions
In our cohort, adrenal insufficiency is the most frequent symptom in males, and a high percentage of females exhibit some symptoms. Communicating data from X-ALD patient series is essential to understand the clinical spectrum of the disease and the true prevalence of symptomatic females.

Redefining diagnostic cut-offs for the indirect water deprivation test

Yash Akkara[1], Kate Lazarus[2,3], Kavita Narula[2,3], Sirazum Choudhury[3,4], Debbie Papadopoulou[3], Niamh Martin[2,3] & Karim Meeran[2,3]
[1]Imperial College London, london, United Kingdom; [2]Imperial College London, United Kingdom; [3]Imperial College Healthcare NHS Trust, United Kingdom; [4]Imperial College London, Division of Diabetes, Endocrinology and Metabolism, Department of Metabolism, Digestion and Reproduction, United Kingdom

Background
The water deprivation test serves as a key diagnostic test to differentiate between Arginine Vasopressin Deficiency (AVP-D), Arginine Vasopressin Resistance (AVP-R), and Psychogenic Polydipsia (PP) in patients presenting with symptoms of polydipsia and polyuria, when common causes such as diabetes mellitus have been excluded. This study evaluated the established diagnostic values for serum osmolality, serum sodium, and urine osmolality.
Methods
This retrospective analysis assessed 135 patients who underwent a water deprivation test between August 2014 and August 2023. All patient diagnoses were reviewed by an expert panel. Variability and receiver operating characteristic (ROC) curves were determined for serum osmolality, serum sodium and urine osmolality, to determine the effectiveness of the current interpretation reference ranges.
Results
A total of 120 patients were included in the study analysis. Use of serum sodium demonstrated reduced variability compared with serum osmolality (0.722% vs 1.16% respectively, 37.5% reduction; $P < 0.001$). Use of the standard serum osmolality cut-off value of ≥ 300 mOsm/kg in diagnosing AVP-D, AVP-R, and PP achieved a sensitivity of 76.19% and specificity of 76.92%. Use of a serum sodium cut-off value of ≥ 148 mmol/l demonstrated 100% specificity in excluding PP. This cut-off was used in tandem with urine osmolality cut-off values of > 630 mOsm/kg (for PP) and < 383 mOsm/kg (for AVP-D and AVP-R). Review of post-desmopressin urine osmolality changes and clinical monitoring was performed in equivocal diagnostic cases ($n = 6$), achieving both 100% sensitivity and 100% specificity within the study sample.
Conclusions
This study demonstrates that use of a serum sodium cut-off value of ≥ 148 mmol/l in combination with urine osmolality yields the best diagnostic accuracy to differentiate between arginine vasopressin deficiency, arginine vasopressin resistance, and psychogenic polydipsia. Serum sodium is superior to serum osmolality, demonstrating lower total variability (including biological and analytical variability).

Jaw Tumor syndrome revealing hyperparathyroidism: about a case report

Neima Hassan, Hind Ouakrim, Sana Rafi, El Mghari Ghizlane & Nawal El Ansari
Centre Hospitalo-Universitaire Mohammed VI Marrakech, Endocrinolgist, Marrakech

Introduction
Hyperparathyroidism is a common medical condition, but in 5-10% of cases, it is part of Jaw Tumor syndrome, an autosomal dominant syndrome linked to a mutation in the HRPT2 gene. This syndrome is characterized by the presence of mandibular brown tumors and primary hyperparathyroidism.
Case report
A 24-year-old patient with a history of severe chronic renal failure in the left single kidney, presenting ureterohydronephrosis, underwent mandibular surgery for a brown tumor exhibiting histological characteristics of bony giant cells. Clinically asthenia, nausea, abdominal pain, constipation, and bone pain, Tachycardia:110 beats/min and painless mass in the right mandible, Laboratory tests indicated primary hyperparathyroidism with corrected serum calcium: 94 mg/l, serum phosphorus of 12.41 mg/l, and PTH:790 pg/ml. Scintigraphic examination showed focal retention of MIBI-Tc99m in the left and right thyroid lobes, measuring 6.7 *4.4 mm and 4.4* 4.3 mm, respectively, suggestive of pathological parathyroid tissue. The patient underwent parathyroid tumor resection, and the histopathological study confirmed parathyroid adenoma without signs of malignancy; however, molecular genetic study could not be performed. The patient's clinical and biological conditions improved significantly during the follow-up.
Discussion
Hyperparathyroidism-Jaw Tumor Syndrome is an inherited disorder associated with increased activity of the parathyroid glands. Due to its rare diagnosis, especially considering its familial nature and the elevated risk of parathyroid carcinoma. Genetic studies should focus on identifying mutations in the HRPT2 gene. Hyperparathyroidism in individuals with HPT-JT is commonly caused by a parathyroid adenoma, leading to symptoms such as kidney stones, reduced bone mass, fatigue, muscle weakness, and bone or joint pain. Surgical removal of a parathyroid gland with a tumor, along with jaw tumor removal, may be necessary for treatment.
Conclusion
The presence of recurrent or multiple jaw lesions or the combination of jaw lesions with hyperparathyroidism bone disease on imaging should prompt consideration of HPT-JT. Early detection and treatment of hyperparathyroidism in this context allow for the timely identification of malignant disease and screening of family members.

Adrenal insufficiency due to adrenal involvement in non-hodgkin's lymphoma

Zineb Ait Si Ali, jaddi oussama, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Centre Hospitalo-Universitaire Mohammed VI Marrakech, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
The non-Hodgkin lymphomas (NHL) involve extralymphatic sites more often than does Hodgkin lymphoma; consequently, tumor involvement of almost every abdominal organ has been recorded. Adrenal involvement in patients with NHL may be present at the time of initial assessment. however, adrenal insufficiency as a consequence of adrenal invasion is rare. We report a case of a patient diagnosed with NHL with breast and bilateral adrenal involvement.
Case report
A 41-years-old female patient, diagnosed 2 months before with a 4 cm breast left tumor classified ACR 4, she had excisional biopsy of this tumor. Anatomo-pathological analysis revealed lymphomatous malignant tumor proliferation with immunohistochemical appearance consistent with diffuse B-type NHL. She underwent positron emission tomography (PET) scan which showed intensely hypermetabolic disease within the left mammary and bilateral adrenal glands. a computed tomography (CT) scan of adrenal glands was done showing Well-limited rounded left adrenal nodular lesion measuring 1.1x1.2 cm (42uh) right adrenal gland was normal. The patient reported asthenia with moderate weight loss and anorexia. Clinical examination noted hypotension 89/61mmhg. Blood tests showed normal natremia and kaliemia, Cortisolemia at 8am was low confirming diagnosis of adrenal insufficiency for which she was started on oral hydrocortisone. The patient received 4 courses of chemotherapy. Control PET-CT scan done after revealed complete morphological and metabolic regression of both adrenal and mammary lesions. The response of these adrenal masses to chemotherapy in a manner similar to the response of mammary masse reinforces the impression that the adrenal pathology was indeed due to the non-Hodgkin lymphoma. During follow up Cortisolemia at 8am was within normal range, oral hydrocortisone was discontinued. Regular follow up is maintained.
Discussion
Lymphoma disseminating to both the adrenals is a common cause of bilateral masses. Adrenals are involved in 24% of cases with disseminated NHL in an autopsy study. Adrenal insufficiency was reported only in four cases with adrenal involvement in a series of 127 patients with NHL. Primary NHL of the adrenal gland is extremely uncommon. Breast's malignant lymphoma can present itself as a primary mammary neoplasm or it can involve the breast as part of a generalized

process. Primary NHL of the breast is a rare disease that has been assessed to represent from 0.04–0.52% of all malignant tumors of the breast. In our case we can not propose which organ system was primarily involved, for this reason we presented our case as the NHL involvement mammary and adrenal glands.

A rare case of antiphospholipid syndrome presenting as primary adrenal insufficiency

Catarina Dias Gama[1], Margarida Oliveira[1], Maria Leonor Guia Lopes[1], Carolina Monteiro Antunes[1], Paula Sprovera[1], Bruna Pimentel[1], Mariana Santos[2], Bernardo Marques[1] & João Manuel Sequeira Duarte[1]
[1]Centro Hospitalar de Lisboa Ocidental, Endocrinologia, Diabetes e Metabolismo, Portugal; [2]Centro Hospitalar de Lisboa Ocidental, Reumatologia, Portugal

Introduction
Antiphospholipid syndrome (APS) is a systemic autoimmune disorder known for recurrent arterial and venous thrombotic events. It may involve multiple organ systems, but its impact on the endocrine system is rare. However, the adrenal glands are one of the most susceptible endocrine organs to APS, due to thrombosis, leading to primary adrenal insufficiency (PAI). Most cases are diagnosed in patients with known history of APS.
Case Report
We report the case of 56-year-old male with history of hypertension and dyslipidemia. He was admitted to the Internal Medicine Department with a 2-week history of fatigue, anorexia, nausea, weakness and weight loss (20% in 3 months). Upon admission, he had a low blood pressure (100/54 mmHg). Blood tests revealed anemia (hemoglobin 9.9 g/dl, NR: 12.0-15.0 g/dl), thrombocytopenia (platelets 94 000×10^6/l, NR: 150-400000×10^6/l), elevated activated partial thromboplastin time (76.4 s, NR: 28-40 s) and hyperkaliemia (potassium 7.11 mmol/l, NR: 3.5-5.2 mmol/l). A thoracic computed tomography (CT) scan was performed and revealed a spiculated nodular lesion with 13x8mm, located in the superior left pulmonary lobe. A subsequent positron emission tomography (PET-FDG) scan was done to rule out malignancy but showed, instead, intense uptake in both adrenal glands, with heterogeneity and areas of necrosis, especially in the right adrenal gland. While in the hospital, the patient developed vomiting and postural dizziness. The endocrinology department was consulted, and hormonal assessments revealed a serum cortisol of 1.9 μg/dl (NR: 6.2-19.4 μg/dl) and adrenocorticotropic hormone (ACTH) of 626.0 pg/ml (NR: 7.2-63.3 pg/m). He was started on intravenous hydrocortisone (200 mg/day), with marked improvement on his blood pressure profile, well-being and appetite, as well as remission of nausea and vomiting. Additional tests showed negative 21-hydroxilase antibodies, along with a normal screening for infectious disease (including tuberculosis and human immunodeficiency virus). The remaining etiological investigation revealed positive lupus anticoagulant antibody, anti-nuclear antibody, anti-double stranded DNA antibody, and nucleosome antibody. Based on both clinical (hemorrhage/infarction of the adrenal glands) and laboratory criteria (positive antiphospholipid antibody), he was diagnosed with APS. Upon discharge, the patient was prescribed hydrocortisone (20 mg/day on divided doses), fludrocortisone 0.05 mg/day and warfarin with dose adjustments following INR (international normalized ratio) measurements. He remains asymptomatic and under regular follow-up. Subsequent MRI scans showed atrophy of the adrenal glands.
Discussion
This is a rare case of APS presenting with bilateral adrenal haemorrhage and subsequent PAI. We would like to highlight this unusual presentation of PAI, in addition to the importance of multidisciplinary teamwork in the diagnosis of such conditions.

Knowledge assessment of patients followed for adrenal insufficiency: a study of 54 cases

Prince Ismael Mbossa Lembopo, Nassim Essabah Haraj, Siham El aziz & Asma Chadli
Faculty of Medicine and Pharmacy, Hassan II University, Endocrinology, Diabetology, Metabolic Diseases, and Nutrition, Casablanca, Morocco

Introduction
Adrenal insufficiency (AI) can pose a life-threatening risk in case of acute decompensation. The absence of specific signs of acute adrenal insufficiency (AAI) and lack of awareness about this medical emergency may lead to diagnostic and therapeutic delays, jeopardizing the patient's prognosis. Hence, the importance of well-conducted therapeutic education for adrenal-insufficient patients. The objective of this study is to assess the level of knowledge among adrenal-insufficient patients regarding the pathology and management of their replacement therapy.
Patients and Methods
A prospective descriptive study was conducted on patients with adrenal insufficiency who had already undergone therapeutic education about the disease. The reassessment was carried out during the subsequent consultation at the Endocrinology Department of the University Hospital Center of Casablanca between 2021-2023. Data analysis was performed using Excel 2017 software.
Results
The study included 54 adrenal-insufficient patients, of whom 64.8% were women. The average age was 38.9 years. Adrenal insufficiency was of peripheral origin in 51.85% (Addison's disease 37%, autoimmune adrenalitis 4.7%, tuberculosis 3.7%, and bilateral adrenalectomy 3.7%) and secondary in 48% (post-corticosteroid therapy 33.33%, antehypopituitarism 14.8%). The definition of adrenal insufficiency was correct in 36% of cases, insufficient in 48%, and no response in 16% of cases, correlating with the level of education. The vital need for treatment was known in 88%, triggers for AAI and management were known in 37%. The average hydrocortisone dose was 30 mg. Episodes of AAI were found in 79.6%, with 44.44% occurring upon treatment cessation. Knowledge of a normosodic diet was present in 33.33%, and awareness of medications to avoid, especially diuretics and laxatives, was observed in 18.5%. All patients received an Addison's card. Therapeutic adherence was observed in 59.2%.
Conclusions
The knowledge of adrenal-insufficient patients remains insufficient. The establishment of a therapeutic education program is necessary to enhance patient understanding.

Prevalence and significance of hypokalemia in primary aldosteronism: a retrospective study

Siddiqa Soomauroo[1], Faten Hadjkacem[1], Abdelmuhaymen Missaoui[1], Ahmad Ridwaan Auckburally[2], Souhir Maalej[1], Wiem Feki[2], Zeinab Mnif[2], Mouna Mnif[1], Mohamed Abid[1] & Nabila Rekik[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Department of Radiology, Sfax, Tunisia

Introduction
Primary hyperaldosteronism (PA) is the autonomous production of aldosterone by a disease primarily affecting the glomerular zone of the adrenal gland. It is one of the most frequent causes of secondary hypertension. The diagnosis should be suspected in the presence of the classic clinico-biological triad in patients presenting with hypertension, low plasma renin activity (PRA), with or without hypokalemia.
Patients and Methods
Retrospective and descriptive study concerning 40 patients with PA, collected in the endocrinology department of the Hedi Chaker University Hospital of Sfax, over the period of 10 years from January 2010 to December 2022.
Results
The average age of our patients was 55.4 years. They were composed of 16 men and 24 women. In 32% of cases, hypertension was recent, evolving for less than than 5 years. Severe hypertension was found in 11 cases. Hypokalemia was noted in 19 cases (47.5%), symptomatic of asthenia in the majority of cases (60%). Analytical study of the correlation between serum potassium levels and plasma aldosterone concentration (PAC) showed that 15 of these patients had PAC above 200 pg/ml. As PAC increased, so did the number of patients with hypokalemia, with a correlation coefficient $r=$-0.350, $P=0.027$. The threshold of the PAC was studied by the ROC curve. A PAC level above 199 pg/ml was predictive of hypokalemia with a sensitivity of 78.9% and specificity of 66.7%. Following specific treatment of the PA (surgery or spironolactone), a significant increase in mean kalemia was observed during patient follow-up ($P<0.001$) compared with kalemia on admission.

Conclusion
Contrary to initial data, normokalemic rather than hypokalemic PA is the most frequent form of hyperaldosteronism. Hypokalemia is neither a sensitive nor a specific marker for the diagnosis of PA. Nevertheless, its presence can help to identify a severe form of the disease, and therefore recognise patients at particularly high cardiovascular risk.

Primary aldosteronism: insights from a single center cohort

Siddiqa Soomauroo[1], Faten Hadjkacem[1], Abdelmuhaymen Missaoui[1], Ahmad Ridwaan Auckburally[2], Souhir Maalej[1], Wiem Feki[2], Zeinab Mnif[2], Mouna Mnif[1], Mohamed Abid[1] & Nabila Rekik[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Department of Radiology, Sfax, Tunisia

Introduction
Primary aldosteronism (PA) is commonly identified as the main cause of secondary hypertension. It is becoming increasingly wide-spread, affecting between 1 and 30% of people suffering from hypertension. We aim to describe the epidemiological, clinical and paraclinical characteristics of PA and to analyse its therapeutic and evolutionary aspects.
Patients and methods
Retrospective and descriptive study concerning 40 patients with PA, collected in the endocrinology department of the Hedi-Chaker University Hospital of Sfax, over the period of 10years from January 2010 to December 2022.
Findings
The average age of our patients was 55.4 years. They were composed of 16 men and 24 women. In 32% of cases, hypertension was recent, evolving for less than than 5 years. Severe hypertension was found in 11 cases and resistant hypertension in 4 others. Hypokalaemia was noted in 47.5% of cases, symptomatic of asthenia in the majority of cases (60%). The mean plasma aldosterone concentration was 250 pg/ml. The mean plasma renin concentration was 3.98 pg/ml, below 4.6 pg/ml in 28 cases. The aldosterone to renin ratio was greater than 23 in all cases, with a mean level of 41. The etiology of PA was dominated by bilateral adrenal hyperplasia (BAH) in 20 cases, aldosterone-producing adenoma in 17 cases and unilateral adrenal hyperplasia in 2 cases. One patient had a malignant adrenocortical carcinoma secreting aldosterone (ACC). Fourteen patients had cardiovascular involvement, characterized by electrical left ventricular hypertrophy and/or hypertrophic cardiomyopathy on echocardiography, and/or evidence of coronary insufficiency. Surgical treatment consisted of unilateral adrenalectomy in 8 cases. Twenty-eight patients were treated medically with spironolactone. The course of the disease was favourable with a reduction in the number of antihypertensive treatments. Follow-up of patients observed blood pressure control and normalization of potassium levels in all cases except the case of the malignant ACC, who died of a massive pulmonary embolism.
Conclusion
PA is an underdiagnosed cause of hypertension. Although it is traditionally associated with hypertension and low potassium levels, many patients with PA do not exhibit hypokalemia. The recommended treatment for those with unilateral disease is adrenalectomy. However, individuals who are unfit for surgery or have BAH can undergo medical treatment using mineralocorticoid antagonists alongside antihypertensive medications to better manage blood pressure. We highlight the need for early detection of PA and appropriate management of all hypertensive patients with cardiovascular comorbidities and/or metabolic syndrome, among others, in order to attenuate the harmful effects of excess aldosteronism.

Do non-functional adrenal incidentalomas present a higher cardiovascular risk?

Sabrina Ayari, Nadia Khessairi, Cherchir Faten, Elyes Kamoun, Fatma Chaker, Meriem Yazidi, Oueslati Ibtissem & Chihaoui Melika
RABTA Hospital, Tunis, Tunisia

Introduction
Non-functioning adrenal incidentaloma (NFAI) is a frequently diagnosed since the increased use of radiological examinations. The recent studies have shown that NFAI might have negative cardiometabolic effects and increased cardiovascular risk. The aim of this case control study was to determine the relationship between NFAI, CRP-hs, uric acid and cardiovascular risk (CVR) based on GLOBORISK algorithm of Tunisia.
Methods
This case-control study included 40 NFAI patients (16 men, 24 women, mean age 52.9 ± 11.2 years) and 40 individuals (17 men, 23 women, mean age 56.8 ± 8 years) in the control group matched for age, sex, and weight. NFAI diagnosis was established according to current guidelines. Patients with mild autonomous cortisol secretion, chronic kidney disease, liver failure or under hypolipidemic drugs, combined contraceptive pills or alcohol were excluded of this study. All participants underwent physical examination, adrenal imaging, biochemical evaluation including baseline cortisol, CRP-hs, lipid profile, uric acid, and fasting plasma glucose (FPG). All participants underwent the assessment of the 10-year risk of cardiovascular mortality based on the GLOBORISK algorithm of Tunisia.
Results
NFAI presented higher basal cortisol level (10.4 µg/dl (8.0-13.2) vs 8.0 µg/dl (7.0-10.6), $P=0.007$), higher uric acid level (51.8 ± 15.3 mg/l vs 43.3 ± 11.2 mg/l $P=0,009$) and higher CRP-hs (2.5 mg/l (1.3-4.6) vs 0.9 mg/l (0.43-1.98), $P<10^{-3}$) compared to control group. Using the GLOBORISK algorithm, NFAI didn't present a higher cardiovascular risk compared to controls. Age ($r=0.692$, $P<10^{-3}$) and systolic hypertension ($r=0.384$, $P=0.014$) were positively correlated to a higher CVR in NFAI patients. Basal cortisol level superior to 10 µg/dl and uricemia superior to 55 mg/l were associated with elevated CVR with odds ratios of 3.73 (95% CI:1.02-14.23) and 5.14 (95% CI:1.29-20.52) respectively.
Conclusion
This study confirms that cardiovascular remodelling in asymptomatic patients with NFAI can be detected in early stages. Therefore, NFAI having higher cardiovascular risk should be monitored regularly.

Impact of 10 years of conventional steroids vs dual-release hydrocortisone on metabolic, cardiovascular, and bone outcomes in treatment-naïve patients with adrenal insufficiency

Valentina Guarnotta, Claudia Di Stefano, Laura Tomasello, Giuseppe Pizzolanti, Giorgio Arnaldi & Carla Giordano
Università degli Studi di Palermo, PROMISE Department, section of endocrinology, Palermo, Italy

Patients with adrenal insufficiency show higher mortality than in the general population, mainly due to non-physiological daily glucocorticoid overexposure and to inadequate cortisol exposure during stress-related events and illness. The aim of the current study is to compare the impact of 10 years of conventional glucocorticoid (GC) replacement treatment and dual-release hydrocortisone (DR-HC), on anthropometric, metabolic, cardiovascular and bone outcomes in treatment-naïve patients with primary adrenal insufficiency (PAI) and secondary adrenal insufficiency (SAI). Forty patients (19 with PAI and 21 with SAI) were randomly allocated to conventional GCs (cortisone acetate or hydrocortisone) administered two or three times a day and 43 (20 with PAI and 23 with SAI) on dual-release hydrocortisone (DR-HC). Anthropometric, metabolic, cardiovascular and bone parameters were evaluated at baseline and after 5 and 10 years of follow-up. All patients enrolled completed the study. Among patients with PAI, one patient developed hypothyroidism after 2 years from the diagnosis of adrenal insufficiency and another patient developed type 1 diabetes mellitus after 1 year from diagnosis of adrenal insufficiency. Patients with SAI mainly had stable control for other pituitary insufficiencies during 10 years of treatment. In patients treated with conventional GCs, a trend of significant increase in BMI ($P=0.040$), waist circumference (WC) ($P=0.001$), systolic and diastolic blood pressure ($P=0.017$ and $P=0.035$), HOMA-IR ($P=0.035$), area under curve-2 hours (AUC_{2h}) of insulin and glucose ($P=0.018$ and $P=0.003$), and a trend of significant decrease in oral disposition index (DIo) ($P=0.025$) and Isi-Matsuda ($P=0.043$) were observed at 5 and 10 years of follow-up. In patients treated with DR-HC, a trend of significant decrease in triglycerides and LDL cholesterol ($P=0.034$ and $P=0.032$, respectively) was observed after 5 and 10 years of follow-up compared to baseline. At 10 years of follow-up, patients with conventional GCs had significantly higher values of BMI ($P=0.031$), WC ($P=0.047$), systolic blood pressure ($P=0.039$), total and LDL cholesterol ($P=0.041$ and $P=0.042$), HbA1c ($P=0.040$), HOMA-IR ($P=0.006$), AUC_{2h} of glucose ($P<0.001$), thickness of the interventricular septum in diastole and of the posterior wall (both $P<0.001$) and significantly lower values of DIo ($P=0.001$) and ISI-Matsuda ($P<0.001$), lumbar spine T score ($P=0.036$) and

femoral neck Z score ($P=0.026$), compared to patients treated with DR-HC. In patients with treatment-naïve AI, 10 years of therapy with conventional GCs was associated with a worsening of metabolic, cardiac and bone outcomes, while DR-HC had no impact on them achieving a lower risk of developing comorbidities.

Incidence and features of adrenal crisis in patients with Addison's Disease

Alberto Scala[1], Marianna Torchio[1], Fabio Presotto[2], Caterina Mian[1], Filippo Ceccato[1], Scaroni Carla[1], Corrado Betterle[1] & Chiara Sabbadin[1]
[1]University Hospital of Padua, Endocrine Unit, Padua, Italy; [2]Ospedale Dell'Angelo, Unit of Internal Medicine, Mestre-Venice, Italy

Introduction
Adrenal crisis (AC) is the most severe manifestation of adrenal insufficiency, still responsible for a high mortality of affected patients, especially with primary adrenal insufficiency (PAI). Its presentation is insidious, leading to a delayed diagnosis and treatment. Patient education is crucial in the prevention and self-management of AC.
Aim of the study
We want to evaluate the incidence, features (symptoms, signs, laboratory findings), precipitating and predisposing factors of AC.
Methods
A total of 132 patients with PAI were enrolled. Patients' characteristics and information on their previous AC were collected through a questionnaire and clinical documentation, supplied by patients or retrieved from archives of the Hospitals of Padova and Venice-Mestre.
Results
Among our patients, the most frequent cause of PAI was autoimmune adrenalitis (92.4%), mainly associated with other autoimmune comorbidities. The 65.9% of patients experienced at least one AC, with an incidence of 10.5/100 patient-years. In 55% of cases, AC occurred after the diagnosis of PAI. The most frequent symptoms and signs of AC were fatigue (96%), gastrointestinal disorders (39-85%), hypotension (57%), and hyperpigmentation (57%). Hyponatremia and hyperkalemia were found respectively in 77% and 32% of cases of AC. The most frequent trigger factors were vomiting and diarrhea (65%), infections (38%) and emotional stress (29%). Patients with a high number of autoimmune comorbidities and those with premature ovarian insufficiency (POI) had a significantly higher risk of AC ($P<0.02$).
Conclusions
AC is still a frequent complication of patients with PAI, especially when affected with other autoimmune comorbidities or with POI. AC awareness among clinicians, patients, and their care-givers is critical to prevent, recognise and adequately treat this life-threatening complication.

Circadian fluctuation of amino acids and biogenic amines in health and in hypercortisolism states

Guido Di Dalmazi, Flaminia Fanelli, Lorenzo Tucci, Valentina Bissi, Greta Galante, Ilaria Improta, Alessandro Perrone, Kimberly Coscia, Giacomo Colombin, Valentina Vicennati, Uberto Pagotto & Guido Di Dalmazi
University of Bologna, Department. of Medical and Surgical Sciences, Bologna, Italy

Background
Chronic hypercortisolism is known to alter the circadian rhythm and to impair protein metabolism. Altered amino acid (AA) and biogenic amine (BA) levels were found in basal blood in patients with hypercortisolism. However, poor information is available on the physiologic circadian fluctuation of these molecules. Furthermore, the potential derangement caused by hypercortisolism was never investigated.
Aim
To characterize diurnal levels and fluctuations of AA and BA in convenient dried blood spots (DBS) from finger-prick in healthy subjects (HS) and in patients affected by autonomous cortisol secretion (ACS) or Cushing syndrome (CS).
Methods
HS (38.0 ± 15.5 y; $n=9$), ACS (64.8 ± 8.4 y; $n=6$) and CS (53.4 ± 8.0 y; $n=5$) patients underwent a 7-days standardized isocaloric Mediterranean diet. On the 7th day, subjects collected DBS at 7 time-points: 30 min before and 2 h after breakfast, lunch and dinner, and at bedtime. 21 AA and 21 BA were measured in DBS by LC-MS/MS.
Results
Compared to HS, ACS patients had lower His ($P=0.026$), while CS patients had lower Asn ($P=0.030$) and higher spermidine ($P=0.003$). CS also had higher spermine ($P=0.028$) and t4-OH-Pro ($P=0.032$) compared to ACS patients. A daily rhythm was detected in HS for 11 AA (Met, Leu, Ile, Arg, Cit, Glu, His, Pro, Trp, Val; P:0.001-0.037) and Met-SO (P:0.010), mostly with levels higher at awakening and bedtime, and lower in the morning (positive quadratic trend). Of these, some maintained their rhythm also in ACS (Ile, Leu, Trp, Val, Met-SO; P:0.043); however, only Leu maintained a similar rhythm in CS patients (P:0.006). Fluctuation of other compounds were found in ACS (Gly, His, Lys, Orn, Phe, Ser, Thr, t4-OH-Pro; P:<0.001-0.006) and in CS (asymmetric-dimethylarginine (ADMA), creatinine, spermine; P:0.003-0.018) with variable trends. AUCs of Arg (R:0.632, P:0.037), spermidine (R:0.743, P:0.009), spermine (R:0.729, P:0.011) and taurine (R:0.788, P:0.004) were directly correlated with post-dexamethasone test cortisol. AUCs of ADMA (R: -0.513, P:0.030) and Orn (R:-0.573, P:0.013) were negatively associated with fat free mass.
Conclusions
A panel of AA displayed a physiologic diurnal fluctuation consistent with day/night protein anabolic/catabolic processes. Daily fluctuations were revealed in ACS for a different panel of AA, and were almost all lost in CS. ACS and CS also showed disease specific fluctuations in some BA. Finally, ACS showed a deranged histidine metabolism, whereas CS showed an enhanced polyamine pathway.

Radiomics for immunohistochemistry prediction in pheochromocytoma: a pilot study

Lorenzo Tucci[1,2], Antonio De Leo[1,3], Giulio Vara[4,5], Kimberly Coscia[1,2], Saverio Selva[6], Claudio Ricci[1,6], Laura Alberici[6], Caterina Balacchi[7], Donatella Santini[3], Valentina Vicennati[1,2], Uberto Pagotto[1,2], Cristina Mosconi[1,7], Giovanni Tallini[1,3] & Guido Di Dalmazi[1,2]

Orsola-Malpighi Polyclinic, Division of Pancreatic and Endocrine Surgery, Bologna, Italy; [7]IRCCS S. Orsola-Malpighi Polyclinic, Diagnostic and interventional abdominal-pelvic radiology Unit, Bologna

Background
Radiomics, or texture analysis, is gaining growing interest for its high prediction performances, mainly for clinical purposes. Radiomics application for pheochromocytoma immunohistochemistry (IHC) and molecular biology prediction is still unexplored.
Aim
To evaluate radiomics ability to predict pheochromocytoma IHC.
Methods
We retrospectively enrolled 38 pheochromocytoma who underwent surgery at Sant'Orsola-Malpighi Polyclinic since 1999 to 2023 with availability of pre-surgery basal computerized tomography (CT) scan and post-surgery IHC results on formalin-fixed, paraffin-embed tissues. IHC for Succinate Dehydrogenase Subunit A (SDHA), B (SDHB) and Somatostatin Receptor 2 (SSTR2A) was performed using Ventana Benchmark Ultra (©Roche Ventana Medical System, USA). IHC scores ranged from 0 (negative) to 3 (strongly positive). Texture analysis was performed on CT basal scan with LifeX software (version 7.2.0, ©LITO, France). Logistic regression was used to assess texture analysis ability to predict IHC scores. Sensitivity, specificity, negative (NPV) and positive predictive value (PPV) of significant predictors were estimated through receiver operating characteristic curve analysis.
Results
0 patients displayed SDHA negativity, 5 patients displayed SDHB negativity, 27 patients displayed SSTR2A IHC positivity. A model including Maximum Grey

Level and Strength predicted SDHB negativity (Odds Ratio (OR): 2.743; 95% Confidence Interval (CI): 1.544 – 4.873; $P<0.001$) with sensitivity 100.0%, specificity 60.6%, NPV 100.0%, PPV 28.0%. A model including Zone Percentage predicted SSTR2A positivity (OR: 2.718; CI: 1.435 – 5.149; $P<0.001$) with sensitivity 77.8%, specificity 80.0%, NPV 57.0%, PPV 91%. A model including Joint Maximum predicted SSTR2A score equal to 3 (OR: 2.718; CI: 1.509 – 4.896; $P<0.001$) with sensitivity 87.5%, specificity 65.5%, NPV 95.0%, PPV 41.2%. A model including Maximum Grey Level and Strength predicted the combination of SDHB negativity and SSTR2A positivity (OR: 2.689; CI: 1.439 – 5.024; $P<0.001$) with sensitivity 75.0%, specificity 93.0%, NPV 96.9%, PPV 75.0%.

Conclusion

Radiomics has shown good performance in predict pheochromocytoma IHC. These findings, if confirmed with wider and prospective studies, may open a new scenario for radiomics. Hence, in the context of pheochromocytoma, texture analysis may reflect pathological molecular pathways, absence or presence of somatic mutations and the individuation and selection of potentially sensitive tumours to nuclear medicine test or treatment.

Adrenocortical carcinomas (ACC) overexpress the insulin-like growth factor 2 (IGF2) that drives a proliferative autocrine loop by binding both IGF1R and isoform A of insulin receptor (IRA). However, the contribution of these receptors in mediating ACC cell growth has been poorly investigated. The aim of this study was to investigate IGF1R and IR expression and localisation in ACC and adrenocortical adenomas (ACA) samples, and to test their involvement in mediating IGF2 tumorigenic effects in ACC cells. To this end, we used four available cell lines and ACC primary cultures. Immunohistochemistry analysis on a cohort of ACC ($n=116$) and ACA ($n=17$) revealed that IGF1R was expressed in 85.3% of ACC and in all ACA. No difference in mean percentage of IGF1R positive cells, but a higher IGF1R plasma membrane localisation was observed in ACC (47.5%) compared to ACA (17.6%) ($P<0.05$). In ACC, IGF1R plasma membrane localisation was associated with a higher Ki67 ($P<0.01$), Weiss score ($P<0.001$) and among Weiss criteria, with a higher mitotic rate, presence of atypical mitoses and venous invasion. Moreover, IGF1R plasma membrane localisation showed a 7.5-fold increased risk of having Ki67 ≥ 10 ($P<0.01$). IR protein expression was found in 45.65% of ACC and in all ACA ($P<0.001$). In ACC, IR immunopositivity was associated with higher ENSAT stage, Ki67, Weiss score and a major risk of having a Ki67 ≥ 10 ($P<0.05$). RT-qPCR revealed that the prevalent isoform of IR was IRA in ACC ($n=8$), but not in ACA ($n=8$) ($P<0.05$). In ACC cell lines double IGF1R + IR silencing reduced cell proliferation in JIL2266 (-44.95 (16.04)%, $P<0.05$), MUC-1 (-46.31 (13.58)%, $P<0.001$) and TVBF-7 (-42.12 (15.89)%, $P<0.001$), but not H295R. The single IGF1R or IR knockdown inhibited cell growth only in MUC-1 cells. In ACC primary cultures ($n=3$), expressing higher levels of IRA than IRB, cell proliferation was reduced after IR but not IGF1R knockdown ($P<0.05$). In conclusion, we demonstrated that IGF1R plasma membrane localisation is more frequent in ACC than in ACA and is associated with a worse tumour behaviour in ACC. We further found in ACC an association between immunopositivity to IR, whose prevalent isoform is IRA, with more aggressive features. We first demonstrated a role of IR in mediating cell growth in ACC cells. Overall, these data suggest that: 1) IGF1R plasma membrane localisation and IR expression could represent biomarkers of more aggressive tumours; 2) IR, and in particular the spliced isoform IRA, might constitute a novel ACC therapeutic target.

Background

It is known that excessive dietary sodium intake increases cardiovascular risks and contributes to elevated blood pressure. Additionally, a high-salt diet is linked to unfavorable inflammatory immune responses. Notably, individuals with primary aldosteronism (PA) commonly exhibit elevated sodium intake. Despite treatment with mineralocorticoid receptor antagonists (MRA), PA patients do not experience a complete reduction in excess cardiovascular risk compared to hypertensive controls. Hence, this study aims to explore the impact of moderately reducing sodium intake on the gut microbiome composition and immunophenotype in PA patients.

Methods

Conducted as a prospective two-stage clinical trial, we compared 15 PA patients before start of MRA therapy with appropriately matched healthy controls (cohort A). Furthermore, in 31 PA patients on stable MRA treatment for at least three months, we evaluated standardized blood pressure measurements, performed laboratory tests, analyzed peripheral blood mononuclear cells using flow cytometry and collected stool samples for microbiome analysis before and after a three-months intentional reduction in dietary sodium (cohort B).

Results

Our findings unveiled alterations in the immunophenotype of PA patients following a median sodium reduction of 3.7 g/d. In cohort A, we could observe an upregulation of regulatory T cells in patients with PA compared to normotensive controls ($P=0.0072$) as well as a downregulation of Tc2 cells. Abundance of *Bacteroides uniformis* was higher in the subgroup of patients with PA compared to the matched control cohort ($P=0.0123$), while abundance of *Lactobacillus*

species was reduced compared to controls ($P=0.0052$). Sodium reduction in cohort B led to a decrease in the percentage of pro-inflammatory and pro-hypertensive Tc17 cells ($P=0.0008$) with major effects in male PA patients ($P=0.0012$) and in Tc17/Treg ratio ($P=0.0007$). While sodium reduction did not lead to changes in microbiota abundance, abundance of *Bacteroides uniformis* was higher in female compared to male PA patients throughout the study. Abundance of *Bacteroides uniformis* showed a trend to decrease upon MRA treatment and sodium reduction.

Conclusion

Our study suggests a less pronounced inflammatory phenotype in patients with PA treated with moderate dietary sodium restriction. This observed immune modulation could potentially contribute to effective blood pressure reduction and positively impact cardiovascular risk. Recognizing the interplay between sodium intake, immune responses, and cardiovascular health underscores the potential therapeutic implications of dietary interventions in the management of PA and associated cardiovascular risks.

Phenotype variability in intron2 splice variant of CYP21A2 gene – a single-centre pilot study on children and adolescents

Iuliana Gherlan[1,2], Procopiuc Cameliua[2], Madalina Vintila[1,2], Radomir Lidia[2], Andreea Cristiana Brehar[2], Elena Braha[2], Suzana Vladoiu[2], Dana Manda[2], Andrei Muresan[2], Poalelungi Catalina[2] & Sorina Schipor[2]
[1]Carol Davila University of Medicine and Pharmacy, Bucure?ti, Romania; [2]C.I. Parhon National Institute of Endocrinology, Bucure?ti, Romania

Introduction

Congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency (21OHD) is caused by mutations in the CYP21A2 gene, located on the short arm of chromosome 6. Approximately 11 point mutations are responsible for over 90% of cases, with good genotype-phenotype correlations. Depending on the residual 21-hydroxylase activity, three distinct phenotypes (classic salt wasting – SW, classic simple virilising – SV and non-classic - NC) with 4 corresponding genotypes have been described (null, A, B, C). Although usually associated with SW forms, higher variability in phenotype has been described in patients with intron 2 (I2) splice (c.293-13A>G) variant.

Aim

To describe the genotype-phenotype correlation in 21OHD patients with I2 splice variant.

Methods

Between January 2021 and December 2023, 40 children and adolescents with 21-hydroxylase deficiency referred to our centre were clinically and genetically characterised. Multiple ligation-dependent probe amplification (MLPA) method using the MRC-Holland SALSA MLPA P050-C1 kit and Coffalyser.net software were used for the evaluation of copy number variations and several point mutations of the CYP21A2 gene. We used Sanger sequencing (CEQ 8000 Genetic Analysis System, Beckman Coulter) to confirm these variants and to analyse the entire gene sequence in probands and their parents.

Results

I2 splice variant was described in 11 patients (27.5% of 21OHD patients) for a total of 17 alleles (21.25% of all alleles). It was observed in 5 patients in a homozygous state and in another 6 patients in a compound heterozygous state. From the homozygous patients, 3 cases were clinically SW, and the other 2 related patients were clinically expressing NC CAH. The compound heterozygous patients had the same predicted and observed salt-wasting phenotype in patients with I2 splice/p.Arg357Trp and I2 splice/p.Gln319Ter genotype. A case with an expected SV predicted phenotype (I2 splice/p.Ile173Asn genotype) had the same clinically expressed one. The association between I2 splice on one allele and p.Pro454Ser and p.Pro31Leu on the other one led to a predicted NC phenotype, but SV-type clinical manifestations. Instead, patients with I2 splice/p.Pro454Ser and I2 splice/p.Pro31Leu, p.Val282Leu had the same predicted and observed NC phenotype. As a result, the relative frequency of predicted phenotype is 0.71 for SW, 1 for SV and 0.66 for NC phenotype, respectively.

Conclusion

In our group of patients I2 splice allele had a similar incidence to other European populations and a good genotype-phenotype correlation.

EP372

Association of X-linked adrenoleukodystrophy with Gitelman syndrome: a hypothesis to be confirmed by genetics

Najoua Lassoued, Elloumi Yassmine, Baha Zantour, Alaya Wafa & Sfar Habib
Taher Sfar University Hospital, Endocrinology Department, Mahdia, Tunisia

Background

X-linked adrenoleukodystrophy (X-ALD) is the most common peroxisomal disorder. The clinical spectrum in males with X-ALD ranges from isolated adrenal insufficiency (AI) and slowly progressive myelopathy to devastating cerebral demyelination. Gitelman syndrome (GS) is a rare autosomal recessive inherited tubular disease which is caused by mutation in the SLC12A3 gene. It is characterized by hypokalemic alkalosis with hypomagnesemia and hypocalciuria. We report the association of these two rare syndromes in a 17-year-old male patient.

Case Presentation

A 17 years old male patient, intellectually disabled, with familial history of an intellectual disability and deaths at a young age, is hospitalized in the Endocrinology Department for acute AI with good evolution under hydrocortisone. The patient had presented several similar episodes since the age of 2 months. Nevertheless the diagnosis of AI hadn't been made by the pediatricians because of the presence of normokalaemia during the acute episodes and the persistent of hypokalaemia after administration of hydrocortisone. The patient had melanoderma on examination. The neurological examination was normal. The brain MRI was normal. Faced with the male sex and mental debility, a dosage of very long chain fatty acids was requested, returning positive. The diagnosis of X-ALD was therefore retained. The evolution was marked by the persistence of hypokalemia with hyperkaliuresis, hypomagnesemia, hypocalciuriaand metabolic alkalosis raising suspicion of the diagnosis of GS. The genetic study in search of the mutation of the SLC12A3 gene is in progress. The patient was discharged on hydrocortisone and potassium supplementation.

Conclusions

The association of X-ALD with GS has never been reported in the literature. Genetic confirmation should be done before discussing the genetic and molecular mechanisms behind this association.

DOI: 10.1530/endoabs.99.EP372

Backpain as first manifestation of malignant pheochromocytoma. Could stable adrenal incidentaloma transform into malignant pheochromocytoma?

Aleksandra Czapla-Iskrzycka[1], Anna Babińska[1], Tomasz Szmuda[2], Maciej Śledziński[3], Grzegorz Romanowicz[4], Anna Lewczuk-Myślicka[1] & Renata Świątkowska-Stodulska[1]
[1]Medical University of Gdansk, Department of Endocrinology and Internal Diseases, Gdańsk, Poland; [2]Medical University of Gdansk, Department of Neurosurgery, Gdansk, Poland; [3]Medical University of Gdansk, Division of General, Endocrine and Transplant Surgery, Gdansk, Poland; [4]Medical University of Gdansk, Division of Nuclear Medicine, Gdansk, Poland

Malignant pheochromocytomas (MP) are rare form of catecholamine-producing tumours that are usually associated with tachycardia, hypertension and diaphoresis. MP are typically diagnosed by symptoms, elevated catecholamine levels and characteristic radiological imaging. Metastases to the vertebrae are extremely rare and usually appear at late stage of the disease, sometimes years after the diagnosis. Backpain as a first manifestation of MP is unusual, especially with history of stable adrenal mass described as adenoma. A 44-year-old male patient was admitted to endocrinology clinic in November 2023 because of backpain since March 2023. Previously patient sought help at least 3 times at neurologists because of increasing backpain (VAS 9/10) and paraesthesia. He was treated for sciatica. The lumbar spine MRI was prescribed in October – in L1 vertebrae large pathological mass causing spinal canal narrowing with nerve compression and pathological mass of right adrenal gland 64x50mm. Patient was scheduled for neurosurgical decompression, which was cancelled due to pheochromocytoma suspicion, eventually confirmed in vertebral mass biopsy. One-day clinic endocrinological assessment proved elevated chromogranin, catecholamines in evaluation. Patient had a history of stable 15mm right adrenal gland tumour described as adenoma. Due to the backpain worsening and being

bedridden the patient was admitted to our endocrinology clinic. He negated any pheochromocytoma symptoms. Elevation of serum normetanephrine was confirmed. In FDG-PET scan – right adrenal gland tumour with infiltration of inferior vena cava (IVC) and metastases to L1 vertebrae, sacrum, left VII rib, Th1 vertebrae and IV liver segment. Somatostatin analogue (SSA) scintigraphy described primary tumour 84x56mm with metastases in previously found sites and at least 9 more lytic lesions in bones – ribs, vertebrae, skull and pelvic bones, which were not visible in FDG-PET scan. SSA was administered. Patient was transferred to neurosurgery clinic – decompression with carbon implant placement was performed. Then, the patient was admitted to general surgery department –right adrenalectomy with a 130mm-tumour infiltrating the IVC and liver metastasectomy was conducted. The PRRT is scheduled for January 2024. For the time being the patient is walking and without severe pain. The clinical presentation of MP might be atypical and not associated with catecholamine overproduction. It should be remembered that first symptoms might derive from the mass of the metastasis. The treatment of patients with MP needs to be multidisciplinary and requires various and sometimes not standardized approaches. The patient's quality of life must be the most important goal during planning all diagnostic and therapeutic procedures.

Pembrolizumab-induced secondary adrenal insufficiency and thyroid dysfunction in an 81 year old male with metastatic cutaneous melanoma - A Case Report

Kurt Bryan Tolentino[1], Sheryl Tugna[2] & Edison So[2]
[1]St. Luke's Medical Center - Global City, Endocrinology, Taguig, Philippines; [2]St. Luke's Medical Center - Global City, Taguig, Philippines

Immune-checkpoint inhibitors have been increasing used in the field of medical oncology for treatment of various early to late-stage malignancies, however, rare occurrences of adrenal insufficiency and thyroid dysfunction may occur. Pembrolizumab, a PD-1 inhibitor, has been associated with adrenal insufficiency in 1-2% of patients, while thyroid related adverse events occurred in 3.2-10.1%. This is a case report of an 81 year-old male, known to have a cutaneous melanoma stage IV (CTxN0M1A of the muscle), with a prolonged use of Pembrolizumab eventually developing both Pembrolizumab-induced hypothyroidism and adrenal insufficiency. This patient had a wide excision with split-thickness skin graft of the right lower extremity back in June 2022 showing a histopathology of melanoma. He was then started on Pembrolizumab therapy on July 2022. Routine laboratories done showed normal TSH. On the 15th cycle (February 2023), there was an incidental finding of an elevated TSH of 17.632, with normal FT4 (1.11 ng/dl) and FT3 (2.56 pg/ml). the patient was then started on Levothyroxine 25 mg once daily. On the 16th cycle of Pembrolizumab showed persistence of an elevated TSH 8.355 uIU/ml, with normal FT4 (1.24 ng/dl) and FT3 (2.47 pg/ml). Levothyroxine supplementation was continued with TSH serially monitored prior to immunotherapy. On his scheduled 24th cycle of Pembrolizumab (Dec 7, 2023), he developed a 1-week history of productive cough, generalized weakness, and exertional dyspnea, managed as pneumonia and was given Azithromycin 500 mg but due to persistence, prompted further evaluation. Vital signs were normal, thyroid function test showed nonthyroidal illness syndrome (TSH 3.383 uIU/ml, FT4 1.16 ng/dl, FT3 1.97 pg/ml), sodium and potassium were normal (142 mEg/l, 4.1 mEq/l respectively), Creatinine was slightly elevated (1.29 mg/dl), Cortisol level was low at 1.82 (mg/dl). Due to low cortisol levels, referral to endocrinology service was done where an ACTH stimulation test was subsequently done. Baseline cortisol was at 1.68 mg/dl, cortisol 30 minutes and 60 minutes post cosyntropin were 7.79 mg/dl and 11.19 mg/dl respectively. Baseline ACTH was low prior to ACTH stimulation test at 3.51 pg/ml. He was diagnosed to have secondary adrenal insufficiency and was initially started on Hydrocortisone 50 mg q6 and was sent home with tapering doses of Prednisone. Both thyroid dysfunction and adrenal insufficiency can occur in patients treated with Pembrolizumab. Thyroid related dysfunction may occur earlier compared to adrenal insuffiency and must be monitored in patients being treated with Pembrolizumab. Levothyroxine and Steroid supplementation still remain to be the treatment of choice.

A case of ectopic adrenal tissue in the fallopian tube

Bruna Pimentel[1], Margarida Oliveira[1], Catarina Gama[1], Paula Sprovera[1], Carolina Monteiro Antunes[1], Maria Leonor Guia Lopes[1], Clara Cunha[1], Ana Brandão[2], Helena Oliveira[3] & João Manuel Sequeira Duarte[1]
[1]Egas Moniz Hospital, Endocrinology, Lisbon, Portugal; [2]Hospital de Cascais, Gynecology and obstetrics, Lisbon, Portugal; [3]Hospital de Cascais, Pathology, Lisbon, Portugal

Introduction
Ectopic adrenal tissue (EAT) occurs in less than 1% of adults, more commonly in males. It may be found anywhere along the path of embryogenic migration, usually in the kidney and retroperitoneal fat. We report a case of EAT in the fallopian tube, a particularly rare localization.
Case
We present a 57-year-old female with a known medical history of nephrolithiasis and previous ectopic pregnancies. The patient was submitted to a laparoscopic right adnexectomy due to a paratubal cyst. The histopathological evaluation of the surgical specimen showed a 7 cm fallopian tube partially adherent to the ovary, with a cystic structure in its distal half measuring 6.5 x 5 x 3.8 cm. A 3 mm nodule composed of clear cells was identified, immunoreactive to calretinin, inhibin, vimentin, ki67 1%, and negative for chromogranin, synaptophysin, S100, CD10, RCC and AE1/AE3 markers, suggesting an ectopic adrenal nodule. The patient had no symptoms of adrenal hyperfunction. On physical examination there was no evidence of hypertension or signs of Cushing's syndrome.
Conclusion
EAT is usually clinically silent, found incidentally, and the diagnosis is made only by histopathological examination, like in our case. Very rarely, some ectopic EAT can become hormonally functional or undergo a malignant transformation. Hence, awareness is important and if detected resection is recommended.

Patient with immune checkpoint inhibitor Pembrolizumab associated endocrine dysfunctions: a report of clinical case

Viktorija Preobrazenska[1,2], Laura Stirane[1,2] & Una Gailisa[1,2]
[1]Pauls Stradins Clinical University Hospital, Endocrinology, Riga, Latvia; [2]University of Latvia, Riga, Latvia

A 38–year-old female was diagnosed with right breast cancer cT2mN0M0G3 with positive BRCA + gene mutation. The patient was treated with neoadjuvant chemotherapy plus one dose immune checkpoint inhibitor Pembrolizumab following bilateral radical mastectomy, extirpation of the right sentinel lymph nodes and bilateral reconstruction with an implant. Approximately one month after using Pembrolizumab the patient noticed extreme fatigue, decreased blood pressure, accelerated pulse, weight loss of 4 kilograms. The blood test showed hyperthyroidism with thyroid stimulating hormone (TSH) <0.011 mU/l [reference range: 0.4 – 4.0], free thyroxine (FT4) – 34.6 pmol/l [reference range: 11.5 – 22.7] and free triiodothyronine (FT3) – 7.9 pmol/l [reference range: 3.5-6.5] without presence of anti-thyroid peroxidase and thyrotropin receptor antibodies. In addition, in blood test repeatedly was revealed adrenal insufficiency with cortisol 3.0 nmol/l [reference range: 166 – 507] and adrenocorticotropic hormone (AKTH) $<$ 1.5 pg/ml [reference range: 7.2 – 63.3]. The therapy with Prednisolone 7.5 mg daily (5 mg in the morning and 2.5 mg in the afternoon) and Thiamazole 10 mg was started immediately. Three weeks after therapy initiation Thiamazole dose was reduced to 5 mg daily. After two more weeks the blood test showed hypothyroidism with TSH 9.7 mU/l [reference range: 0.4 – 4.0], FT4 – 11.1 pmol/l [reference range: 11.5 – 22.7] and Thiamazole was discontinued. The patient was observed, in three months with no medication thyroid hormones stabilized and no more therapy was needed in further observation period. Pituitary MRI showed no convincing indications of pathological changes in the pituitary gland. The therapy with prednisolone was continued in the same dose, a gradual improvement in clinical manifestations was observed. We hypothesize that immune checkpoint inhibitor Pembrolizumab caused permanent secondary adrenal insufficiency and transient hyperthyroidism.

Adrenocortical carcinoma and addison's disease. Is it possible?: a case report

Jose Antonio Ariza Jimenez[1], Isabel Manoja Bustos[2] & Jorge Marín Martín[2]
[1]Hospital la Merced, Endocrinology and Nutrition, Osuna (Sevilla), Spain; [2]Hospital la Merced, Internal Medicine, Osuna (Sevilla), Spain

Introduction
Adrenocortical carcinoma is a rare tumour, with an annual incidence of 1 to 2 case per million. Hypercortisolism constitutes the predominant clinical manifestation in patients with hormone excess, presenting in 50% to 80% of all adrenocortical carcinomas. Non-functioning tumors are even rarer, comprising only 20% of adrenal carcinomas in the largest reported series. Conversely, Addison's disease is also an infrequent disorder, with estimated incidence rates in Europe ranging from 4.4 to 6.2 new cases per million per year. Currently, autoimmunity stands as the prevailing etiology of Addison's disease in Europe, accounting for 75-96% of all cases. Herein, we present an unprecedented case involving a woman diagnosed with both adrenocortical carcinoma and Addison's disease.
Case report
A 45-year-old woman with a medical history marked by multiple allergies and autoimmune disorders, including vitiligo, autoimmune vasculitis, and myasthenia gravis underwent thymoma surgery in 2013. An incidental finding on CT revealed a 52 x 44 mm right adrenal adenoma with suspected malignancy. Functionality studies demonstrated normal 24-hour urine metanephrines and slightly elevated 24-hour urine cortisol. Subsequently, a right adrenalectomy was performed, yielding biopsy results indicative of carcinoma staged as T2N0M0. No oncological treatments were administered during ten years of follow-up, with no evidence of recurrence or hormonal abnormalities. After a decade without issues, the patient was referred to our clinic due to significant asthenia and weight loss. Physical examination unveiled marked cutaneous and mucosal hyperpigmentation, accompanied by a propensity toward hypotension. In light of suspected adrenal insufficiency, blood tests and a CT scan were conducted. The CT scan revealed no abnormalities in the contralateral adrenal gland, but analysis confirmed primary adrenal insufficiency, reflected in decreased cortisol levels (1.86 µg/dl, reference range: 4.8-20.00 µg/dl) and elevated ACTH (1835 pg/ml, reference range: 3.6-60.5 pg/ml). Aldosterone and DHEA levels were also diminished. Positive 21-OHAbs (3.35, reference range: 0.00-1.00) confirmed autoimmune adrenal insufficiency. Treatment commenced with hydrocortisone 20 mg/24h and fludrocortisone 50 mg/24h, resulting in notable improvement in asthenia and hyperpigmentation, enabling the patient to resume her usual activities.
Conclusions
Addison's disease should be consistently contemplated in the differential diagnosis of adrenal insufficiency. Prompt initiation of corticosteroid therapy is imperative in the management of adrenal insufficiency.

Endocrinopathys in poems syndrome – what's its clinical implications?

Carolina Peixe, José Vicente Rocha, Mariana De Griné Severino, Marta Lopes, Ana Raquel Gomes, Maria Inês Alexandre & Ana Paula Barbosa
Hospital de Santa Maria, Lisboa, Portugal

Introduction
POEMS syndrome is a rare multisystem disorder characterized by polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma-proliferative disorder and skin changes. Different endocrinopathies are found in 58-80% of patients, however, its pathophysiology remains unknown. Hypogonadism (primary and secondary) is the most common endocrinopathy (79% of patients), with other abnormalities including hyperprolactinemia (56%), primary hypothyroidism (54%), abnormal glucose metabolism (24%), primary adrenal insufficiency (17%), and elevated IGF-1 levels (14.8%). We present two cases of endocrinopathy in POEMS syndrome.
Clinical Cases
Patient 1, 59-year-old female, and Patient 2, 52-year-old male, diagnosed with POEMS Syndrome, initiated follow-up in our clinic due to the potential risk of associated endocrinopathies. Patient 1 presented fatigue and cutaneous hyperpigmentation. The initial assessment revealed primary hypothyroidism and suspicion of primary adrenal insufficiency - TSH 15.6 µU/ml (RR:0.30-4.20), FT4 0.74 ng/dl (RR:0.85-1.70); ACTH 66.3 pg/ml (RR:0-46), cortisol 6.3 µg/dl (RR:4-23), confirmed by the Synacthen® test with a cortisol peak of 10.6 mg/dl at 30 min. Treatment with hydrocortisone followed by levothyroxine was initiated. Five years after, in the period post-menopause, asymptomatic hyperprolactinemia and hypogonadotropic hypogonadism (HH) were observed - prolactin 131.4 ng/ml (RR:4.7-23.0), FSH 5.3 U/l (RR:25.0-134.9), LH 2.43 U/l (RR:7.7-58.5). The pituitary MRI showed an empty sella turcica. Patient 2 had decreased libido, fatigue, and muscle weakness. The initial endocrine evaluation revealed HH and subclinical hypothyroidism – FSH 2.8 U/l (RR:1.5-12.9), LH 1.8 U/l (RR:1.3-9.8), total testosterone 55.7 ng/dl (RR:190-740); TSH 13.8 µU/ml, FT4 1.03 ng/dl. It was also suggestive of primary adrenal insufficiency - ACTH 164 pg/ml, cortisol 9.6 µg/dl, later confirmed by the Synacthen® test – cortisol peak 10.6 mg/dl at 60 min. Hydrocortisone treatment was initiated but testosterone replacement therapy was not due to the associated thrombotic risk.
Discussion
Both patients presented HH, the most common endocrinopathy in POEMS Syndrome. The association between hypothyroidism and POEMS Syndrome remains unclear, considering its prevalence in the general population. Although rare, primary adrenal insufficiency was observed in both cases. The literature suggests a potential association between POEMS Syndrome and an empty sella turcica, as seen in Patient 1. Despite this evidence, the only pituitary deficit identified in this patient was HH, without any relation with hypothyroidism and adrenal insufficiency.
Conclusions
Unrecognized endocrinopathy poses a significant risk for morbidity in POEMS syndrome. A multidisciplinary approach is crucial for systematic endocrine assessment in these patients to enhance early detection and management.

Pheochromocytomas are most commonly detected as Adrenal Incidentalomas

Debbah Wissame, Mezoued Mouna, Bessaid Khadidja & Azzouz Malha
Endocrinology-diabetology department of the public hospital establishment (EPH) of Bologhine Ibn Ziri-, Algiers, Algeria

Introduction/objective
Pheochromocytomas are increasingly diagnosed in incidentally detected adrenal masses, with the advent of modern imaging modalities and increased access to imaging. The proportion of pheochromocytomas in adrenal incidentalomas is relatively low, ranging from 7% to 25% of cases recently. Given the evolution of the presentation of pheochromocytomas, we sought to evaluate the proportion and clinical, biochemical and radiological characteristics of incidental pheochromocytomas and compare them to pheochromocytomas whose mode of discovery was adrenergic symptoms and/or uncontrolled hypertension.
Patients and methods
A retrospective descriptive and analytical study including 48 patients hospitalized for pheochromocytoma in the endocrinology-diabetology department of the public hospital (EPH) Bologhine Ibn Ziri - Algiers, Algeria, spread over a period of 20 years.
Results
After excluding pheochromocytomas diagnosed via screening of genetically predisposed individuals ($n=7$; 14.6%), we individualized two groups: group 1, pheochromocytoma diagnosed in a context of adrenal incidentaloma (63.4% of patients) and group 2, pheochromocytoma diagnosed by adrenergic symptoms and/or uncontrolled hypertension (36.6% of patients). Patients detected by incidentaloma were older (median age 48 years) than those detected due to clinical suspicion (30 years) ($P=0.006$). Tumors identified by incidentaloma were significantly larger (median size 65.7 mm) than tumors detected due to adrenergic symptoms/uncontrolled hypertension (55 mm) ($P<0.05$). There was no difference in catecholamine secretion in the two groups ($P=0.13$) (the median increase in metanephrines is: 13× ULN in group 1, and 10× ULN in group 2).
Conclusion
Due to the better availability and more frequent use of complementary examinations, the prevalence of incidental pheochromocytomas continues to increase. It would be legitimate to follow a diagnostic approach and adequate care so as not to ignore them.

EP392

Stress cardiomyopathy secondary to pheochromocytoma

Isabel Losada Gata, Alberto García Piorno, Mónica Gómez-Gordo Hernanz, Gloria Collado González, Ignacio Jiménez Hernando, Marta Pérez Noguero, Amaya Morales Jaurrieta, Blanca Farache Suberviola, Laura González Fernández & Olga González Albarrán
Gregorio Marañón General University Hospital, Endocrinology, Madrid, Spain

Introduction
Pheochromocytoma, a rare catecholamine-secreting tumor, typically presents with paroxystic hypertension, tachycardia, headache, and diaphoresis. Less frequently, symptoms imply substantial hemodynamic compromise and cardiogenic shock may occur. The delay time in diagnosis is approximately 3 years.
Case Presentation
This is a 41-year-old woman with no relevant history or cardiovascular risk factors, who presented with stress-induced cardiomyopathy or TakoTsubo syndrome, associated with intense headache. The hemodynamic study revealed normal coronary arteries and a reduced left ventricular ejection fraction (LVEF) of 40%, with altered segmental contraction on cardiac magnetic resonance. A year later, she required a new admission due to angina refractory to diltiazem and nitrates; a diagnosis of Prinzmetal's angina was made. A CT scan was performed to rule out non-coronary etiology, and an 8 cm adrenal mass compatible with pheochromocytoma was incidentally found. The study was completed with metanephrines in urine and PET-CT, confirming the diagnosis. Prior to the intervention, alpha blockade with doxazosin was started, with notable difficulties in management, requiring a multidisciplinary approach with cardiology and intensive medicine for dosing, due to the patient's symptomatic hypotension when the dose was increased, and rest angina associated with alterations in repolarization with its decrease. After beta blockade with metoprolol, right adrenalectomy was performed, without incident. The patient's evolution was favorable, with recovery of the LVEF and disappearance of arterial hypertension and headache, although maintaining some occasional episodes of vasospastic angina. Postoperative urinary metanephrines were normal. The genetic study was negative for MEN-1, VHL, NF-1, RET, SDHAF2 SDHB, SDHC, SDHD, TSC1, TSC2.
Discussion and Conclusions
Endocrine causes should be taken into account and ruled out in the differential diagnosis of angina, given that catecolamine-induced cardiomyopathy is potentially reversible.

Solitary abdominal pain unveiling pheochromocytoma in a young patient: a case report

Romana Marušić[1,2], Ines Bilić-Ćurčić[2,3], Ivana Prpić-Križevac[2,3], Ema Schönberger[2,3], Kristina Steiner[3], Klara Ormanac[2,3] & Silvija Canecki-Varžić[2,3]
[1]General Hospital Vukovar, Department of Internal Medicine, Vukovar, Croatia; [2]Faculty of Medicine Osijek, Osijek, Croatia; [3]Clinical Hospital Center Osijek, Department of Endocrinology, Osijek, Croatia

Introduction
Pheochromocytomas are rare neuroendocrine tumors originating from chromaffin cells in the adrenal medulla, secreting catecholamines and causing symptoms such as hypertension, anxiety, panic attacks, palpitations, and headaches. An adrenal gland incidentaloma is identified as an unintentional discovery in approximately 3 - 4 % of computed tomography (CT) abdomens performed. Pheochromocytoma is diagnosed in about 5% of adrenal incidentalomas. Diagnosing pheochromocytoma is challenging due to symptoms overlapping with other medical conditions.
Case report
We present a 33-year-old patient evaluated in the emergency department for abdominal pain. Ultrasound revealed a 12 cm oval heterogeneous formation near the lower spleen pole of unclear origin and inflammatory changes at the descending to sigmoid colon transition. A subsequent upper abdomen CT revealed a left adrenal gland formation measuring 11 $\times$ 8.8 $\times$ 11 cm with a native density of 30 Hounsfield units (HU), with 60 % absolute wash-out and 40 % relative wash-out. An irregular hypervascular zone (21 $\times$ 20 $\times$ 25 mm) in the left kidney's lower pole mesentery prompted gastroenterological examinations (esophagogastroscopy, colonoscopy, magnetic resonance (MR) enterography), all yielding normal results. The patient had normal blood pressure; his only symptom was mild abdominal pain. Laboratory findings showed slightly elevated normetanephrine in serum (0.80 nmol/l, reference interval 0.13-0.62 nmol/l) and twice-elevated normetanephrine in urine (0.48 umol/dU, reference interval $<$0.24 umol/dU). Metanephrine values in serum and urine were within reference intervals. Repeated urine metanephrine and normetanephrine findings were normal as well as androgen and cortisol levels. Therefore, the differential diagnosis included pheochromocytoma and adrenocortical carcinoma which was considered as more plausible option. Surgery was recommended, however perioperative preparation according to the protocol for pheochromocytoma was not performed since the biochemical findings were not confirmatory for the diagnosis of pheochromocytoma. The patient underwent a left-sided adrenalectomy without complications. Pathohistological analysis confirmed a composite pheochromocytoma with a ganglioneuroma component in 5 - 10 % of tumors, a PASS score (a pheochromocytoma of the adrenal gland scaled score) $>$4, and a GAPP score (the grading of adrenal pheochromocytoma and paraganglioma) of 5/10. Follow-up adrenal gland MRI revealed no disease recurrence.
Conclusion
The diverse clinical presentations of pheochromocytoma, ranging from asymptomatic to displaying atypical symptoms, underscore the diagnostic challenges posed by this rare neuroendocrine tumor. Given its potential to precipitate hypertensive crises, arrhythmias, and myocardial infarctions, early recognition and prompt intervention become imperative for mitigating severe complications.

Adrenal incidentalomas and arterial hypertension

Oumayma Zarrouk, ACH Taieb, Ghada Saad, Asma Ben Abdelkarim, Molka Chadli Chaieb & Koussay Ach
University Hospital of Farhat Hached, Endocrinology departement, sousse

Introduction
Endocrine hypertension is the most common cause of secondary hypertension affecting nearly 3% of the population. Adrenal etiologies play a significant role in these cases. An adrenal incidentaloma is an asymptomatic adrenal tumor, at least one cm in diameter, discovered incidentally during a medical imaging examination. It requires an investigation into its secretory or malignant nature leading to the development of arterial hypertension.
Materials and Methods
This is a retrospective descriptive study focusing on patient records where an adrenal incidentaloma was discovered during hospitalization for hypertension. We documented clinical and biological presentation, etiological profile as well as diagnostic and therapeutic methods.
Results
Our series included 22 patients:2males and 20 females, aged between 29 and 76 years, with a mean age of 52 years. Family history revealed familial hypertension in 18 patients (81.8%), 3 cases of early stroke and 1 case of myocardial infarction. At the time of diagnosis, 6 patients had type 2 diabetes(average duration of 4 months) and a standard deviation (SD) of 3 months. Only one patient was a smoker, and one had dyslipidemia treated with statin. The discovery of hypertension occurred with headache in 7 patients (31.8%), Menard triad (headache, palpitations and sweats) in 5 patients (22.7%), tinnitus in 2 patients (9.1%)and was incidental in 8 patients (36.4%). Among these, 4 cases had refractory hypertension (18.2%) and 2 cases had malignant hypertension (9.1%). No patient experienced complications. The mean systolic blood pressure was 16.1mmHg and the mean diastolic blood pressure was 9.1mmHg. The average weight of the population was 79.8 kg, the average height of 159.19 cm, the average BMI of 31.13 kg/m^2; and the average waist circumference of 105 cm with a SD of 26.6 cm. Biologically, the average blood glucose was 6.57 mmol/l and the average serum potassium was 3.8 mmol/l with a SD of 0.57 mmol/l. Ten patients had a confirmed hypokalemia. A CT scan focused on the adrenals revealed an incidentaloma with an average size of 21.5 mm and a standard deviation of19.21mm. The etiological diagnosis included pheochromocytoma in 7 patients(31.8%), clinically and biologically confirmed hypercortisolism in 9 cases (27.3%)of which6 were adenomas, 1 corticosurrenaloma and 2 bilateral adrenal hyperplasia. There were also 4 cases of primary hyperaldosteronism (18.2%). Two patients did not have hormonal secretion and thus had essential hypertension. For etiological treatment, 18 patients underwent unilateral adrenalectomy for endocrine hypertension (81.8%), while 4 patients received medical treatment(18.2%). Medical treatment for hypertension included ACE inhibitors in 5 patients (22.7%) calcium channel blockers in 4 patients (18.2%), angiotensin receptor antagonists in 2 patients (9.1%), and 1 patient received thiazide diuretic alone. Combination therapy was used in 6 patients, and triple therapy in 4 patients.
Conclusion
Adrenal hypertension is a treatable cause of secondary hypertension. The clinical signs resulting from hyperadrenergic activity, hypercortisolism, or hyperaldosteronism are not specific, but they disappear after surgery, which remains the only curative treatment.

Adrenal lesions in in patients with MUTYH syndrome

Joaquin de Carlos[1], Lucia Zabalza[2], Ana Irigaray[1], Maria Rosario Aznarez[1], Jon Yoldi[1], Miguel Marti[1], Xabier Ayarza-Marien[1] & Emma Anda Apiñariz[1]
[1]Hospital Universitario de Navarra, Endocrinology, Pamplona, Spain; [2]Hospital Universitario de Navarra, Gastroenterology, Pamplona, Spain

Introduction
MUTYH (MutY homolog Escherichia coli, homolog of MYH, hMYH) is a repair enzyme with a crucial role in the correction of DNA errors, being considered a protective factor of the cell. MUTYH mutations have been linked to MUTYH-associated polyposis syndrome (MAP), an autosomal recessive disorder characterized by multiple colorectal adenomas. Patients with MAP show a much higher lifetime risk of gastrointestinal cancers as an additional role of MUTYH, it appears to contribute in the involvement of pathologies based on oxidative stress damage, as well as in the prevention of inflammatory and degenerative based disorders. Although the development of extraintestinal pathology is not fully defined, it seems to increase the risk of tumors and endocrinological pathology.
Materials and methods
Prospective study, selecting 27 living patients diagnosed and registered with MUTYH syndrome under follow-up from the Digestive Department of the Hospital Universitario de Navarra (HUN) with current or past follow-up in the Endocrinology Department. Radiological tests, clinical, and analytical variables were analyzed.
Results
The study population included 14 men (51.8%) and 13 women (48.2%), with a mean age of 56 years. The median age at diagnosis of FAP was 48 years, with a mean follow-up time of 8 years. All patients had an abdominal imaging study (CT or MRI), detecting lesions in 3/27 (11.11%). The average size was 2 cm. One of the patients had bilateral adenomas, while the other two were unilateral. Of note, one of them showed calcifications in both glands in the CT scan. All were incidental findings presented as non-functioning adenomas in the analytical tests performed. The study consisted of the overnight 1 mg dexamethasone suppression test, catecholamine/metanephrine determination, adrenal androgen production, and if appropriate, screening of primary hyperaldosteronism. No major endocrinological alterations (defined as nodular disease or thyroid carcinoma, thyroid autoimmunity, diabetes, obesity) were detected when comparing both groups. There were also no differences in gender, age, or time since diagnosis.
Conclusions
Adrenal lesions are common in patients with MUTYH who undergo abdominal imaging. They appear to follow a benign and slowly progressive course, presenting clinically and analytically as non-functioning lesions.

Adrenal venous sampling in patients with bilateral adrenal lesions and ACTH-independent cushing's sydrome

Zydrune Visockiene[1,2], Jogaile Gudaite[1], Gintare Naskauskiene[1,2], Valentinas Jakubkevicius[1,2], Nida Jugulyte[1], Domas Grigoravicius[1] & Marius Kurminas[1,2]
[1]Faculty of Medicine of Vilnius University, Vilnius, Lithuania; [2]Vilnius University Hospital Santaros Klinikos, Vilnius, Lithuania

Background
ACTH-independent Cushing's syndrome (AICS) due to bilateral adrenal lesions (BAL) is a challenge as determining whether autonomous cortisol secretion is unilateral or bilateral is crucial in guiding the treatment strategy.
Aim
To analyse the usefulness of adrenal venous sampling (AVS) in differentiating between unilateral and bilateral cortisol secretion in patients with AICS and BAL.
Methods
We performed a retrospective single center analysis of 6 patient cases with AICS who had AVS done at Vilnius University Hospital Santaros Klinikos between 2018 and 2023. AICS diagnosis was clarified by 1 mg dexamethasone suppression test as well as testing late night cortisol, 24 h urine cortisol and ACTH. Successful cannulation was defined as adrenal to peripheral vein ratio of aldosterone >2. Unilateral cortisol secretion was defined as side-to-side lateralization index >2 using aldosterone as a reference hormone.
Results
Concomitant diseases were diagnosed as follows: hypertension – in all 6 patients, dyslipidemia – in 4, osteoporosis – in 2 (with multiple fractures in one case), cardiovascular diseases – in 1, diabetes – in 1 patient. Two out of six patients presented with overt Cushing's syndrome. Both had BAL on computed tomography (CT). Based on the AVS results, one of these patients had unilateral secretion and percutaneous radiofrequency ablation of the functioning tumor was performed. Following the ablation the patient developed transient adrenal insufficiency and was treated with hydrocortisone for two years. The other patient underwent bilateral adrenalectomy. Mild autonomous cortisol secretion was diagnosed in four other patients – all of which showed BAL on CT. One of these patients had unilateral cortisol secretion based on the AVS results and is scheduled for a unilateral adrenalectomy. The remaining three patients had different treatment strategies - one of them underwent unilateral adrenalectomy which did not result in adrenal insufficiency. Furthermore, this led to the discontinuation of antihypertensive treatment as blood pressure normalized. The second patient underwent a two-stage bilateral laparoscopic adrenalectomy with a break of 3 months between operations when hypercortisolism remained after the first one. The third patient had bilateral adrenalectomy.
Conclusions
AVS is an important procedure that may contribute to appropriate treatment in patients with AICS and BAL. In our case, AVS helped to avoid unnecessary bilateral adrenalectomies in 2 out of 4 cases. However, the rare clinical scenario of BAL needs an individualised treatment approach based on the agreement of both the patient and the medical team.

Unusual cause of cushing's syndrome

Mayet Roxana Padilla Segura[1], Maria del Carmen De Mingo Alemany[2], Maria Francisca Moreno Macian[2], Begoña Pla Peris[1], Pablo Abellan Galiana[1], Alicia Rizo Gellida[1], Esther Serisuelo Meneu[1], Angela Bono Velilla[1], Francisco Javier Maravall Royo[1] & Agustin Ángel Merchante Alfaro[1]
[1]Hospital General Universitario de Castellon, Endocrinology and Nutrition, Castellon de la plana, Spain; [2]Hospital Universitario y Politecnico La Fe de Valencia, Pediatric Endocrinology, Valencia, Spain

Introduction
Carney Complex (CNC) is a rare syndrome characterized by multiple endocrine and non-endocrine tumors, which may be accompanied by macular pigmentation of the skin. This is an autosomal dominant disorder with high penetrance and heterogeneous expression. It is caused by inactivating pathogenic variants in the PRKAR1A gene in over 70% of cases which encodes the regulatory type 1 alpha subunit of protein kinase A. Diagnosis is made by identifying specific criteria. At least two criteria are necessary, but only one is needed if the patient or a first-degree relative has the genetic alteration.
Case report
An 11-year-old girl with a history of polycystic kidney disease with dysplastic, nonfunctional left kidney and compensatory enlargement of right kidney. She also had a history of melanotic shwannomas on the abdomen, scalp, and lower eyelid. She was referred for suspicion of Cushing's syndrome (CS) due to a one-year history of weight gain, moon face, truncal obesity, purplish streaks, dorsocervical fat pad, and mild hirsutism. On biochemical study, 24 h urinary cortisol (24hUC) was inconsistent: 3.397 ->132->1270 mg reference range (RR:21-143) and midnight salivary cortisol 0.75 mg/dl (RR: <0.27). We found a nonsuppressible serum cortisol (SC): 6.7 mg/dl (RR:6-18), after dexamethasone (DST) 1 mg followed by administration of DST 8 mg finding SC remained high after 48h: 12.10 mg/dl, with also elevated 24 hUC: 403 mg, undetectable serum ACTH <5 pg/ml (RR:5-60), and low dehydroepiandrosterone sulfate: 25.9 mg/dl (RR:33.9-280), confirming an ACTH-independent CS (ACTHICS) with a cyclic pattern. In addition, a paradoxical increase in 24 hUC was detected at day 6, measuring 6,137 mg/24 h. This finding is consistent with primary pigmented nodular adrenocortical disease (PPNAD), which is the most common endocrine neoplasm in CNC and one of the main diagnostic criteria, in addition to the mentioned schwannomas. A contrast-enhanced CT scan of the abdomen revealed normal-appearing adrenal glands, and genetic testing identified a likely pathogenic variant in heterozygosis of the PKRAR1A gene (Chr17: c.658_659 of p(Asn220 Cysfs*12). Histopathological confirmation of PPNAD was obtained after performing bilateral adrenalectomy and left nephrectomy. A search for potential relatives was conducted, but yielded no results.
Conclusion
CNC should be considered in the differential diagnosis of ACTHICS, especially if it has a cyclic pattern and the imaging studies appear to be normal. We present a novel variant of the PKRAR1A mutation, with pathogenic implication. Timely diagnosis and treatment of the patient, in conjunction to screening first-degree relatives who may be affected, can help prevent further complications.

Introduction
Pseudo Cushing syndrome (PCS) is caused by non-neoplastic over activity of the hypothalamic-pituitary-adrenal axis. Differentiating between PCS and Cushing disease (CD) can be challenging because of their overlapping clinical and biochemical features.
Case presentation 15 year old male presenting with watery diarrhea of 2 months duration occurring 3 times per day with lower limb weakness No rectal bleeding, fever, or weight loss
Physical examination
Blood pressure: 125/90 mm Hg. Pulse: 125 /mint, normal RR and temperature. BMI: 41 kg/m2 and no cushingoid features. The abdominal examination showed hepatomegaly. The neurological examination showed nystagmus and decreased motor power of both L.L (grade 1) with intact sensations. The Cardiac and chest examination were normal. Investigations: Labs: Infectious work-up including ova and parasites, culture were negative (Hb 9.9 gm/dl), microcytic hypochromic anemia hypokalemia (2.5 mEq/l) (3.5-5.5 mEq/l) hypoalbuminemia (2.7 mmol/l), Normal liver and kidney functions Anti-transglutaminase, and anti-endomysial antibodies, ANA, ANCA, LKMA, ASMA were also negative. Colonoscopy revealed erythematous mucosa in the transverse colon, Esophagogastroduodenoscopy (EGD) revealed diffuse gastric erythema with erosions and duodenitis, cortisol was done to exclude adrenal insufficiency instead it was markedly elevated Serum cortisol 9 am: 48.23 mg/dl (4.3-22.4), cortisol 9 pm: 40.73 mg/dl ($>$ 10), ACTH: 89.3 pg/ml (7.2-63.3), free urinary cortisol $<$ 1140 mg/24 hr Serum cortisol 9 am after low dose dexamethasone suppression test:30.2 mg/dl Serum cortisol 9 am after high dose dexamethasone test: 3.18 mg/dl Imaging: Abdominal CT with oral and I.V contrast: hepatomegaly (27 cm), enlarged celiac and porta hepatis lymph node (largest 1.7 cm) Biopsy of porta hepatis lymph node: non-caseating microgranulomas picture of sarcoidosis Angiotensin-converting enzyme (ACE) was elevated at 93 U/l (8-52), Chest CT was unremarkable and the patient started to receive 40 mg prednisone Outcome and follow up: The diarrhea stopped, L.L weakness improved (grade 4) as well as the anemia (Hb 12 gm/dl). Morning cortisol 14.5 mg/dl. ACTH 37.2 pg/ml
Conclusion
We present a case of PCS with severe hypercortisolism mimicking CD in critical ill adolescent with GIT sarcoidosis that improved spontaneously with the treatment of underlying aetiology

DOI: 10.1530/endoabs.99.EP408

Impact of sampling device on quantification of 11-oxygenated androgens in saliva by liquid chromatography tandem mass spectrometry

Sonja Kunz[1], Ilja Dubinski[2], Katharina Schiergens[2], James Hawley[3], Brian Keevil[3], Nicole Reisch[1], Martin Reincke[1], Heinrich Schmidt[2] & Martin Bidlingmaier[1]
[1]University Hospital, Ludwig Maximilian University Munich, Department of Medicine IV, Munich, Germany; [2]Dr. von Hauner Children's Hospital, University Hospital, Ludwig Maximilian University Munich, Department of Pediatrics, Division of Pediatric Endocrinology, Munich, Germany; [3]Manchester University Foundation NHS Trust, Manchester Academic Health Sciences Centre, Department of Clinical Biochemistry, United Kingdom

Introduction
11-ketotestosterone (11KT) and 11β-hydroxyandrostenedione (11OHA4) are new biomarkers for hyperandrogenic disorders. Steroids can be measured in saliva, allowing non-invasive sampling by patients. We modified a published LC-MS/MS method[1] for quantification of 11-oxygenated androgens in saliva with respect to sample volume, extraction procedure and equipment, and assessed the potential impact of different sampling devices on results.
Method
Calibrators were prepared from primary standards (Merck KGaA, Steraloids Inc.) in artificial saliva. Samples were extracted by supported-liquid-extraction with dichloromethane without online solid-phase-extraction. 11-oxygenated androgens were quantified using a 1290 Infinity II HPLC (Agilent Technologies; injection volume 20 µL) coupled to a 6500+ QTRAP mass spectrometer (AB Sciex) via gradient elution and multi-reaction monitoring in positive ESI mode. After method validation, 30 samples from volunteers and patients with adrenal diseases covering a broad concentration range were measured in parallel at our laboratory and the laboratory which originally described the method. To test a potential impact of the sampling device, spiked artificial, and individual or pooled native saliva was applied to three sampling tools (Salivette® and Salivette® Cortisol (Sarstedt), SalivaBio Infant's Swab (Salimetrics)), or used directly. Sample volumes of 20-300 µL were compared.
Results
Performance characteristics were largely comparable to the original method, although our limits of quantification were higher (11KT: 30 vs. 5 pmol/l; 11OHA4: 60 vs. 50 mol/l). Measured concentrations correlated well (intercept 3.18/10.19, slope 1.14/1.54 for 11KT/11OHA4, respectively). Bias between the methods was 17% for 11KT, but 59% for 11OHA4. At very high cortisol and low 11OHA4 concentrations we observed a weak interference from cortisol on 11OHA4 that was not described for the original method. Results from measurement by our method did not differ for saliva volumes between 50 and 300 µL. Measured concentrations were significantly affected by the choice of the sampling tool. Samples collected by the SalivaBio Infant's Swab exhibited the least deviation (-/+6%) from sampling without tool.
Conclusion
We transferred and modified an established method for quantification of 11-oxygenated androgens to allow application if no online SPE is available. While results for 11KT agreed, a significant bias in results for 11OHA4 was observed, perhaps relating to differences in calibrators. To avoid interference from extreme cortisol concentrations on 11OHA4 signals we recommend sampling before hydrocortisone intake. Required volume can be reduced to 50 µl, facilitating analysis of samples from newborns. The impact of sampling devices on measured concentrations must be considered for future studies.

The incidence of cancers in patients with non-functional adrenal tumors: a swedish population-based national cohort study

Jekaterina Patrova[1], Buster Mannheimer[1], Jonatan D. Lindh[2] & Henrik Falhammar[3]
[1]Karolinska Institutet, Department of Clinical Science and Education, Södersjukhuset, Stockholm; [2]Karolinska Institutet, Department of Laboratory Medicine, Division of Clinical Pharmacology, Stockholm, Sweden; [3]Karolinska Intitutet, Department of Molecular Medicine and Surgery, Stockholm, Sweden

Importance
It is unclear if non-functional adrenal tumors (NFAT) are associated with higher cancer incidence.
Objective
To analyze the cancer incidence in patients with NFAT.
Design, Settings and Participants
A national retrospective register-based study involving cases with NFAT diagnosed in Sweden 2005-2019 and controls was conducted. Both cases and controls were followed until death or 2020. Individuals with diagnosed adrenal hormonal excess or malignancy were excluded. Follow-up started after 3-months malignancy-free survival following the date of the NFAT diagnosis. Sensitivity analyses were performed in subgroups of individuals in whom we would presume controls would also have had a CT: those with acute appendicitis (in whom we would also assume there was no concern of cancer), and in patients with a combination of gallbladder/biliary tract/pancreas disorders, and 6- and 12-months malignancy-free survival following the date of the NFAT diagnosis.
Setting
A national retrospective register-based study.
Exposures
NFAT diagnosis.
Main outcomes and measures
The primary outcome was all types of cancer, after adjustment for sex, age and comorbidities. Secondary outcomes were specific types of cancer.

Results
Among 17,726 cases, 10,777 (60.8%) were women, and the median (IQR) age was 65 (57;73) years. Among 124,366 controls, 69,514 (55.9%) were women, and the median (IQR) age was 66 (58;73) years. The incidence of any cancer was higher in patients with NFAT compared to controls (hazard ratio (HR) 1.35, 95%CI 1.29-1.40, adjusted HR (aHR) 1.31, 95% CI 1.26-1.37), slightly higher among females than males (HR 1.44, 95% CI 1.36-1.52, aHR 1.34, 95% CI 1.26-1.41 vs. HR 1.28, 95% CI 1.20-1.36, aHR 1.29, 95% CI 1.21-1.37). The incidence of thyroid, lung, stomach and small intestine, kidney, and pancreatic cancer were increased in cases. The thyroid and kidney cancer incidences were particularly high in cases younger than 65 years. Sensitivity analyses did not change the overall results.
Conclusions and Relevance
The incidence of cancer in NFAT was increased. Long-term follow-up is indicated.

Modified release hydrocortisone, a new treatment for congenital adrenal hyperplasia due to 21-hydroxylase deficiency: a single center 'real-world evidence' preliminary study

Chiara Simeoli[1], Erminio M. Crescenzo[1], Augusta M. Pulci Doria[1], Angelica Larocca[1], Nicola Di Paola[1], Claudia Pivonello[2], Mariarosaria Negri[3], Annamaria Colao[1] & Rosario Pivonello[1]
[1]Dipartimento di Medicina Clinica e Chirurgia, Sezione di Endocrinologia, Diabetologia, Andrologia e Nutrizione, Università Federico II di Napoli, Naples, Italy; [2]Dipartimento di Sanità Pubblica, Università Federico II di Napoli, Naples, Italy; [3]Dipartimento di Scienze Umanistiche, Università Telematica Pegaso, Naples, Italy

Life-long glucocorticoid (GC) treatment is needed in patients with congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency, to replace GC deficiency and to control androgens excess. Multiple daily immediate-release-hydrocortisone (IR-HC), characterized by GC overexposure, peaks and troughs, is frequently associated with a suboptimal androgen control, due to ACTH overnight increase. Once daily dual-release-HC (DR-HC), approved for adrenal insufficiency and, despite a near-physiological daily cortisol profile, characterized by suppressed evening cortisol levels, appears not able to avoid ACTH overnight increase and consequent morning androgens excess. A novel twice daily modified-release-HC (MR-HC), recently approved for CAH patients >12 years, simulating the overnight increase of cortisol, appears able to control ACTH overnight increase and consequent morning androgens excess. The current study aimed at investigating the impact of the switch from IR-HC/DR-HC to MR-HC on 3-month metabolic and androgen profiles, and quality of life in 15 CAH females. Nine (60%) patients with classic-form [four (44.4%) with salt-wasting and five (55.6%) with simple-virilizing] and six (40%) with non-classic form, aged 30.1±11.1,15-60 yrs, were enrolled. Seven (46.7%) patients treated with thrice daily IR-HC (23.4±8.2 mg/day) and eight (53.3%) treated with DR-HC (14.4±8.2 mg/day) were switched to equivalent doses of twice daily MR-HC (20.7±7.8 mg/day). The primary outcome was the change from baseline to 3 months of MR-HC in the percentage of patients with good disease control, defined as morning 17OH-progesterone (17OHP)<3 times the upper limit of normal (ULN) and androstenedione within the reference range, according to the phase3 study. Secondary outcomes included changes in hormones and metabolic parameters. Lastly, a questionnaire focusing on asthenia, sleep quality, hyperandrogenisms signs, stress doses and adrenal crises, was administered to all patients before and after the switch. The percentage of patients with controlled disease was 20% (3/15) at baseline and 73.3% (11/15) 3 months after the switch to MR-HC ($P=0.0034$). Particularly, a significant decrease in testosterone (0.4±0.6 *vs* 1.3±2.5ULN at baseline, $P=0.011$) and 17OHP (2.5±3.1 *vs* 22±21.6ULN at baseline, $P=0.005$) was observed. No changes were observed in the other evaluated parameters. Considering patients with alterations at baseline, MR-HC resulted in patient-reported benefits including menses restoration (4/4=100%), asthenia (7/9=77.8%), sleep quality (4/8=50%) and hirsutism (1/11=9.1%). In the 3 months before the switch, twelve patients [12/15 (80%)] adjusted their GC doses for fever/surgery/stress events compared with one [1/15 (6.7%)] patient in the 3 months after the switch. No adrenal crises were observed both 3 months before and after the switch. In conclusion, these preliminary data showed that MR-HC improved disease control in CAH females, with overall patient-reported benefits, mainly in menses, asthenia and sleep quality.

Osilodrostat in cushing's disease: Risk of adrenal insufficiency should be monitored

Fatma Ben Abdessalem[1], Hamza ELFEKIH[1,2], Ghada Saad[1,2], Koussay Aich[1,2] & Molka Chadli-Chaieb[1,2]
[1]Faculty of Medicine Ibn El Jazzar, University of Sousse, Sousse, Tunisia; [2]Endocrinology-Diabetology Department, Farhat-Hached University Hospital, Sousse, Tunisia

Introduction
Endogenous Cushing's disease is a serious and rare endocrine disorder. Medical therapy is mostly used as second-line treatment after failed surgery or recurrence and comprises several pituitary-directed drugs, glucocorticoid receptor blocker and adrenal steroidogenesis inhibitors such as osilodrostat. We here describe a case of a Tunisian patient with uncured cushing's disease who developed iatrogenic adrenal insufficiency in the setting of Osilodrostat treatment.
Case Presentation
A 46-year-old female presented to our department with invalidant asthenia and abdominal pain. She has an uncured cushing's disease, following transsphenoidal surgery, complicated with diabetes and hypertension. There was no visible residue on the post operative pituitary MRI. Adrenal CT-scan showed: Nodule of the external arm of the left adrenal gland of 30x17 mm with spontaneous density 7UH, Nodule of the external arm of the right adrenal gland of 15×9 mm with spontaneous density 7UH. She was proposed for bilateral adrenalectomy which was not performed; hence she was given osilodrostat with an initiation dose of 2 mg *2/day. The patient wrongly took a dose of 7 mg *2/day for 13 days then consulted us with an acute adrenal insufficiency: asthenia, vomiting and abdominal pain. Physical examination showed melanoderma with low blood pressure at 80/60 mm Hg. Basal cortisol was low at 17 ng/ml. Natremia and kaliemia were in the normal ranges. Osilodrostat was stopped and hydrocortisone was commenced (200 mg/day). The dose of hydrocortisone was rapidly decreased to 20 mg/day, and osilodrostat was reinitiated (5 mg in the morning, 5 mg in the evening) on Day 7.
Discussion
The effective cortisol inhibition achieved by osilodrostat therapy in Cushing's disease has been demonstrated by several studies. Detailed education of patients treated with osilodrostat should be systematically performed. Titration should be very progressive, or the dose increase could be more rapid in patients for whom a 'block and replace' approach may appear necessary. Given the risk of adrenal insufficiency in this setting of a highly effective drug, our case suggest that 'block and replace' approach should be systematically considered in patients treated with osilodrostat.

Adrenal specific functional imaging with 123I-IMAZA for non-invasive diagnostic evaluation of TART - a case series

Stefanie Hahner[1], Schirbel Andreas[2], Schlötelburg Wiebke[2], Carmina Teresa Fuss[1], Ann-Christin Welp[3], Matthias Auer[3], Christian Lottspeich[3], Britta Heinze[1] & Nicole Reisch[3]
[1]University Hospital Würzburg, Division of Endocrinology and Diabetology, Würzburg; [2]University Hospital Würzburg, Department of Nuclear Medicine, Würzburg; [3]LMU University Hospital, Department of Medicine IV, Munich

Background
Distinction of benign testicular adrenal rest tumours (TART) and potentially malign Leydig cell tumors (LCT) is challenging but important to prevent unnecessary surgery of TART. Ultrasound or magnetic resonance imaging can reliably detect but not distinguish between both tumour entities.
Methods
Functional imaging results using the specific CYP11B1/2-inhibitor ^{123}I-IMAZA were investigated in seven adult male patients with classic congenital adrenal hyperplasia and incidentally detected testicular masses and in one patient with seminoma. Planar whole body images and in part additional SPECT images were acquired 4 hours after injection of 130-180 MBq ^{123}I-IMAZA. Uptake was compared with testicular uptake in 20 males receiving ^{123}I-IMAZA imaging for other adrenal diseases. Operated testicular lesions were stained for expression of CYP11B1 and 2.
Results
In four cases, scintigraphy showed significant scrotal and adrenal uptake with depiction of even small testicular masses below one cm of diameter. In these patients, no surgical intervention was performed. In two patients with missing tracer uptake, tumour resection showed a Leydig cell tumour not expressing

CYP11B. In one, we suspect low detection limit of scintigraphy being responsible for missing tracer uptake. As this patient had very small and for many years known and stable tumour, the likelihood of benign TART was extremely high and surgical intervention was not performed.
Conclusion
This is a unique, first time report of adrenal specific functional imaging for non-invasive diagnostic evaluation of TART.

Idiopathic unilateral genycomastia in a child

Neima Hassan, Hind Ouakrim, Sana Rafi, El Mghari Ghizlane & Nawal El Ansari
Centre Hospitalo-Universitaire Mohammed VI Marrakech, Endocrinolgist, Marrakech

Introduction
Gynecomastia, marked by mammary gland hypertrophy, arises from an imbalance between androgens and estrogens. Notable etiologies include hypogonadism, tumors, iatrogenic causes, and idiopathic factors.
A case report
A patient aged 8 years and 10 months, with no pathological history, was admitted for further management of right unilateral gynecomastia. The functional signs included unilateral right hypertrophy in the retroareolar region. On physical examination, firm unilateral palpation of 3 cm on the right, eccentric, with no signs of hyperthyroidism or hypercorticism, and the right and left testicular size measuring 4 ml. The diagnosis of idiopathic gynecomastia was confirmed by examination results, revealing a nodular tumefaction, well-limited, regular in contour, hypoechoic, finely heterogeneous, measuring $3\times3\times0.6$ cm. Testicular ultrasound showed no abnormalities. Additional tests, including TSH:1.6 uui/ml, renal and hepatic tests without abnormalities, FSH:1 mui/l, LH:0.12 mui/l, Testosterone:0.10 mg/l, BHCG:0.11 mui/l, and estradiol:2 pg/ml, were within normal ranges. Due to aesthetic discomfort, the patient was referred to the plastic surgery department for further care.
Discussion
In contrast to gynecomastia in adolescents and adult men, prepubertal gynecomastia is a rare occurrence. The primary objective of the interview and clinical examination is to identify warning signs of non-physiological gynecomastia. Various drugs, whether toxic or topical, are linked to gynecomastia and warrant investigation before any additional work-up. The key etiological emergencies to rule out involve tumoral origins, including germinal testicular and adrenal causes. To biology of renal, hepatic, and thyroid function, alongside a hormonal workup (LH, FSH, estradiol, total and free testosterone, SHBG, β-HCG), is necessary. Management relies, on one hand, on reconstructive surgery in cases of significant discomfort. Aromatase inhibitors can also contribute to preventing recurrence.
Conclusion
Gynecomastia represents an infrequent clinical scenario that may signify an underlying disease. A thorough clinical evaluation, paired with an initial work-up, guides the etiological diagnosis. A specific cause is seldom identified, and in 90% of cases, prepubertal gynecomastia is classified as idiopathic

Plasma cortisol measurement: ordering practices

Mohamed Chaher Rabah[1], Rim Marrakchi[1], Dhouha Zouari[1], Mariem Boudaya[1], Kamel Jamoussi[1], Mohamed Abid[2] & Mouna Turki[1]
[1]Laboratory of Biochemistry, Hédi-Chaker Hospital, Sfax, Tunisia; [2]Endocrinology departement, Hedi Chaker Hospital, Sfax, Tunisie

Introduction
Cortisol level measurement is required in the diagnosis and management of adrenal, pituitary and hypothalamic pathologies.
Aim
The aim of this study was to evaluate clinician's practice in ordering cortisol test.
Methods
A retrospective study concerning 63 cortisol requests data collected by the laboratory computer system (Health Lab) between January 2024 and February 2024. Only requests of 0800 hours plasma cortisol were included. We collected age, sex and ordering's origins. Cortisol tests were performed based on electrochemiluminescence immunoassay (eCLIA) by Dxi600® Beckman Coulter. Frequencies of cortisol requests were classified according to the reasons and origins of ordering.
Results
The mean age of patients was 38.8 years, with extremes ranging from 6 months to 85 years with a male/female sex ratio of 0,8. The majority of cortisol requests were from the endocrinology department (54%) followed by the paediatrics department (17.5%) and the internal medicine department (14.3%). Reasons for prescribing a cortisol test were as follows: 66.7% for suspecting of adrenal insufficiency, 4.8% for following-up of a confirmed adrenal tumour and 7.9% for following-up of pituitary and hypothalamic pathologies. Among cortisol requests 11.1% were not renseigned. Among cortisol test requests with clinical indications of suspecting adrenal insufficiency, following-up adrenal insufficiency and following-up of pituitary and hypothalamic pathologies only 31%, 25% and 40% were pathological respectively.
Conclusion
There was an over-ordering for cortisol tests in our hospital practice. This suggests this request should be more rational in order to limit healthcare costs

DOI: 10.1530/endoabs.99.EP417

EP418

Clinical and hormonal characterisation of 71 patients with bilateral macronodular adrenocortical disease (BMAD)

Andreea Vladan[1], Ionela Baciu[1,2], Nicoleta Baculescu[1,2], Iulia Burcea[1,2], Cristina Capatana[1,2], Ramona Dobre[1,2], Roxana Dusceac[2], Simona Galoiu[1,2], Radu Iorgulescu[3], Dan Niculescu[1,2], Raluca Trifanescu[1,2], Anda Dumitrascu[2], Larisa Buduluca[2], Mircea Diculescu[1,4], Serban Radian[1,2] & Catalina Poiana[1,2]
[1]Carol Davila University of Medicine and Pharmacy; [2]Parhon National Institute of Endocrinology; [3]Sf Ioan Emergency Hospital, Bucharest; [4]Fundeni Clinical Institute

Background
BMAD is defined as development of multiple large nodules, >1 cm diameter, with bilateral involvement of the adrenal glands. It is typically associated with endogenous Cushing's syndrome (CS) and occurs in adults, in the 4th-7th decade of life.
Aim
To describe the clinical presentation, the biochemical peculiarities and the management of 71 patients diagnosed with BMAD in a tertiary endocrinology centre.
Results
We described 71 patients with BMAD (54F/17M), aged 65 years old (32-82, median/range), age at onset 61 years old (30-78, median/range). 59 patients were diagnosed incidentally by computed tomography (47), MRI (8) or abdominal ultrasound (4), while 9 of them were referred to the endocrinologist with high suspicion of CS and 2 to be screened for endocrine causes of hypertension. 46 patients were overweight or obese, with a median BMI of 27 kg/m^2 (17.5-44.2), 28 patients had diabetes or prediabetes and 56 patients presented hypertension. 37 patients presented CS, 3 of whom associated primary aldosteronism – 19 patients with MACS, 32 patients presented nonfunctional bilateral macronodular adrenocortical disease and one single patient was diagnosed with adrenocortical carcinoma. Cortisol after dexamethasone 1 mg overnight was 3.43 mg/dl (1.04-23.75) in patients with CS. UFC was high in 3 patients with CS. Median ACTH was 5.19 pg/ml (1-19.98) in patients with CS. All patients had done an enhanced computed tomography, the maximum diameter of the adrenal nodule was 2.8 cm (1.19-7.8). 15 patients with CS were screened for aberrantly expressed hormone receptors, 7 patients presented a positive response after a mixed meal, suggestive for GIP expression, 1 patient presented a positive response after Diphereline administration suggestive for GnRH/l H/FSH/beta-hCG expression. 19 patients were submitted to adrenal surgery, 4 of whom needed bilateral adrenalectomy, while the other patients were followed-up. The median follow-up was 3 years (0-19). During follow-up, 2 of the 15 patients who were submitted to unilateral adrenalectomy had inefficient suppression of cortisol in dexamethasone suppression tests.
Conclusions
Diagnosis of BMAD in our cohort was done mainly by imaging. CS due to BMAD is frequently pauci-symptomatic, warranting biochemical screening in patients

with metabolic syndrome and atypical Cushing's. Bilateral adrenalectomy is curative. Management depends on the severity of Cushing's and availability of medical therapy (requiring biochemical aberrant adrenal receptor profiling). Patients subjected to conservative management need long-term follow-up.

Correlation of hypothalamic-pituitary-adrenal axis parameters with the size of adrenal incidentaloma

Sanja Ognjanovic, Bojana Popovic, Valentina Elezovic Kovacevic, Dusan Ilic, Milica Opalic Palibrk, Lena Radic, Katarina Krstic & Djuro P. Macut
Clinic for Endocrinology, Diabetes and Metabolic Diseases, University Clinical Centre of Serbia, Department for Endocrine Tumors and Hereditary Cancer Syndromes, Belgrade, Serbia

Introduction
The majority of adrenocortical incidentalomas (AIs) are nonfunctional adenomas. Some of them demonstrate an autonomous cortisol secretion (ACS), a pathologic condition defined as biochemical evidence of hypercortisolism without typical signs or symptoms of Cushing's syndrome.
Subjects and methods
In this cross-sectional study, we evaluated 152 consecutive patients, aged 58.3 years (range, 25-84 years) of whom 105 (69.1%) with unilateral adrenal incidentalomas (UAIs) and 47 (30.9%) with bilateral adrenal incidentalomas (BAIs). The hypothalamic-pituitary-adrenal (HPA) axis activity was evaluated using basal cortisol and ACTH levels, midnight cortisol level, 24-h urinary free cortisol (UFC), and post 1 mg overnight dexamethasone suppression test (1 mg-DST) cortisol level. We measured the maximum adrenal nodule diameter on CT and MRI.
Results
There was no significant difference between the longest diameter of the largest adrenal nodule between BAI and UAI patients (3.2 $\pm$ 1.0 *vs* 3.0 $\pm$ 1.2mm $P=0.254$). We found that the maximum adrenal nodule diameter negatively correlated with the ACTH level ($r=-0.213$; $P=0.009$), and positively correlated with midnight serum cortisol level ($r=0.274$; $P=0.001$), UFC ($r=0.264$; $P=0.044$), post DST-1 mg cortisol level ($r=0.206$; $P=0.011$), and probability for ACS ($r=0.276$; $P=0.001$). Multivariate Logistic Regression for ACS showed, after controlling for age, waist circumference, Body Mass Index, UAI *vs* BAI, that adrenal adenoma size was an independent predictor of occurrence of ACS (OR = 1.055, 95% CI 1.017-1.094, $P=0.004$).
Conclusion
These results suggest that critical adrenal tumor mass is required to increase the capacity of steroidogenesis and to result in mild cortisol excess, but probably different pathogeneses are also involved.

Background
Ehlers–Danlos syndrome is a group of genetic conditions characterized by alterations in connective tissue structure, which produces various symptoms. Some subtypes of this syndrome are associated with structural alterations of tenascin-X, an extracellular matrix glycoprotein encoded by the TNXB gene, which partially overlaps the CYP21A2 gene, which encodes adrenal 21-hydroxylase. The purpose of this study was to assess the relationship between tenascin-X levels and adrenal hormones in female patients with Ehlers–Danlos syndrome.
Material and methods
The purpose of this study was to prospectively assess 30 female patients, aged 20–53 years, with hypermobile or classical Ehlers–Danlos syndrome. All patients underwent tests of their tenascin-X levels as well as adrenocorticotropic hormone (ACTH), cortisol, androstendion, and 17-hydroxyprogesterone levels, and urine steroid profile, and magnetic resonance imaging of the adrenal glands.
Results
The study showed no statistically significant correlation between tenascin-X levels and either of the following: 17-hydroxyprogesterone (r_s -0.02, $P=0.933$), cortisol (r_s 0.18, $P=0.346$), ACTH (r_s 0.22, $P=0.233$), androstendion (r_s 0.244, $P=0.194$). There was a positive correlation between tenascin-X levels and dehydroepiandrosterone sulfate (DHEA-S) (r_s 0.362, $P=0.049$). Univariate logistic regression demonstrated that tenascin-X cannot be a predictor of late-onset congenital adrenal hyperplasia (OR 0.49, 95% CI 0–1.3, $P=0.99$).
Conclusions
Tenascin-X levels show no significant correlation with 17-OH-progesterone levels and show a positive correlation with DHEA-S levels. However, the study did not demonstrate tenascin-X to be a predictor of late-onset congenital adrenal hyperplasia in women with Ehlers–Danlos syndrome.

Clinical, biological, radiological and therapeutic profiles of pheochromocytomas/paragangliomas

Debbah Wissame, Mezoued Mouna, Bessaid Khadidja & Azzouz Malha
Endocrinology-diabetology department of the public hospital establishment (EPH) of Bologhine Ibn Ziri-, Algiers, Algeria

Introduction
Pheochromocytomas-paragangliomas are rare neuroendocrine tumors that secrete catecholamines from chromaffin cells of the adrenal medulla, sympathetic or parasympathetic ganglia. Unrecognized pheochromocytomas are associated with high mortality, most often due to cardiovascular disorders.
Objective of the study
The objective of our work is to study the clinical, biological, radiological and therapeutic characteristics of pheochromocytomas/paragangliomas
Patients and methods
This is a retrospective descriptive and analytical study spread over a period of 20 years involving 48 patients hospitalized for pheochromocytoma/PPGL in the endocrinology-diabetology department of the public hospital (EPH) Bologhine ibn ziri - Algiers, Algeria.
Results
The analysis of our series finds a clear female predominance, with a mean age at diagnosis of 39 $\pm$ 16.02 (13-76) years. The circumstances of discovery were dominated by adrenal incidentaloma in 26 patients (54.2%). We observed in our cohort: arterial hypertension in 81.2% of our patients including 13 cases of resistant hypertension, 35.4% of patients are diabetic with 41% of cases with cardiovascular complications such as left ventricular hypertrophy in the majority of cases. The determination of urinary methoxylated derivatives was carried out in 75% of cases, with a mixed secretory predominance of 58%. An adrenal CT scan was performed in 95.83% of cases, apart from two patients in a pregnancy context. The mean size of the tumor was 65.7 $\pm$ 30 (10-150) mm with a mean spontaneous density (SD) (specified in 32.6% of cases) of 40.3 $\pm$ 19 (18 -98) HU. A significant positive correlation was observed between the size of the tumor and the rate of MN These pheochromocytomas were included in the context of MEN 2a in 9 cases, Von Hippel Lindau disease (VHL) in 2 cases and neurofibromatosis 1 (NF1) in 2 cases. Pathological examination confirmed the diagnosis in all cases. An average PASS score of 4.7 and a Ki 67 of 3.7%. A malignant form was observed in 6 cases. The postoperative evolution was marked by a normalization of blood pressure figures in 17 patients (58%) and normalization of the glycemic cycle in 04 patients (33.3%).
Conclusion
Most pheochromocytomas were diagnosed incidentally in our cohort. The clinical characteristics and management of our patients are consistent with those in the literature. Pheochromocytoma requires long-term monitoring.

Management of adrenal incidentalomas: a single-centre experience

Furhana Hussein[1], Haneen Eltayeb[2], Samrah Ejaz[2,3,3], Alida Akter Ani[2], Gideon Mlawa[2], Belayet Hossain[2] & Edel Casey[2]
[1]Queen's Hospital, Endocrinology and Diabetes/Acute Medicine, London, United Kingdom; [2]Queen's Hospital, London, United Kingdom; [3]Queens Hospital, Endocrinology, London, United Kingdom

Introduction
An adrenal incidentaloma is an adrenal mass lesion greater than 1 cm in diameter, which is incidentally discovered by radiological investigation. The prevalence of adrenal incidentalomas increases with age, increasing to around 3% at aged 50years and 10% in the elderly. The majority of these lesions are benign >80%. Adrenal incidentalomas fall into one of three categories: Non-functioning tumours: these lesions are benign e.g. adenomas, adrenal cysts, haematomas, etc. Functioning tumours: these lesions produce excess of hormones that the adrenal gland normally produces such as in phaeochromocytoma, Cushing's, Conn's, etc. Malignant tumours: these could include adrenocortical carcinoma and metastatic disease.
Aim
of this study was to look at the diagnosis and management of patients referred for adrenal incidentalomas at Queen's Hospital, London, UK (BHRUT–Barking, Havering and Redbridge University Hospitals NHS Trust) in 2014-2020 (7 years).
Method
Retrospective single-centre study looking at patients referred for adrenal incidentaloma between 2014-2020. 154 patients were identified and data was collected on investigations, diagnosis and management. This was compared to the European Society of Endocrine guidelines 2023.
Results
154 patients identified of which 61% female and 39% male. Initial scan showing adenoma leading to referral were CT 84% and MRI 16% Age of presentation more common in the age range of 61-70years (30%) and the least common was age range 20-30years (1%). Majority of the adrenal incidentalomas were non-functioning (65%). The second most common was cortisol secreting adenomas which included 28 patients with 21 possible autonomous cortisol secreting adenomas (PACS) and 7 autonomous cortisol secreting adenomas (ACS). Looking further at these patients and their co-morbidities such as hypertension, diabetes mellitus, dyslipidaemia; 100% had dyslipidaemia and 81% of PACS and 57% ACS had 2 or more co-morbidities. The remaining adrenal incidentalomas consisted of 8% Conn's, 4% Cushing's, 3% Phaeochromocytoma, 3% myelolipoma, 3% malignancy and 5% had no diagnosis. No diagnosis was either due to patient's wishes for not having further investigations or patient passed away before completing investigations.
Conclusion
Our single-centre study showed that majority of adrenal incidentalomas are non-functioning (65%) which correlates with the literature. However, it is important not to miss relevant diseases such as phaeochromocytoma, adrenocortical carcinoma, etc. It is important to send relevant investigations including hormone profile. It is important to have an MDT approach which is individualised for each patient.

How concordant is cardiovascular risk stratification using various risk scoring system compared with coronary artery calcium scoring in asymptomatic Thai people with diabetes mellitus?

Yotsapon Thewjitcharoen, Waralee Chatchomchuan, Soontaree Nakasatien, Sirinate Krittiyawong & Thep Himathongkam
Theptarin Hospital, Diabetes and Thyroid center, Bangkok, Thailand

Background
People with type 2diabetes (T2D) often referred as cardiovascular disease (CVD) risk equivalent. However, CVD risk in diabetes varies greatly and substantial proportion of people with T2D have low CVD risk as with the general healthy population. The latest European Society of Cardiology (ESC) guidelines 2023 endorsed the T2D-specific CVD risk score (SCORE2-Diabetes) for people with T2D. However, current prediction models are developed from non-Asian populations, and their utility in other parts of the world is unknown.
Objectives
This study aims to compare various CVD risk prediction tools and validate their performances with the severity of subclinical coronary atherosclerosis assessed by coronary artery calcium (CAC) risk scoring system in asymptomatic Thai people with T2D.
Methods
This cross-sectional study included asymptomatic Thai people with DM who underwent CAC measurement at Theptarin Hospital, Bangkok, Thailand. Four CV risk scores (Thai CV risk score, SCORE2 model, SCORE2-Diabetes model, and UKPDS risk score) were applied and estimated risk scores were correlated with the severity of CAC. Both low-risk and moderate-risk countries were applied in SCORE2 and SCORE2-Diabetes models.
Results
A total of 83 participants (female 39.8%, mean age 59.0±7.2 years, mean DM duration 10.0±8.9 years, BMI 26.5±5.1 kg/m^2, A1C 7.3±1.7%, insulin usage 24.1%) were studied. Zero calcium score was found in 25.3% and CAC score ≥ 100 AU was found in 49.4% of all participants. In people with a duration of diabetes ≥ 10 years, zero calcium score was also found in 6.1%. The Thai CV risk score classified the highest proportion of patients into very high-risk category of CVD (28.9%), followed by SCORE2 (9.6%), SCORE2-Diabetes (9.6%), and UKPDS (7.2%). Spearman correlation coefficients for CAC score with various CV scores ranged from 0.314 to 0.419 with SCORE2-Diabetes performed the best.
Conclusions
Our data showed that when CAC measurements were done in asymptomatic people with DM, almost one-fourth of subjects were found to have zero score, indicating very low-risk for CVD in the future. Although there had been many efforts to create CV risk scoring systems both general population and diabetes-specific risk scores for CVD risk stratification, currently available CVD risk scores (both non-DM and DM-specific risk scores) did not accurately predict the severity of CAC burden in Thai people with T2D.

Lipid risk factors for cardiovascular mortality and chronic inflammation in functionally dependent elderly persons

Olga Vasovic
Euromedic General Hospital, Belgrade, Endocrinology, Belgrade, Serbia

Introduction
Many studies have pointed to the importance of chronic inflammation and dyslipidemia in the development of atherosclerosis, but data related to the elderly population are still inconsistent. The aim of the work: To determine the importance of determination of markers of inflammation (C-reactive protein - CRP) and lipid status in elderly (≥65 years), functionally dependent persons.
Methods
A prospective study that included 257 patients (aged 65-99 years, 76.9% women) of the City Institute for Gerontology, Belgrade. At the beginning of the study patients were divided into three groups based on CRP values: group A (CRP<1 mg/l, n= 70), group B (CRP 1-3 mg/l, n= 69) and group C (CRP >3 mg/l, n=69). Patients with CRP>10 mg/l were excluded from the study. Lipidogram, glycemia, HbA1c, then anthropometric measurements, blood pressure and pulse were measured in each patient. After a two-year follow-up, mortality and the factors that influenced its occurrence were analyzed.
Results
CRP showed a significant positive correlation with waist circumference (P=0.005), hips (P=0.012), HbA1c (P=0.033) and triglycerides (P=0.028), and a negative correlation with Hdl-cholesterol (P=0.013). Of the lipid risk factors, only the ratios total cholesterol/Hdl (P=0.019) and triglycerides/Hdl (P=0.045) were significantly lower in group A compared to group B, and without differences compared to group C. However, elevated cholesterol is an independent risk factor for Mt only in group C: OR=3.71 (95%C:1.09-12.63).
Conclusion
Determination of CRP helps to identify old people who are at high risk and in whom the treatment of hyperlipidemia is most important in the prevention of mortality.

Safety and efficiency of short-term glucocorticoid treatment in laryngological patients – pilot study

Lucyna Papierska[1], Wiktor Miechowski[2], Karolina Dżaman[2] & Wojciech Zgliczynski[1]
[1]Centre of Postgraduate Medical Education, Department of Endocrinology, Warsaw, Poland; [2]Centre of Postgraduate Medical Education, Department of Otolaryngology, Warsaw, Poland

Patients with chronic sinusitis with polyps are prepared for surgery (FESS) in one of two ways: through intranasal steroid therapy or oral preparation. The high-dose oral glucocorticoids are not often used in Poland, because of the due to the risk of developing side effects including pituitary-adrenal axis inhibition with the need for steroid cover during surgery. The 30 patients before FESS were randomly divided into two equal-sized groups. Patients in the first group received intranasal fluticasone propionate at a dose of 800 µg /day for 8 consecutive weeks before surgery. Patients in the second group received oral prednisone at a dose of 0.5 mg/kg/day for 7 days. The degree of polyposis assessed by sinus CT decreased statistically significantly only after treatment with oral steroid (13.14 (95%CI 8.95-15.92) vs. 8.0 (95%CI 4.05-10.59) $P=0.000012$ on a Lund-Mackay scale). There was no statistically significant difference in ACTH levels (14,73 (95%CI 11,85-19,49) vs. 21,09 (95%CI 12,28-41,08) and in morning cortisol levels before and after oral steroid treatment 1.41 (95%CI 8.44-14.20) vs. 8.16 (95%CI 6.69-14.2) $P=0.39$) and this effect did not differ from that observed after intranasal therapy. Electrolytes, glucose, and insulin levels also did not change significantly after this treatment. The operation was performed without hydrocortisone cover and no complications were observed. In conclusion, we have stated that our data confirmed the lack of inhibition of the pituitary-adrenal axis after short-term high-doses GCS therapy. We are planning further research in this area with the goal of introducing oral GCS into the standard preparation for FESS.

EP599

Ophthalmic artery doppler as a test for gut-brain axis modulation: feasibility study

Rostyslav Bubnov[1] & Mykola Spivak[2]
[1]Clinical hospital`Pheophanià, Ultrasound, Kyiv, Ukraine; [2]Zabolotny Institute of Microbiology and Virology, National Academy of Sciences of Ukraine, Kyiv, Ukraine

Introduction
The Gut-Brain Axis (GBA) is implicated in various conditions, including migraine, headache disorders, Irritable Bowel Syndrome (IBS), hypertension, and vascular dysregulation. While ophthalmic artery Doppler shows promise in conditions like migraine and stroke prevention [2], effective treatments targeting these mechanisms are still under exploration. Probiotic therapy, as a potential molecular and cellular modulator, may balance regulatory systems leading to pathological conditions.
Aim
To explore the relevance of ophthalmic artery Doppler as a test for the efficacy of probiotic therapy in potentially modulating the gut-brain axis.
Methods
A cohort of 10 patients diagnosed with migraine, headache disorders, seasonal dizziness, nausea, IBS, and hypertension underwent general clinical, lab tests, and radiology tests for a metabolic biomarker panel. Probiotic strains, including Lactobacillus and Bifidobacterium genera, were administered at a dose of 10^9 CFU per day for ten days was based on symptoms [3-5]. Ophthalmic artery Doppler analysis was conducted before and after interventions to assess changes in blood flow parameters. Standardized scales evaluated improvements in eye symptoms. Kidney Doppler, blood flow resistive index in segmental arteries, and parameters like visceral fat were also tested.
Results
Analysis revealed significant changes in ophthalmic artery Doppler parameters post-interventions. Peak systolic velocity increased from 25 cm/sec to 35 cm/sec ($P<0.05$), indicating enhanced blood flow, accompanied by a decrease in resistivity index from 0.78 to 0.65 ($P<0.01$), suggesting reduced vascular resistance. Similar trends were noted in ciliary and other ophthalmic parameters. Effective outcomes were observed in kidney blood flow, with decreased IR. Low and normal BMI patients experiencing treatment effects exhibited increased visceral fat. Other symptoms related to GBA, including IBS, asthma, and hypertension, showed alleviation.
Conclusion
Microbiome modification via probiotic therapy may impact certain diseases in both short-term and long-term scales. The Gut-Brain Axis emerges as a potential mechanism, urging further exploration and clinical consideration. Future research should delve into mycobiome, neuromodulators, interleukins (IL-6), cortisol levels, metabolites, Short-Chain Fatty Acids (SCFA), serotonergic agents, CGRP-signaling, hypoxic signaling, and the modulation of calcitonin gene-related peptide (CGRP) within the trigeminal system [1-3].

Epidemiological data of primary and secondary adrenal insufficiency in southern province of seville

Pavle Puzigaca, Eyvee Arturo Cuéllar Lloclla, José Álvaro Romero Porcel, Sara Hami Gil & María Victoria Cózar León
Virgen de Valme University Hospital, Department of Endocrinology and Nutrition, Seville, Spain

Objective
Evaluate the prevalence of adrenal insufficiency (AI) in Southern Province of Seville that comprises around 400.000 people.
Materials and methods
Retrospective descriptive study that includes patients diagnosed with primary (PAI) and secondary (SAI) adrenal insufficiency that are followed up at Virgen de Valme University Hospital.
Results
Out of the 125 patients with AI, 51 patients (40,8%) had PAI and 74 patients had SAI (59.2%). PAI was diagnosed in 30 men (59%) and 21 women (41%). Age at diagnosis was 32 $\pm$ 21 years. The most common cause was of autoimmune origin (51%), followed by adrenalectomy (31%), congenital adrenal hyperplasia (16%), and tuberculosis (2%). Among patients with autoimmune origin of PAI, 15 (58%) had at least one associated autoimmune disease, most commonly Hashimoto's thyroiditis (80%), type 1 DM (27%), pernicious anemia (13%), celiac disease (7%), Grave's disease (7%), Goodpasture's syndrome (7%), and psoriasis (7%). As for adrenalectomy, the cause of surgery were pheochromocytoma (37.5%), Cushing's syndrome (37.5%), and metastasis (25%). Regarding treatment, the mean dose of hydrocortisone was 23.2 $\pm$ 7.9 mg and of fludrocortisone 0,08 $\pm$ 0.5 mg. SAI was diagnosed in 41 men (55%) and 33 women (45%). Age at diagnosis was 48 $\pm$ 21 years. The main etiology was non-functioning pituitary macroadenoma (25.7%), followed by craniopharyngioma (10.8%), functioning pituitary adenoma (8.1%), Sheehan syndrome (6.8%), pituitary apoplexy (6.8%), empty sella turcica (6.8%), traumatic head injury (5.4%), immunotherapy (4.1%), hypophysitis (4.1%), exogenous corticosteroids (4.1%), radiotherapy (2.7%), idiopathic panhypopituitarism (2.7%), pituitary hypoplasia (2.7%), pituitary carcinoma (1.4%), and other causes (8.1%). The mean hydrocortisone dose for treatment was 18.8 $\pm$ 5.3 mg.
Conclusions
In our study population, it was observed that AI occurs more frequently in men. SAI is more common and occurs almost 15 years after PAI, with the dose of hydrocortisone being almost 5 mg less than in PAI. The most common cause of SAI was non-functioning pituitary macroadenoma, while in the case of PAI, it was of autoimmune origin and most commonly associated with Hashimoto's thyroiditis.

Long term management of adult bilateral adrenal hyperplasia with mild autonomous cortisol secretion - data from a Romanian tertiary center

Vlad Radulescu[1], Anastasia Stanescu[1], Cristina Stancu[1], Monica Gheorghiu[1,2], Dana Manda[1], Anda Dumitrascu[1] & Corin Badiu[1,2]
[1]C.I. Parhon National Institute of Endocrinology, Bucureşti, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucureşti, Romania

Introduction
Adrenal hyperplasia is found in more than 15% of abdominal imaging procedures in adults, unrelated to endocrine disorders, especially after the COVID era. Adrenal management is consequently recommended.
Aim
To retrospectively evaluate the adrenal status in terms of morphological progression and functional impairment of adrenal function, in a cohort of cases admitted at least yearly in the National Institute of Endocrinology, Bucharest, Romania, between 2019-2023.

Patients and Methods
141 patients (104 women, 37 men) were evaluated for bilateral adrenal hyperplasia. Adrenal function was assessed by basal and dynamic cortisol (suppression tests) and ACTH, testosterone, DHEA-S, aldosterone and renin as well as urinary and plasma metanephrines and normetanephrines.
Results
There were recorded 18 (12.8%) cases of ACTH dependent Cushing, 14 (9.9%) cases of ACTH independent Cushing, 9 (6.3%) cases of Non Classical congenital adrenal hyperplasia (CAH), 7(4.9%) cases of pheochromocytoma/PPGL, 4 (2.8%) cases of primary hyperaldosteronism, 3 (2.1%) cases of metastatic adrenals, 3 (2.1%) of CCAH and 3(2.1%) paraneoplastic Cushing and 2 (1.4%) of each: adrenal carcinoma and androgens secreting tumors; 58 (41.1%) cases remained non-functional. All PPGL cases underwent surgery with one case of bilateral adrenalectomy. Bilateral adrenal surgery was performed for ACTH independent Cushing ($n=2$) while unilateral surgery was performed for 7 cases. For ACTH dependent Cushing there was only one case of bilateral adrenalectomy, 7 cases of pituitary surgery and 4 cases of pituitary + bilateral adrenal surgery with only 2 cases where unilateral adrenalectomy was chosen. Only 4 cases of non-functional adrenal lesions underwent unilateral surgery because of their higher growth rate. From those with mild autonomous cortisol secretion ($n=18$, 12.8%), a number of ($n=6$) were submitted to unilateral adrenal surgery and declared cured; the site of surgery was decided upon size. From those MACS followed up without surgery, the cortisol autonomy increased during follow-up in 2, remained similar in 8 and diminished in other 2. Several comorbidities (diabetes, high blood pressure, dyslipidemia, osteoporosis) were also subject to follow-up in MACS cases.
Conclusion
The detailed follow-up at 6-12 months of patients with nodular or non-nodular adrenal hyperplasia is required, for proper and individualized management

Haematuria as an atypical presentation of pheochromocytoma: a case report

Ana Matijaca[1] & Magdalena Kujundžić[2]
[1]Clinical Hospital Dubrava, Department of Endocrinology and Diabetology, Zagreb, Croatia; [2]Dom zdravlja Zagreb

Pheochromocytomas are rare catecholamine-producing tumors that arise from chromaffin cells located in the adrenal medulla. They are usually benign, but approximately 10% of pheochromocytomas are malignant. The most common clinical features include Menard triad: headache, sweating and palpitations, and permanent or paroxysmal hypertension. Haematuria as a presenting feature of adrenal pheochromocytoma is rarely seen. We report a case of pheochromocytoma in a 61-year-old female patient who presented with haematuria, sporadic left-sided lumbar pressure with some diaphoresis, and well-regulated permanent hypertension. Due to the suspected left adrenal mass seen on the ultrasound, abdominal computed tomography (CT) was done and revealed a 70 mm large left adrenal gland mass. Subsequently, a left-sided adrenalectomy was performed in 2015. Pathohistological examination confirmed pheochromocytoma with an increased risk of malignant behavior. Annual follow-up in 2019. detected elevated urinary metanephrines and normetanephrin. CT scan confirmed 30x24 mm tumor recurrence in left kidney hilus and the patient was submitted to reoperation. Two years after – in 2021. slightly increased values of urinary normetanephrine were noticed although the patient didn't have any symptoms related to excessive catecholamine level once again. Contrast-enhanced thorax CT scan of the abdomen didn't show any suspected lesions but multiple 7 mm large solid lung nodules at bilateral lung basis were noticed. Further, thoracic CT set suspicion of lung metastases so following PET/CT as well as SPECT- CT – MIBG 131 confirmed the suspected metabolically active spread of malignant pheochromocytoma and the patient was referred to an oncologist. Clinical feature of pheochromocytoma are primarily associated with excessive catecholamine production with levels that are expected to be proportional to tumor size. In this case report we wanted to show patient who, except of haematuria as first symptom to be evaluated for, pheochromocytoma was clinicaly silent, as well as the reccurence of tumor or presence of (lung) metastases. Patient did not have any adrenergic symptoms before surgical removal as well as after reaccurance of tumor or lung metastases. Early diagnosis accompanied by lifelong anual follow-up is essential to enable early detection of recurrence and potential malignant complications and in our case report we wanted to emphasis the importance of urinary catecholamine metabolites measurment in follow-up of these patients.

A thousand faces of pheochromocytoma: Insights from a case series

Romana Marušić[1,2], Ines Bilić-Ćurčić[2,3], Ema Schönberger[2,3], Kristina Steiner[3], Klara Ormanac[2,3], Eduard Oštarijaš[4] & Silvija Canecki-Varžić[2,3]
[1]General Hospital Vukovar, Department of Internal Medicine, Vukovar, Croatia; [2]Faculty of Medicine Osijek, Osijek, Croatia; [3]Clinical Hospital Center Osijek, Department of Endocrinology, Osijek, Croatia; [4]General Hospital Virovitica, Department of Internal Medicine, Virovitica, Croatia

Introduction
Pheochromocytomas, rare neuroendocrine tumors originating from adrenal medulla chromaffin cells, excessively secrete catecholamines, manifesting diverse symptoms. With an incidence of 2-9 per million inhabitants, these tumors pose diagnostic challenges due to their varied clinical presentation.
Case Description
We present five patients diagnosed with pheochromocytoma at the Clinical Hospital Center Osijek. The incidentaloma of the adrenal gland was discovered while diagnosing unrelated conditions, and none of the patients displayed typical pheochromocytoma symptoms. While one patient reported abdominal pain, others remained asymptomatic. CT was performed, and all patients exhibited significantly elevated normetanephrine levels in serum and urine, with only one showing marginally elevated metanephrine in urine. Patients' characteristics are shown in Table 1.

Conclusion
Pheochromocytoma, lacking specific symptoms, often evades recognition. If there is a clinical suspicion or imaging finding of incidentaloma of the adrenal gland, biochemical testing for pheochromocytoma is crucial.

Pseudopheochromocytoma in a patient with depression: a case report

Sawsen Nouira, Hamza Elfekih, Fatma Ben Abdessalem, Asma Gorchene, Kussay Ach, Yosra Hasni & Molka Chaieb
University Hospital Farhat Hached, Endocrinology-Diabetology Department, Sousse

Introduction
Pseudopheochromocytoma is a poorly comprehended entity believed to arise from an overstimulated sympathetic nervous system. Individuals with pseudopheochromocytoma seem to demonstrate heightened cardiovascular reactivity to catecholamines, along with an increased release of epinephrine from the adrenal glands in response to stimulation from the sympathetic nervous system. This clinical report presents an observation of pseudopheochromocytoma in a patient diagnosed with a depressive disorder.
Case Presentation
A 29-year-old patient was admitted to our endocrinology department for the evaluation of hypertension. The onset of his medical history dates to the age of 18-year-old, when he was receiving psychiatric care for depression. The patient's clinical course revealed a sudden-onset hypertension, palpitations, and headache lasting for few minutes followed by spontaneous resolution. He noted a worsening of blood pressure while on antidepressants medications. We conducted a 24-hour ambulatory blood pressure monitoring, revealing consistently normal blood pressure levels interspersed with two episodes of elevated systolic blood pressure reaching 140 mmHg. Investigations have ruled out renal artery stenosis. Aldosterone (257 pg/ml [42-209]) and direct renin (17.7 pg/ml [2.7-16.5]) levels were in favor of secondary hyperaldosteronism. Urinary normetanephrines were mildly elevated, below twice the upper limit of normal (Metanephrines: 276 nmol/24 h [$<$159 nmol/24 h]). 3-methoxytyramine were mildly elevated. Repeating metanephrines in the plasma after 30 min rest showed normal result and the abdominal CT-scan eliminated adrenal tumors.
Discussion
Pseudopheochromocytoma is characterized by the presence of symptoms of catecholamine excess and is commonly considered as a diagnosis of exclusion, yet it possesses distinct characteristics. It is strongly linked to psychiatric disorder, which may not be immediately apparent. Pharmacological approaches for managing this condition encompass antihypertensive medications, antidepressants, and anxiolytics. Additionally, psychotherapeutic interventions prove beneficial in addressing this association. The management of pseudopheochromocytoma is frequently challenging.

Vitamin D status in young healthcare workers: association with lipid parameters

Zeineb Rekaya, Samir Mekaouer, Meriem Yazidi, Nadia Khessairi, Elyes Kammoun, Ibtissem Oueslati, Fatma Chaker & Melika Chihaoui
La Rabta university hospital, Endocrinology

Introduction
Vitamin D deficiency is an emerging concern that has the potential to impact one's health, even in sunny Mediterranean countries like Tunisia. This issue is particularly notable among indoor workers in the healthcare sector, who experience minimal sun exposure. The aim of this study was to describe the Vitamin D profile within this specific population and to establish its association with lipid parameters.
Methods
This cross-sectional observational study, conducted from August 2022 to October 2023, involved 64 young and healthy hospital-based healthcare workers. Exclusions were made for individuals with medical conditions that might impact phosphocalcic metabolism. Vitamin D levels were classified as Deficiency ($<$10 ng/ml) and Insufficiency (10-29 ng/ml).
Results
The study participants had a mean age of 29.51 $\pm$ 7.064 years, with 57% being women and 43% men. Among women, 28.6% wore veils. The mean vitamin D level was 21.05 ng/ml [12.87; 21.05]. A vitamin D deficiency was present in 16.7% of cases, and an insufficiency in 62.5% of cases. Women had a lower Vitamin D level compared to men (15.5 vs 16.4 ng/ml, $P=0.57$). The frequency of vitamin D deficiency was higher in women than in men (29.6% vs 0% $P=0.007$). A positive correlation was found between Vitamin D and Ldl levels ($P=0.042$), and between vitamin D and total cholesterol level ($P=0,024$). Healthcare workers with vitamin D deficiency had lower Hdl levels than workers with vitamin D insufficiency. (1.41 vs 1.24 mmol/l, $P=0.028$).
Conclusion
This study revealed a significant prevalence of vitamin D deficiency and insufficiency among young healthcare workers, with women exhibiting a higher deficiency rate. The positive correlations with Ldl and total cholesterol levels emphasize potential links with lipid metabolism. The lower level of Hdl observed in workers with a vitamin D deficiency highlight the need for targeted interventions to improve the vitamin D status among healthcare professionals.

Clinical significance of adrenal venous sampling in primary hyperaldosteronism: a case report

Natia Katamadze
clinic ENMEDIC, endocrinology, tbilisi, Georgia

Primary hyperaldosteronism represents a current and underdiagnosed cause of secondary hypertension, characterized by inordinate and independent aldosterone production. While adrenal venous sampling (AVS) has surfaced as the gold standard for lateralization of aldosterone excess, its operation in cases of grueling primary hyperaldosteronism remains less explored. In this unique case history, we present the clinical script of a case with suspected primary hyperaldosteronism, flaunting atypical biochemical and imaging findings. This case of a 45- year old male who presented to the clinic with complaints of high blood pressure, rhythm disturbances, palpitaions, dyspnea and muscle cramps. While all the symptoms were experiences unexpectedly, he had no memory of these symptoms in the past. He was being managed in an outpatient department for hypokalemia and hypertension since the age of 38. He has been taking three antihypertensives (amlodipine, enalapril, labetalol) and supplemental potassium (2 tablets of 10 mEq three times a day). Initial investigations revealed normal hematological and renal parametres but sodium showed 135 mmol/l and potassium 2.5 mmol/l. ECG performed at the time of admission were unremarkable as well. Serum Aldosterone and renin levels were 97 ng/dl and 0.19 ng/ml/hour, respectively, and cortisol levels were 11.7 g/dl. The Aldosterone-Renin ratio was calculated to be 510 ng/dl per ng/(mg/hour). These markers were obvious in stating that there are some discrepancies in some of these levels of some parametres listes above. The abdominal contrast-enhanced Computed Tomography scan showed nodular lesions in the adrenal glands ; 7mm on the right and 37mm on the left which were probably adenoids with low lipid substrate (32 HU- hounsfield unit densities). A selective Adrenal Venous Sampling with Adrenocorticotropic Hormone Stimulation tests were performed. While the aldosterone and cortisol levels in the left adrenal vein were 97 ng/dl and $>$120 µg/dl, the levels in the right adrenal vein were 4086 ng/dl and $>$120 µg/dl, suggesting a diagnosis for Unilateral Adrenal Hyperplasia. Sarcastically, in this case, size didn't matter but infact the hyperactivity did the work. A right adrenelectomy was done to the patient and medications such as spironolactone and oral potassium chloride were given orally during his hospital stay. His electrolytes and blood pressure were corrected 5th day after the surgery and he was subsequently discharged with verapamil, hydralizine, doxasozin and spironolactone. The aldosterone-renin ratio levels came 125 ng/dl(ml/hour)

Primary adrenal carcinoma: review and experience of 8 cases in the hospital of málaga

Maria Jose Vallejo Herrera, Veronica Vallejo Herrera, Stella Gonzalez Romero & Viyey Kishore Doulatram Gamgaram
Hospital Regional Málaga, Malaga

Introduction
Primary adrenal carcinoma is a very rare pathology, its treatment is fundamentally surgical and adjuvant treatment with mitotane can prevent recurrences. The prognosis

varies depending on the patient, the stage and the histopathological diagnosis. We present the case mix of patients diagnosed with adrenal cortex carcinoma in our center between 2012-2022 and review the management of this pathology.
Patients and Methods
Retrospective study on adult patients diagnosed with adrenal carcinoma in our center between 2012-2022. We include hormonal study, imaging tests, treatment, histopathological findings and evolution. In carrying out this work we have followed the ethics rules for publication, informed consent has been obtained from the patients and it has been approved by the corresponding ethics committee.
Results
We included eight patients (Table 1), five women and three men, with a mean age of 47 years (range 25-68 years). Three consulted for locoregional symptoms, 4 for functional syndrome and one was diagnosed incidentally. The majority had hyperproduction of sex hormones and cortisol and one case turned out to be non-functioning. Half of the tumors were located on the left adrenal gland and the other half on the right. Two patients had metastasis at diagnosis and one case had a second concomitant primary lung neoplasia. The sites of metastases were liver, lung and bone. Of the eight cases presented, 6 patients underwent adrenalectomy with radical intent. Surgery was not performed in the two patients with stage IV disease; In both cases, metastasis of adrenal carcinoma was confirmed by biopsy of liver metastasis. The patient with a second primary lung tumor first underwent adrenalectomy and then resection of the lung tumor. Regarding the histological study of the surgical specimens, in all cases it was described the Weiss score and the Ki67. Three were low grade and three were high grade. Five patients received treatment with mitotane, due to high grade to prevent recurrence (3 cases) or due to advanced stage of the disease (2 cases). One patient received chemotherapy with EDP (etoposide, doxorubicin and cisplatin) with partial response. In follow-up, until 2022-2023, four patients are in remission, three Patients presented a recurrence of the disease and 3 patients died (one after a recurrence and the other two -stage IV- one month and one year after diagnosis).

Familial congenital adrenal hyperplasia (CAH) presenting as addisonian crises – case series

Man Yan Hamilton, Furhana Hussein, Keiko Carter, Bashir Mahamud, Mohammad Saleki, Ayan Mohamed & Gideon Mlawa
[1]Queens Hospital, Endocrinology and Diabetes, Romford, United Kingdom

Introduction
This case series consist of three brothers who are aged 24, 27 and 28. The eldest brother was diagnosed with CAH at 18 days when he presented with poor weight gain, vomiting and persistent jaundice with hyponatraemia. The parents received genetic counselling for the next two pregnancies and all three children were managed with hydrocortisone and fludrocortisone maintainence therapy. They were closely monitored for their growth rates, signs of precocious puberty and any preciptious weight gain during their childhood.
Recurrent admissions
Their care were transferred from paediatric endocrinologists to the adult service since 2016. From 2016-2024, there were more than 28 acute admissions between the 3 brothers. They often present with gastrointestinal symptoms such as recurrent vomitting, abdominal pain and most of them were treated for gastroenteritis with addisonian crisis. None of them wore a steroid alert bracelet nor carry a steroid emergency card and we noted that their emergency steroid ampules sometimes expired. Repeated counselling were held with the patients and their families to highlight the importance of the above issues and sick day rules. At times there were delays with fluid and intravenous hydrocortisone treatment due to London Ambulance Service having limited understanding of CAH. We created an emergency plan to notify these 3 brothers to the ambulance service to ensure timely treatment will be given in future cases.
Routine monitoring and symptoms management
Testicular screening and Vitamin D levels with bone density scans were regularly carried out. Their weights were monitored with periodic steroid day curves to ensure there was no over-replacement of cortisol. We provide regular counselling regarding health and lifestyle choices to avoid the development of metabolic syndrome. Secondary hypogonadism was managed with a trial of testosterone replacement therapy. Patients were referred to reproductive endocrinologist or a fertility specialist early, whilst checking sperm count and discussing possibility of sperm cryopreservation.
Conclusion
A MDT approach is crucial in supporting paediatric CAH patients transitioning to adult services. The team involves paediatric endocrinologists, geneticists, endocrinologists, fertility specialists, dietitians, physiotherapists and the local ambulance service. In this case we highlight the importance of clear communication between teams to support the early recognition and treatment of adrenal crisis in adults prior to admission. Following the establishment of emergency care plan, the family of 3 brothers are able to receive their treatment in a timely matter and potentially reduce their length of stay at the hospital.

Adrenocortical carcinoma revealed by pulmonary embolism

Oumeyma Trimeche, sana abid, Ines Bayar, Bilel Ben Amor, Ekram Hajji, Héla Marmouch, Hanene Sayadi & Inès Khochteli
Fattouma Bourguiba University hospital, Endocrinology, Monastir, Tunisia

Introduction
Adrenocortical carcinoma is a very rare tumor with a heterogenous prognosis.
Case report
Patient R.B is a 58-year-old female patient with no particular familial history. She had a personal history of hypertension, discovered 6 months ago well controlled with beta blockers and amlodipine. Two weeks before her admission to the hospital, she reported having constantly worsening abdominal pain followed by frequent vomiting few days later. The patient consulted a gastroenterologist and an abdominal CT was performed. It revealed the presence of a massive 12×11 cm heterogenous right adrenal mass, invading the IV segment of the liver along with the inferior cavernous vein. She also had bilateral and proximal pulmonary embolism with a right thrombus in her right atrium from tumor extension and suggestive signs of pulmonary metastasis on thoracic CT. Upon her admission in the intensive care unit, clinical examination revealed excessive hirsutism notably in her face and deepening of her voice. Those symptoms were insidious and neglected by the patient for 5 months. She had no evident clinical signs of Cushing syndrome in spite of cutaneous fragility. Laboratory exams showed cytolysis and persistent biological inflammatory syndrome despite the absence of infection. She had no hypokalemia. Hormonal assessment revealed normal Metanephrines and preserved cortisol nychthemeral rhythm as well as urinary free cortisol level. However, she had an extremely high testosterone level: 117 ng/ml, increased dehydroepiandrosterone sulfate: >27 µmol/l (normal level $<$ 6.6) and high 17 alpha hydroxy-progesterone. Few days later, the patient deceased from cardiac arrythmia.
Discussion
Pulmonary embolism in the setting of adrenocortical carcinoma is a rather rare finding. Hypercoagubality associated with Cushing syndrome, cancer thrombi and direct tumor invasion are the pathophysiological mechanisms explaining this finding. The latter hypothesis is the most likely to be the cause of embolism in our case. Albeit, non-secreting adrenal cancer are the most incriminated, our report suggest otherwise.

Emerging endocrine complications in cancer immunotherapy

Ruxandra Paula Ristea[1], Teodora Puscas[1], Claudiu Zaharia[1], Serghei Tutovan[1] & Mihaela Stanciu[1,2]
[1]County Clinical Emergency Hospital of Sibiu, Endocrinology, Sibiu, Romania; [2]'Lucian Blaga' University of Sibiu, Faculty of Medicine, Endocrinology, Sibiu, Romania

Introduction
Immune-checkpoint inhibitors (ICIs) have revolutionised cancer treatment, offering superior efficacy compared to traditional chemotherapy. The use of immune checkpoint inhibitors has been associated with the occurrence of multiple endocrine immune-related adverse events (irAEs), such as primary hypothyroidism, thyroiditis, primary adrenal insufficiency, type 1 diabetes mellitus, and hypophysitis. In certain instances, these irAEs may necessitate the discontinuation of treatment.
Case Report
We present a 50-year-old female patient with a history of multinodular goiter and previously treated Graves' disease who was diagnosed with malignant melanoma in 2020. Immune checkpoint blockade therapy was initiated using anti-PD-1 antibodies and anti-CTLA-4. Within 2 months, the patient developed multiple immune-related endocrine complications. Clinical evaluation and laboratory investigations revealed autoimmune thyroiditis with elevated thyroid peroxidase antibodies (TPO), resulting in hypothyroidism requiring levothyroxine substitution (50 mg/day). Additionally, the patient was diagnosed with type 1 diabetes

and autoimmune hepatitis. Subsequently, she presented with symptoms like asthenia, significant weight loss, hypotension, loss of appetite, nausea, and vomiting, leading to the diagnosis of primary adrenal insufficiency. Corticosteroid treatment was initiated.
Conclusions
This case highlights the importance of monitoring patients undergoing immune checkpoint blockade therapy for the emergence of immune-related endocrine complications. Routine assessment of hormone levels and pre-treatment baseline evaluations are crucial for timely intervention. Prompt intervention and appropriate therapeutic approaches successfully controlled the patient's immune-related endocrine adverse events, allowing the continuation of immune checkpoint blockade therapy for melanoma.

ACTH-independent cushing's syndrome in a patient with bilateral adrenal tumors: complete remission after unilateral adrenalectomy

Larisa Nicoleta Chetan[1], Andreea Vladan[2], Cretoiu Rebeca[2], Radu Iorgulescu[3], Serban Radian[2,4] & Poiana Catalina[2,4]
[1]C.I. Parhon National Institute of Endocrinology, Pituitary and Neuroendocrine Pathology, Bucureşti, Romania; [2]C.I. Parhon National Institute of Endocrinology, Pituitary and Neuroendocrine Pathology, Bucharest, Romania; [3]Sf. Ioan Clinical Emergency Hospital, Bucureşti, Romania; [4]Carol Davila University of Medicine and Pharmacy, Bucureşti, Romania

Introduction
Bilateral adrenal tumors in patients with adrenal Cushing's syndrome (CS) are rare, lending to differential diagnosis which includes bilateral macronodular adrenal disease (BMAD), synchronous adrenal adenomas and even adrenocortical carcinoma. The treatment consists of unilateral adrenalectomy, followed by contralateral adrenalectomy, if warranted by persistent significant CS.
Aim
To present a case highlighting unilateral adrenalectomy as an effective treatment of CS in patients with bilateral adrenal tumors.
Case Report
A 54 year old woman with a history of arterial hypertension, and incidentally discovered bilateral adrenal tumors presented to our clinic with minimal clinical signs of CS. Serum cortisol did not suppress after 1 mg dexamethasone overnight, showing mild autonomous cortisol secretion (cortisolemia 3.8 mg/dl). 24-hour urinary free cortisol showed two increased values, midnight serum cortisolemia was mildly elevated and ACTH was suppressed ($<$ 5 pg/ml). Co-secretion of adrenal androgens was absent and 17 HO-progesteron was low. Aldosteronoma and pheochromocytoma were excluded. Family history was negative for endocrine tumors and biochemical screening for hyperparathyroidism and pituitary disease was negative, making MEN1 syndrome unlikely. Adrenal CT scan demonstrated a large heterogenous right adrenal tumor (6/6.75 cm), with native density $>$10 HU and peripheral calcification and a left adrenal homogeneous macronodule (1.91/2.79 cm) with density $>$10 HU. We tested cortisol response to stimuli, to detect the expression of aberrant adrenal receptors and observed responses to ortostatism and partially to GnRH analog. Right laparoscopic adrenalectomy was performed and while initial pathology reported an adrenal endothelial vascular cyst, the immunohistochemical diagnosis was of adrenal cortical adenoma with cystic-hemorrhagic changes. Basal cortisolemia was normal and ACTH unsuppressed one week postoperatively and we discontinued glucocorticoid replacement. Later testing demonstrated complete cortisol suppression after overnight 1 mg dexamethasone and normal midnight cortisolemia, consistent with CS remission.
Conclusion
Unilateral adrenalectomy was curative for our patient. Interestingly, adrenal function resumed rapidly. Regular follow-up of the left adrenal nodule is mandated.

Pericarditis as a presentation of adrenal crisis in non compliante patient with congenital adrenal hyperplasia

Marianna Bystrianska[1], Adrian Bystriansky[2], Marcela Sýkorová[3], Lýdia Opravilová[4], Dušan Kapusta[4] & Ľubomír Skladaný[4]
[1]University Hospital Banska Bystrica, Department of Internal Medicine, Banská Bystrica; [2]Institute of Cardiovascular Disease Banská Bystrica, Department of Arrhythmology, Banská Bystrica, Slovakia; [3]Institute of Cardiovascular Disease Banská Bystrica, Department of Cardiology, Banská Bystrica, Slovakia; [4]University Hospital Banska Bystrica, Department of Internal Medicine, Banská Bystrica, Slovakia

Background
Pericarditis as a presentation of sever adrenal insufficiency (AI) is very rarely documented. We would like to present a rarely case of sever AI whose first clinical presentation was pericarditis with heart failure and cardiac tamponade.
Case presentation
A 35 years old man was hospitalized on Department of Internal Medicine for chest pain, shortness of breath and hypotension. On ECG was documented sinus tachycardia with diffuse ST elevation. Cardio specific enzymes were negative, D-Dimers increased, serum hyponatremia and hyperkalemia. Urgent CT pulmonal angiography ruled out suspected pulmonary embolism and revealed pleural and pericardial effusion. Bedside echocardiography confirmed severe cardiac tamponade. Despite of urgent pericardiocentesis in emergency settings with a total amount of 1,000 ml, hypotension continued without adequate effect od high dose of vasopressors' therapy. The prolonged shock status was based on unmeasured plasmatic concentration of cortisol: 20 nmol/l (185- 624). In addition, we found out that the patient was treated for congenital adrenal insufficiency (CAH) in childhood, unfortunately without compliance for treatment as an adult (12 years did not used glucocorticoids). On abdominal CT scan has been detected bilateral adrenal hyperplasia. In the next 6 months he was repeatedly hospitalized for relapsing pericardial effusion accompanied with shock as well as hepatic and renal failure. The definitive clinical stabilization was achieved after adequate substitution therapy (glucocortiocoids and fludrocortisone). Genetic test confirmed the deficiency of 21 – hydroxylase.
Conclusion
Pericarditis and cardiogenic shock, or prolonged hypotension without vasopressors effects can be sign of unknown adrenal insufficiency. Early diagnosis and urgent treatment with supplementation of glucocorticoids is important to avoid morbidity and mortality.

Adrenal vs pituitary hypercortisolism: population characteristics and metabolic complications

Miruna-Viorela Nacu[1], Carmen Sorina Martin[1,2], Ana-Maria Simonescu[3], Anca Sirbu[1,2], Carmen Barbu[1,2], Luminita Cima[1,2], Iulia Stoian[1,2] & Simona Fica[1,2]
[1]"Elias" Hospital, Department of Endocrinology, Diabetes Mellitus, Nutrition and Metabolic Disorders, Bucharest, Romania; [2]'Carol Davila' University of Medicine and Pharmacy, Department of Endocrinology, Diabetes, Nutrition and Metabolic Disorders, Bucharest, Romania; [3]CF 1 'Witting' Hospital, Ophthalmology Department, Bucharest, Romania

Introduction
Cushing's syndrome (CS) is associated with a plethora of metabolic consequences. Current literature regarding the impact of different aetiologies on metabolic complications is scarce, and results are inconsistent. More studies are needed to validate previous findings.
Aim and methods
In order to compare the outcomes of pituitary and adrenal CS, we conducted an observational retrospective study, investigating the medical records of 72 patients diagnosed with CS between 2010-2021. Mean time of follow-up was 5.53$\pm$4.27 years (median 5 years).
Results
We included 35 patients (91.4% females) with pituitary CS and 37 (83.7% females) patients with adrenal CS. Patients with Cushing's disease were diagnosed at a younger age (37.77$\pm$13.04 vs 53.49$\pm$13.33 years, P $<$0.01) and were more likely to present with clinical signs of hypercortisolism, including central obesity, hirsutism, and purple striae (P=0.002). At diagnosis, cortisol levels, evaluated by early morning and midnight serum cortisol, were similar between our groups (p value was 0.61 and 0.07) and there were no statistically significant differences regarding body mass index, systolic and diastolic blood pressure, lipid profile, fasting plasma glucose, glycated haemoglobin and personal history of arterial hypertension, type 2 diabetes, or osteoporosis. Neither lumbar nor femoral bone mineral density and T scores differed between the two aetiologies. Comparing datasets from first admission with their recent counterparts, a significant reduction in systolic blood pressure was found (134.14$\pm$19.29 vs 121.66$\pm$14.87 mmHg, P=0.01) in patients with Cushing's disease, while their diastolic blood pressure was stationary. In patients with adrenal adenoma, this reduction was not significant (140.33$\pm$25.54 vs 132.86$\pm$18.47 mmHg, P=0.06), although the groups were similar in terms of active disease (P=0.176) and use of antihypertensive medication (P=0.722).

Conclusions
In line with previous studies, Cushing's disease is diagnosed at an earlier age and is more frequently associated with clinical signs of hypercortisolism as opposed to adrenal CS, despite similar cortisol levels. Conversely, the impact on glucose, lipid and bone metabolism appears to be comparable in these groups. Systolic blood pressure seems less likely to improve overtime in adrenal vs pituitary Cushing's syndrome.

Developing of a clinico-biological score to predict the diagnosis of cushing's syndrome

Ameni Terzi[1], Ibtissem Ouesleti[1], Elyes Kammoun[1], Yesmine Merhbene[1], Meriem Mabrouk[1], Arige Abid[1], Meriem Yazidi[1] & Mélika Chihaoui[1]
[1]Rabta, Endocrinology, Tunis

Introduction
Cushing's syndrome (CS) has relevant morbidity and mortality and poses several diagnostic challenges underlining the need for a prompt diagnosis in order to initiate earlier treatment. The aim of the present study was to develop a new clinical and biological score to predict the diagnosis of CS.
Methods
This was a monocentric retrospective study including patients who were admitted to the Department of Endocrinology of La Rabta Hospital, Tunis for suspicion of CS. Clinical and biological data were collected from medical records. Univariate analysis was conducted to assess CS associated signs.
Results
One hundredtwo patients (69 women and 33 men) were enrolled in this study. Their mean age was 56.6 $\pm$ 14.7 years. The CS's diagnosis was established in 63 patients (62%) and ruled out in 39 patients (38%). Proximal amyotrophy (OR : 9.88, IC95% : 1.2-78.8, $P=0.010$), headache (OR :2.93, IC95% :0.99-8.66, $P=0.045$), sleep disorders (OR = 9.22, IC95% : 2.02-42.06, $P=0.001$), and cortisol level after 1-mg dexamethasone suppression test (DST) $>$ 5µg/dl (OR : 2.5, IC95% : 1.02-6.12, $P=0.042$) were associated with the diagnosis of CS. We developed a new score to predict CS based on four items including proximal amyotrophy (10 points), headache (3 points), sleep disorders (9 points) and cortisol level after DST $>$ 5 µg/dl (2 points). The total score was 24 points. The total score median was 3 (Interquartile interval:0-12) in patients with CS and 0 (Interquartile interval:0-2) in patients without CS ($P<0.001$). This score had an area under the ROC curve of 0.746 (95%-CI: 0.65-0.842, $P<0.001$). A total score $\geq$12 points was positively associated with the diagnosis of CS (OR = 12.9, 95% CI: 1.64-102.01, $P=0.003$). This cut-off had a specificity of 97% but a sensitivity of 25%.
Conclusion
In the present study, we generated a new score to establish the diagnosisof CS. This score was positively associated with the diagnosis of CS with a good specificity but a very low sensitivity.

DOI: 10.1530/endoabs.99.EP727

EP728

17 alpha hydroxylase deficiency, a case report

Youcef Sellami[1], Khadidja Bessaid[2], Mouna Mezoued[2] & Malha Azzouz[2]
[1]Algeria, EPH bologhine ibn ziri, Alger, Algeria; [2]EPH bologhine Ibn ziri, Endocrinology, Alger, Algeria

Introduction
Congenital adrenal hyperplasia (CAH) due to 17-alpha-hydroxylase deficiency is a very rare form of CAH characterized by glucocorticoid deficiency, hypergonadotropic hypogonadism and hypertension with hypokalemia. It is an autosomal recessive disorder with an estimated incidence of one in 1,000,000 newborns. Over 100 mutations in the CYP17A1 gene have been identified with combined 17-hydroxylase/17,20-lyase deficiency, but in some authentic cases no mutation has been found.
Case report
Our patient was 24 years old, with no specific pathological history, referred to us for investigation of impuberty associated with arterial hypertension. Clinically, the patient presented an impuberty and severe hypertension onset at the age of 17, with no clinical signs of adrenal insufficiency or hyperandrogenism. Biochemical: hypokalemia of around 3 meq/l Hormonal investigation was in favor of hypergonadotropic hypogonadism, E2 : 11.53 pg/ml(12.5-166) FSH : 46.67 Mui/ml(25.8-21.5) LH : 31.28 Mui/ml(1.0-11.4) With 46 XX karyotype. We found primary adrenal insufficiency, CP at 0800 h :19 nmol/l (154-638) vs ACTH:165 pg/ml In this context, 17 hydroxylase deficiency was evoked, confirmed by a DOC: 5015 pg/ml(40-170) Corticosterone: 657 nmol/l (0.8-59) Morphologically, we realized an abdominal scan, which revealed bilateral adrenal nodules measuring 16$\times$14 mm on the left and 14$\times$10 mm on the right, consistent with adrenal adenomas. A genetic study is underway. Therapeutically, we introduced spironolactone at a dose of 75 mg/d. We opted for Hydrocortisone at a dose of 10 mg/d in the evening, as a brake, and gradually introduced estradiol valerate. Various reassessments revealed normalization of blood pressure and kalemia, with satisfactory breast development.
Conclusion
The diagnosis and management of 17-alpha-hydroxylase block is a challenge, given the rarity of this entity. Early diagnosis is very important, enabling appropriate treatment to reduce the severity of disorders and improve quality of life.

EP729

The cost burden of hospitalisation for adrenal insufficiency patients in the NHS in england

Leonardo Ruiz[1], Beate Ritz[1], Robert Murray[2], Matthew Beckett[3] & Janet Wild[3]
[1]Advanz Pharma, United Kingdom; [2]Leeds General Infirmary, United Kingdom; [3]CSL, United Kingdom

Introduction
Adrenal Insufficiency (AI) is a heterogeneous condition comprising primary, secondary and tertiary disease. Individuals with AI suffer more frequent infections and take longer to recover. Adrenal Crises (ACs), most commonly precipitated by infections, are an acute life-threatening complication with a reported mortality of 6%. ACs are, at least in part, potentially preventable and outcomes are improved by early initiation of high-dose glucocorticoids. Currently, there is a scarcity of information concerning the burden of AI episodes. We therefore utilised 'Hospital Episode Statistics' (HES) data to understand current practices and resources associated with AI patients.
Materials and Methods
The HES dataset contains details of all admissions and outpatient appointments at NHS hospitals in England after translating clinical information into a standardised set of codes. Spells between 1st April 2018 and 31st March 2023, focusing on HES codes E27.1 (Primary AI) [$n=57,125$], E27.2 (Adrenal Crisis) [$n=12,640$] and E27.4 (Other and unspecified AI) [$n=79,965$] were analysed for admissions, length of stay, costs, follow-up, and readmissions.
Results
The data reveal stable admissions for E27.2, reduced E27.1 admissions during COVID-19, and steadily increasing E27.4 admissions. The largest number of patients were coded as E27.4 rising consistently since 2018/2019. Length of stay was between 10 and 18 days and increased for E27.2 by 44% since 2018/19. Patients with primary pneumonia and concomitant AI had a longer mean duration of admission than those without AI; and were more likely to require critical care. Overall, $<$3% of patients were admitted to ICU. The mean cost per hospital stay increased over the analysis period, with the most marked increase being for E27.2 which rose 26% since 2019/20. Average costs in 2022/23 were £4,409 for E27.1; £6,579 for E27.2; and £4,726 for E27.4 Ten percent of patients had more than one non-elective readmission within 12 months of initial admission. Specialist Endocrinology follow-up following admission was low. Centres treating $>$400 episodes a year followed-up between 19% and 30% of patients with primary or secondary AI within 26 weeks. Only 33% of patients admitted with AC in 2022/23 were followed up.
Conclusion
The number of patients admitted to hospital with AI has increased since 2018/19. Costs and length of stay have risen significantly. Patients with AI and concomitant disease are more likely to have longer duration of admission and be re-admitted than those without AI. Follow-up of these patients by endocrinologists appears surprisingly low.

DOI: 10.1530/endoabs.99.EP729

EP730

11-DOC secreting adrenal lesion as a cause of mineralocorticoid induced hypertension

Lina Alomari[1,2] & David Hughes[1]

[1]University Hospitals Derby & Burton NHS Trust, Department of Endocrinology, United Kingdom; [2]Royal Derby Hospital

Background
It is well recognised that the most frequent cause of mineralocorticoid induced hypertension is primary hyperaldosteronism. Excess 11-deoxycorticosterone (11-DOC), which is a precursor molecule for the production of aldosterone, may in rare cases be the cause of the mineralocorticoid induced hypertension in patients with normal or low aldosterone levels.
Case
We describe a 70 year old female patient with a background of treated breast cancer who was referred to the endocrinology team in 2019 by her GP with a two-year history of mild hypokalaemia with hypertension requiring two antihypertensive agents for blood pressure control. Further assessment in the endocrinology clinic revealed low renin and low aldosterone levels, normal overnight dexamethasone suppression test, normal metadrenalines, testosterone and DHEAS levels. She underwent CT adrenal which showed a 1.6×1.9 cm indeterminate right adrenal mass (HU = 50). MRI adrenal confirmed the presence of a right adrenal mass with restricted diffusion, described as "not a simple adenoma". Spironolactone was added to her antihypertensives and a plan for right adrenalectomy was made. Due to the COVID pandemic pressures, her surgery & follow upwas delayed. A repeat CT adrenal in 2021 showed no change in size of the adrenal lesion. The patient was no longer keen to proceed with surgery and preferred a more conservative management approach. At that point, she had her hormonal profile repeated which again revealed low renin with low aldosterone, A post low dose dexamethasone suppression test revealed that the 11 deoxycorticosterone remaining elevated at 12 nmol/l, mildly elevated cortisol at 99 nmol/l, normal androstenedione and normal 17 OHP. A urine steroid profile confirmed a marked increase corticosterone metabolite compared to cortisol metabolites and hence a diagnosis of DOC secreting adrenal adenoma was confirmed. An FDG PET CT showed low uptake with stability in size over two years suggesting the adenoma was non-cancerous. A PET 11C metomidate scan performed at Cambridge hospital confirmed increased activity in the right adrenal adenoma.
Conclusion
11-DOC is a mineralocorticoid precursor with a weaker effect than aldosterone. While a lesion secreting 11-DOC is rare, It is an important cause to consider in patients with hypertension with suppressed aldosterone and renin levels. Serum 11-DOC level and urine steroid profile are essential to aid diagnosis, but there may also be a role for PET 11C metomidate scan in localisation.

Prevalence of metabolic syndrome in non functional adrenal incidentaloma: a case-control study

Sabrina Ayari[1], Nadia Khessairi[1], Sahar Abidi[1], Elyes Kamoun[1], Oueslati Ibtissem[1] & Chihaoui Melika[1]
[1]Rabta Hospital, Endocrinology, Tunisia

Background
The diagnosis of adrenal incidentaloma (AI) is becoming more common with the rising use of radiological tests. Most of AI are nonfunctional adrenal incidentalomas (NFAI) that may produce small amounts of glucorcorticoids that, in consequence, may cause metabolic disorders. Metabolic syndrome being a significant health concern should be evaluated in patients with NFAI. The objective of the study was to assess metabolic syndrome (MS) prevalence and characteristics in NFAI patients according to International Diabetes Federation (IDF) criteria compared to a control group.
Methods
This case-control study included 40 NFAI patients (16 men, 24 women, mean age 52.9 ± 11.2 years) and 40 individuals (17 men, 23 women, mean age 56.8 ± 8 years) in the control group matched for age, sex, and weight. NFAI diagnosis was established according to current guidelines. Patients with mild autonomous cortisol secretion, chronic kidney disease, liver failure or under hypolipidemic drugs, combined contraceptive pills, alcohol or depression, were excluded of this study All participants underwent physical examination (waist circumference (WC), blood pressure), adrenal imaging, and biochemical evaluation including triglyceride (TG), high-density lipoprotein cholesterol (HDL-C), cholesterol total (CT) and fasting plasma glucose (FPG). All participants underwent the assesment of characteristics of the metabolic syndrome according to IDF.
Results
The NFAI group had significantly higher WC ($P < 0.02$), higher obesity ($P = 0.025$) higher fasting plasma glucose ($P = 0.014$), higher score of metabolic syndrome according to IDF (3 (2-3) vs 2 (1-3), $P = 0.076$) and higher prevalence of metabolic syndrome (21 patients (53%) vs 12 patients (30%); $P = 0.041$) compared to the control group. NFAI was positively associated with metabolic syndrome (OR = 2.58; 95% confidence interval (CI): 1.03-6.46; $P = 0.041$). Obesity (OR = 7.29, IC: 1.74-30.56, $P = 0.001$) and female genre (OR = 7.29; IC: 1.74-30.56; $P = 0.004$) were positively correlated to metabolic syndrome in NFAI patients. In multivariate analyses including gender, WC, hypertension and diabetes, NFAI was not a factor independently associated with metabolic syndrome ($P = 0.862$).
Conclusion
NFAI are common and they are associated with adverse metabolic changes. Threshold, NFAI should be considered as an innovative factor for metabolic syndrome.

Hypothalamic-pituitary-adrenal axis, type 1b glycogen storage disease & pregnancy

Fotini Pouliasi[1], Ioannis Ilias[2], Vasiliki Papadopoulou[1], Konstantina Barouti[1] & Eftychia Koukkou[1]
[1]Elena Venizelou, Endocrinology, Diabetes and Metabolism, Athina, Greece; [2]Ippokrateio General Hospital of Athens, Endocrinology, Athina, Greece

Introduction
Individuals with glycogen storage disease type 1b (GSD1b) usually have low blood glucose and are at constant risk of hypoglycemia. We recently hospitalized a pregnant woman with GSD1b, where despite nutritional management, her glycemia values were almost unwaveringly towards the lower physiological limits. In a recent study (Rossi *et al*. Orphanet Journal of Rare Diseases 2020; 15: 99, https://doi.org/10.1186/s13023-020-01377-w) it was reported that under resting conditions and after stimulation with corticotropin (ACTH), individuals with GSD1b (n:7) show lower cortisol levels compared to a control group.
Aim
Considering that the stimulus of hypoglycemia is strong for the hypothalamic-pituitary-adrenal (HPA) axis, we investigated the postpartum diurnal variation of salivary cortisol (sF) in a woman with GSD1b.
Methods
Postpartum, in a 35-year-old woman with GSD1b, we assessed the diurnal variation in sF (5 samples per day) for two days, the first week postpartum and after three months. Corresponding sampling was performed in two, age-matched healthy women, 2-4 months postpartum, who formed the control group. The sF determinations were performed using the Elecsys Cortisol II assay (Roche) with electrochemiluminescence. The Sign test was applied for statistical analysis.
Results
The diurnal profile of sF changes was similar in shape for the patient and control group, with a peak at wake-up and nadir at 20:00-midnight. Overall, the patient's early sF measurements were higher than her late ones (*P*:0.03). The patient's late sF measurements were higher than those of the control group on the first day (*P*:0.05). On the second day, the patient's late cortisol awakening response (CAR, sF at 08:00 - sF at 08:30) was marginally lower, compared to the control group (*P*:0.06).
Discussion
The early sF measurements of the GSD1b patient point towards a stimulation of the HPA, however this is also a finding in normal women postpartum, where within a few days after delivery, plasma total and free F values gradually return to pre-pregnancy levels after increasing, especially in the third trimester of pregnancy (Jung *et al* J Clin Endocrinol Metab 2011; 96:1533-1540 & Mistry *et al*. Reproductive Biology and Endocrinology 2015; 13:101). According to our results, in GSD1b, no particular effect of the sustained stimulus of hypoglycemia on HPA is found.

Adrenal Insufficiency Detection Challenges in Adult Beta-Thalassemia

Seda Hanife Oguz[1], Alperen Onur İşler[1] & Uğur Unluturk[1]
[1]Hacettepe University School of Medicine, Division of Endocrinology and Metabolism, Department of Internal Medicine, Ankara, Turkey

Background
Adult beta-thalassemia patients experience various endocrine complications associated with iron deposition. However, data regarding adrenal insufficiency (AI) are limited.

Subjects and Methods
A total of 104 beta-thalassemia patients examined between 2015 and 2024 in our outpatient clinic had at least one measurement of morning serum ACTH and cortisol levels. At the time of presentation, two male patients had already been diagnosed with primary AI. Twenty-two additional patients opted for screening with a 250 mg-tetracosactid stimulation test. Among them, 20 tests were performed on 18 patients who agreed to be tested in a median follow-up period of 3 years.
Results
The mean age in the test group was 30.6 ± 6.7 years. Sixteen patients had beta-thalassemia major (5 F, 11 M), while the remaining three had beta-thalassemia intermedia (all F). All patients were transfusion-dependent except the patients with beta-thalassemia intermedia. Three patients showed maximum cortisol responses of less than 18 mg/dl (16.6%). Two of the three patients with inadequate cortisol responses had thalassemia intermedia. Four additional patients had less than 20 mg/dl peak cortisol responses. Only two patients in the test group had ACTH levels higher than twice the upper normal limit at baseline, with peak cortisol responses of 14.8 mg/dl and 20.6 mg/dl, respectively. None of the patients had baseline morning cortisol levels of less than 5 mg/dl, and none exhibited typical symptoms or signs of AI except for mild fatigue. All patients remained asymptomatic during a median of 3-years' follow-up, with no glucocorticoid requirement. The mineralocorticoid axis was evaluated in ten patients: none had low aldosterone levels; however, seven revealed high renin levels. Among these seven, three had peak cortisol responses <18 mg/dl, while the remaining four had responses >20 mg/dl. All patients but one had additional beta-thalassemia-related endocrinopathies, bone metabolism disorders being the most common (84.2%), followed by hypogonadism (73.7%).
Conclusions
Subclinical AI may be more common than overt AI in beta-thalassemia patients. Our findings highlight the difficulty of detecting AI in beta-thalassemia patients, indicating that standard symptoms, signs, and laboratory parameters might be unreliable. The discordance between the pituitary and adrenal glands may further complicate the diagnostic process. Moreover, iron accumulation in the adrenal gland might not involve all regions, but only the glomerulosa region in some patients. Our study proposes the utilization of the 250 mg-tetracosactid stimulation test, as a more accurate method to diagnose adrenal insufficiency in patients with beta-thalassemia, regardless of transfusion dependence and disease severity.

Hydrocortisone vs prednisolone for treatment of adrenal insufficiency disease (HYPER-AID Study) – interim results from a single, tertiary care centre

Bianca Maria Leca[1], Puja Thadani[1], Dineesha Dineesha Kumarathunga[1], Vindya Wellala[1], Allan Davasgaium[1], Rojet George[1], Parminder Seehra[1], Rajan Mattu[1] & Harpal S. Randeva[1]
[1]University Hospital Coventry & Warwickshire, Warwickshire Institute for the Study of Diabetes, Endocrinology and Metabolism (WISDEM), United Kingdom

Introduction
Adrenal insufficiency (AI) requires lifelong steroid replacement therapy, traditionally with hydrocortisone (HC), which, taken in divided doses, mimics the normal daytime cortisol profile. Prednisolone, with its longer duration of action, presents a cost-effective, once-daily alternative, yet its comparative efficacy and safety profile in AI management still need to be explored. Therefore, the current study aims to assess the metabolic and cardiovascular outcomes in AI patients transitioning from HC to prednisolone.
Methods
The study was conducted following the protocol for 'Hydrocortisone vs Prednisolone for the Treatment of Adrenal Insufficiency Disease' (HYPER-AID Study), IRAS ID: 234243. Patients diagnosed with AI according to the standard diagnostic criteria, on stable HC replacement (for a minimum of four months), were recruited. Baseline assessments were conducted before switching to prednisolone, and a follow-up visit was scheduled after at least four months on the new regimen. Measurements included anthropometric data, cardiovascular risk factors, glycaemic control markers, and safety profiles. Statistical analysis was performed using SPSS statistics version 29.0, considering $P<0.05$ statistically significant.
Results
Fifteen patients with AI were recruited. Two patients withdrew due to altered mood and fatigue. Of 13 participants, 7 were male (53.8%), with a mean age of 60.69 ± 11.56 years. The majority (92.3%) had secondary AI. The total daily HC dose ranged between 17.5 and 25 mg and was substituted by 3 to 5 mg of prednisolone. Notably, 61.5% of patients were effectively replaced with a 4 mg dose. At follow-up, the mean body mass index (BMI) showed a marginal decrease from 31.56 ± 7.01 kg/m^2 to 30.87 ± 6.97 kg/m^2 ($P=0.016$). Similarly, the waist circumference slightly decreased from 106.11 ± 11.94 cm to 103.26 ± 10.6 cm ($P=0.011$). Furthermore, no marked changes were observed in blood pressure, heart rate, lipid profiles, glycaemic control, serum electrolytes, renal and liver function, or haematological parameters. Interestingly, all participants opted to continue treatment with prednisolone, highlighting a preference potentially linked to the simplified administration regimen.
Conclusion
Switching from HC to prednisolone in patients with AI appears safe and results in minor yet statistically significant reductions in BMI and waist circumference, suggesting possible metabolic benefits. The absence of adverse effects on cardiovascular risk factors further supports prednisolone as a feasible, cost-effective alternative to HC in AI management. Nevertheless, further studies with larger sample sizes are required to validate these findings and assess the long-term treatment implications.

Heart failure and its reversibility in patients with cushing's syndrome

Raisa Kosharnaia[1], Zhanna Belaya[1], Elizaveta Mamedova[1], Elena Przhiyalkovskaya[1], Zamira Zuraeva[1], Marina Michurova[1] & Victor Kalashnikov[1]
[1]Endocrinology Research Centre, Moscow, Russian Federation

Myopathy is a common complication of Cushing's syndrome (CS), which predicts the possibility of heart muscle damage and may be a cause of heart failure. Goal of this study is to evaluate the prevalence of heart failure in patients with active CS and the probability of recovery after achieving a remission.
Materials and methods
We enrolled patients with CS hospitalized in our clinic from October 2018 to December 2022. To confirm the diagnosis of CS we measured: late-night salivary cortisol (LNSC) (reference range 0.5-9.65 nmol/l); 24 hours urine free cortisol (reference range 100-379 nmol/day)., midnight serum cortisol levels (reference range 46.0-270.0 nmol/l). All patients underwent clinical investigation including expert echocardiography with speckle tracking and evaluation of N-terminal pro–B-type natriuretic peptide (NT-proBNP) (reference <125 pg/ml Cobas 6000) and Soluble suppression of tumorigenicity 2 (ST2) (reference <35 ng/ml ; Presage ST2 Assay Kit (Critical Diagnostics, USA) at the baseline and 6 months after surgical treatment. In patients with preserved ejection fraction the H2FPEF and HFA-PEFF heart failure diagnostic algorithms were used.
Results
The study included 70 patients with active CS ($n=54$ women, 24h urine cortisol = 1193.5 [690.9; 2034.6] nmol/24h, LNSC 21.57 [13.03; 43.89] nmol/l. The causes of CS were Cushing' disease in 51 patients; Ectopic-ACTH-syndrome in 9 cases and benign cortisol-secreting adrenal adenoma in 10 cases. The diagnosis of heart failure was verified in 46 (65.7%) patients. According to the results of echocardiography, 16 (22%) patients revealed dilation of the left atrium, 3 (4.3%) - left ventricle (LV), 37 (52.9%) patients had LV hypertrophy, 4 patients - decrease of LV ejection fraction (LVEF 40-50%); impaired diastolic function was detected in 37 (52.9%) patients. A decrease in global longitudinal myocardial strain was detected in 28 (39.4%) patients. Remission was confirmed in 52 patients 6 months after surgical treatment. Among 36 re-examined patients with 6 months remission of CS, the heart failure was confirmed in 26 patients, whereas in 16 of them heart failure regressed. The initially elevated NT-proBNP 132.8 [49.2; 444.4] and ST2 31.9 [22.7; 72.6] decreased to 71.8 [13.4; 163.2] $P=0.004$ and 25.9 [19.9; 33.3] $P=0.031$ respectively, supporting the reversibility of heart failure.
Conclusion
CS causes heart muscle damage with the development of heart failure in 65.7% of patients. Achieving CS remission led to regression of heart muscle myopathy in 44.4% of the recorded cases after 6 months of observation, which supports the reversibility of this damage.

Jebsen Center for Autoimmune Disorders, Bergen, Norway; [5]Norwegian Institute of Public Health, Department of Genetics and Bioinformatics, Bergen, Norway; [6]Haukeland University Hospital, Department of Medicine, Bergen, Norway; [7]Haukeland University Hospital, Department of Medical Genetics, Bergen, Norway; [8]Karolinska Institutet, Department of Molecular Medicine and Surgery, Stockholm, Sweden; [9]Uppsala University, Department of Immunology, Genetics and Pathology, Uppsala, Sweden

Background
Primary adrenal insufficiency (PAI) is sometimes misdiagnosed as autoimmune Addison's disease (AAD), affecting clinical management and genetic counselling. We tested a polygenic risk score (PRS) for AAD ($PRS14_{AAD}$) as a tool to reevaluate disease etiology and identify patients misdiagnosed with AAD.
Methods
We calculated the $PRS14_{AAD}$ in a cohort of patients diagnosed with AAD but lacking 21-hydroxylase autoantibodies ($n=124$). Patients with low genetic susceptibility to AAD were selected for whole-genome sequencing to detect potential monogenic causes ($n=35$).
Results
Among the 35 patients, monogenic PAI was found in 5 (14%) and suspected in 3 additional cases (9%). Three out of the 5 rediagnosed patients developed the disease in adulthood, indicating late-onset monogenic disease associated with hypomorphic genetic variants.
Conclusion
A PRS for AAD can help identify potential monogenic cases, regardless of the age at diagnosis. Early identification of the underlying cause of PAI enables accurate management and correct genetic counselling

Measurement of cortisol in hair using a commercial ELISA

Nico Rauchschwalbe[1], Lucia Maß[1], Elisabeth Schmitter[1], Thomas Neiße[1], Kristin Meyer-Schlinkmann[1] & Michael Doelle[1]
[1]Labor Krone GbR, Bad Salzuflen, Germany

Increased cortisol production (Cushing's syndrome) is a rare disease that is sometimes very difficult to diagnose. Cyclical Cushing's syndrome in particular is a major challenge. In this case of hypercortisolism, which is not always present, longitudinal diagnostic methods are advantageous. In the past, it has already been shown several times that the measurement of cortisol in the scalp hair shows significantly increased values in patients with Cushing's syndrome. However, the measurement of cortisol in hair is not yet widely available. Our aim was therefore to use a commercially available assay for the determination of cortisol in saliva for the determination of cortisol in hair. Our study introduces a cutting-edge method for quantifying cortisol levels in scalp hair through the utilization of an commercially available automated Enzyme-Linked-Immunosorbent Assay (ELISA). For the analysis of cortisol in hair, 25 mg of washed and milled scalp hair were extracted within 3 hours using methanol and ultrasound-assisted extraction. The supernatant was transferred to a glass vial and evaporated to dryness at 50 °C under a constant stream of nitrogen. The dry residue was redissolved in deionized water and vortexed for 30 seconds. Cortisol concentrations were determined using a commercially available cortisol-saliva ELISA from IBL International GmbH. The test protocol was modified for this purpose by reducing the sample volume used and adjusting the calibration points to a range of 40 pg/mg to 600 pg/mg to meet the expected concentrations of cortisol in hair. Processing and analysis were performed on a fully automated ELISA processor (Analyzer 1 from Euroimmun). For further development, individual reference values for healthy individuals, mild autonomous cortisol secretion and Cushing's syndrome still need to be determined. Our study outlines the successful adaptation and optimization of a saliva cortisol measurement protocol for assessing cortisol level in scalp hair. Unlike existing techniques primarily restricted to research applications, we aim for commercial viability of an automated processed protocol, providing an efficient and reproducible means for routine analysis, paving the way for broader applications in clinical and diagnostic setting.

Adrenal lesions prevalence and hormonal profiles in a tertiary endocrinology center from romania

Carmen Barbu[1,2], Luana Zuga[2], Suzana Florea[2], Roxana Bunghez[2], Sorina Martin[1,2], Anca Sîrbu[1,2], Luminita Cima[1,2], Alice Albu[1,2], Iulia Stoian[1,2] & Simona Fica[1,2]
[1]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [2]Elias Hospital, Bucharest, Romania

Backround
The increased frequency of performing imaging investigations in the period following the SARS-COV-2 pandemic has led to more frequent identification of adrenal lesions in patients who subsequently required further endocrine evaluation.
Objective
To compare the functional profile of the newly diagnosed lesions vs those coming for follow up over 2023.
Methods
Retrospective observational study aiming all of the patients admitted in our endocrinology department for adrenal lesions evaluation within the 2023 year. Variables such as age, sex, chronic diseases (arterial hypertension, diabetes, dyslipidemia, obesity, osteoporosis), laboratory investigations (adrenal hormones: cortisol, aldosterone, metanephrines, normetanephrines), the results of imagistic investigations used to diagnose the adrenal lesion and the choices of treatment were collected from 160 patients's medical records. Comparisons were made between the newly diagnosed patients (85) and those who had already previous evaluations (75).
Results
160 patients were included with comprehensive evaluation for adrenal lesions in our department over the whole 2023 year: 85 newly diagnosed patients and 75 patients with previous evaluation (diagnosed between 2007-2022) with a majority of women (65/85, and 62/75 respectively), aged between 23 and 80 (mean age 58.8 y). The diagnostics were as follows : unilateral adenoma 53 out of 85 in new cases vs 51 out of 75 in 'old' cases (NS), bilateral adrenal hyperplasia (30/85 in new vs 24/75 in old cases group, NS) and two adrenal carcinomas (both cortisol-secreting, one of them also secreting androgens) only in the newly diagnosed cases. Functional profile was present in 24/85 in new cases vs 28/75 in old cases ($P<0.05$) as following: hypercortisolism 11 out of 24 functional lesions vs 10 out of 27 functional lesions in old cases, subclinical hypercortisolism 3/24 vs 2/27 cases, hyperaldosteronism 7/24 vs 9/27 cases, paraganglioma 5/24 vs 7/27 cases. Sixty of the 85 new cases and 51 of the 75 reevaluated patients were hypertensive. The most frequent management decision was periodic imagistic and hormonal reevaluation. Surgery was recommended in 10 of the new cases and 20 of the cases diagnosed between 2007-2022.
Conclusions
In the newly diagnosed group (over 2023), a functional profile was present in a smaller proportion than in those with previous evaluation. Among new patients, functional lesions were more frequent in men. Out of all 160 patients in the study, there was a correlation between secretor status and lesion distribution. More bilateral adrenal hyperplasias appear secretory than unilateral adenomas, but a larger sample is needed.

Surgical management of adrenal masses: experience of a tertiary center

Sara Santos[1], Miguel Saraiva[2], Francisca Marques Puga[2] & Isabel Palma[2]
[1]Instituto Português de Oncologia do Porto, Porto, Portugal; [2]Unidade Local de Saúde de Santo António, Porto, Portugal

Introduction
Adrenal masses (AM) are being increasingly diagnosed but only a small portion will need surgical treatment.
Methods
We retrospectively reviewed patients referred to the Endocrinology Clinic that underwent adrenalectomy between 1996 and 2023.
Results
We included 57 patients. Most AM were diagnosed incidentally (53%) and had a median size of 32 (25) mm. Forty (70%) patients had hormonal hypersecretion (HH): pheocromocytoma (PC) (15; 37%), primary hyperaldosteronism (PHA) (15; 37%), ACTH independent Cushing's syndrome (CS) (6; 15%), mild autonomous cortisol secretion (MACS) (3; 8%) and cortisol and androgens co-secretion (1; 3%). Patients with PC were initially referred to our clinic for incidentaloma (10; 71%), hypertension (HT) (3; 22%) or as a part of screening for a genetic syndrome (1;

7%). Patients with PHA had HT with (7; 54%) or without (6; 46%) hypokalemia. Patients with CS presented with an incidentaloma (4; 67%) or features of hypercortisolism (2; 33%). Reasons for surgery included HH (39; 68%), imaging features not suggestive of benign adenoma (NB) (9; 16%) and others (9; 16%). All masses described as adenoma (23; 40%) on imaging exams had a benign diagnosis after surgery. AM described as NB (21; 37%) were later diagnosed as PC (8; 40%), cortical adenoma (CA) (2; 10%), ganglioneuroma (2; 10%), oncocytic CA (1; 5%), tumor of uncertain malignant potential (1; 5%), myelolipoma (1; 5%), nodular hyperplasia (1; 5%), black adenoma (1; 5%) and infarcted adrenal neoplasia (1; 5%). Two patients (10%) had AM with features suggestive of adrenal carcinoma: 1 was diagnosed with an infarcted cavernous hemangioma, and 1, deemed irresectable. AM with a diagnosis of PC after surgery and an accessible imaging exam (12; 26%) were initially described as NB (8; 67%), PC (3; 25%) or myelolipoma (1; 8%). All patients with PC and CS were biochemically cured after surgery. Of the 15 patients with PHA, 13 (87%) were biochemically cured, with resolution of HT and hypokalemia, when present. Of the remaining 2 (13%), 1 (50%) had an imaging exam describing an adenoma and bilateral hyperplasia, and 1 (50%) had a diagnosis of nodular hyperplasia after surgery.

Conclusions

Imaging exams were accurate in detecting benign lesions. All patients with PHA had relevant clinical manifestations of HH while most patients with PC and CS presented with an incidentaloma. Surgery was effective in most cases and the patients who were not cured likely had bilateral HH.

Significance of screening and confirmatory tests in identifying primary hyperaldosteronism among patients investigated for secondary endocrine hypertension

Raluca Bocai[1], Găloiu Simona Andreea[1,2], Trifanescu Raluca Alexandra[1,2], Dana Alice Manda[1] & Catalina Poiana[1,2]
[1]Endocrinology Institute "C.I.Parhon", Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania

Introduction

Delayed diagnosis of secondary hypertension, notably primary aldosteronism, challenges healthcare. Inconsistent guideline adherence hampers detection rates and diagnostic uniformity, emphasizing the imperative for improved diagnostic strategies in identifying primary hyperaldosteronism. Our study directly addresses this critical gap in clinical care, underscoring the need for enhanced diagnostics in patients undergoing investigation for secondary endocrine hypertension.

Methods

A retrospective study at a Bucharest tertiary center analyzed 83 consecutive medical records between January 2023 and December 2023 during screening for secondary hypertension. Diagnosing primary hyperaldosteronism involved aldosterone-to-renin ratio (ARR) measurements, with confirmatory saline infusion or captopril suppression tests aligned with the 2016 European Society guideline for hyperaldosteronism. Sensitivity, specificity, and predictive values for ARR cutoffs (38, 57, 77 pg/ml/pg/ml) and confirmatory tests were calculated. Receiver operating characteristic (ROC) curve analysis and the area under the curve (AUC) assessed the diagnostic performance.

Results

In the cohort of 83 patients undergoing screening for secondary hypertension, the gender distribution revealed 31 men (37%) and 52 women (63%), with a median age of 45 years. Of these, 24 cases (28.9%) were diagnosed as primary hyperaldosteronism. Additional diagnoses included 1 case (1.2%) of acromegaly, 13 cases (15.6%) of Cushing syndrome, and 4 cases (4.8%) of pheochromocytoma, while the remaining cases tested negative for secondary endocrine hypertension. At ARR cut-off of 38, the study observed a sensitivity of 88%, specificity of 90%, positive predictive value (PPV) of 78%, and negative predictive value (NPV) of 95%. At ARR cut-offs of 57 and 77, sensitivities were 75%, with specificities of 92% and 98%, respectively. The corresponding positive predictive values (PPV) were 78% and 95%, and negative predictive values (NPV) were 90% and 91%, respectively. In the confirmatory phase, 15 patients underwent the saline infusion test, resulting in 9 positive confirmations (sensitivity: 69%, specificity: 100%, PPV: 100%, NPV: 33%). Nine patients underwent the Captopril suppression test, obtaining 5 positive confirmations and 4 negative results, hindering reliable sensitivity and specificity calculations due to the limited sample size. After ROC curve analysis, the optimal cutoff was 37.25, exhibiting the best balance of sensitivity and specificity ($AUC = 0.929$, $P < 0.001$) in our data set.

Conclusion

The identified cutoff value of 37.25 in our study aligns closely with literature findings, affirming its relevance in diagnosing primary hyperaldosteronism. However, to enhance diagnostic accuracy, additional confirmation tests and a larger patient cohort are crucial, ensuring broader clinical validation.

Clinical and biochemical data for the diagnosis of endogenous hypercortisolism: the "Cushingomic" approach

Filippo Ceccato[1], Alessandro Bavaresco[1], Eugenio Ragazzi[1], Mattia Barbot[1], Marco Boscaro[1], Daniela Basso[1], Scaroni Carla[1] & Giorgia Antonelli[1]
[1]University of Padova, Italy

Background

The recommended first-line screening tests for Cushing's syndrome (CS) are serum cortisol after 1-mg dexamethasone suppression test (F^{DST}), urinary free cortisol (UFC), and late-night salivary cortisol (LNSC). CS is often diagnosed late: the clinical presentation of endogenous hypercortisolism overlaps with common clinical conditions.

Methods

We analyzed the diagnostic test accuracy of F^{DST}, UFC, and LNSC in patients without CS (263 suspected CS, 319 adrenal incidentaloma, and 33 pituitary incidentaloma) and 40 with CS. Non-parametric multivariate methods (principal component analysis, K-means clustering, random forest, and supervised learning algorithm) were used to compute an integrated analysis among screening tests (sF^{DST}, UFC, LNSC), cortisol-related comorbidities and signs-symptoms of CS.

Findings

The three tests were able to individuate CS, F^{DST} and UFC were slightly superior to LNSC. The threshold of F^{DST} should be adapted to the population considered, especially in adrenal incidentaloma with mild autonomous cortisol secretion. The diagnostic accuracy of UFC and LNSC was independent of the group or high-risk condition considered. Some cortisol-related chief complaints (diabetes, hypertension, and obesity) were more common in patients without CS: the direction of their vectors was not aligned and their correlation with screening tests was poor. A neural network model that combined screening tests and clinical presentation was able to predict the CS diagnosis in the validation cohort with 99% sensitivity, 86% specificity, 99% precision, and 86% accuracy.

Interpretation

Screening tests for CS performed adequately. The presence of cortisol-related comorbidities and mild autonomous cortisol secretion should be interpreted carefully.

Cushing's syndrome in a patient with non-hodgkin's lymphoma

Iuliana Ilie[1], Lidia Felicia Mihai[2], Gabriel Lepadat[3] & Madalina Musat[4,5]
[1]Gral Medical Clinic, Endocrinology Department, Bucuresti, Romania; [2]Clinical Hospital Colentina, Hematology Department, Bucureşti, Romania; [3]Clinical Hospital Colentina, Department of Surgery,, Romania; [4]Carol Davila University of Medicine and Pharmacy, Bucureşti, Romania; [5]CI Parhon Institute of Endocrinology, Bucuresti, Romania

Endogenous Cushing's syndrome is a rare disease, with an incidence of 0.7–2.4 per million people per year. Adrenal origin is described in approximately 20 percent of all cases. Adrenal lymphoma presenting as adrenal incidentaloma with autonomous cortisol production has recently been described, though this is a rare condition. We report a rare case of adrenal Cushing's syndrome in a patient diagnosed with a low-grade non-Hodgkin's lymphoma. Female patient, age 53, was diagnosed in 2018 with low grade follicular lymphoma (biopsy from a inguinal adenopathy) with no indication of hematological treatment. The patient had multiple CT scans in the follow up of her lymphoma; which revealed a left heterogeneous adrenal mass of 29/32 mm; relatively stable since 2018. Recently she presented to the endocrinology department with a history of progressive weight gain of approx. 10 kg in the last year, hypertension, dyslipidemia, decreased muscle strength and right leg pain with recent swelling; At presentation she had facial plethora, central obesity with a BMI of 36 kg/m^2; moon face, bilateral varicose veins with signs of thrombosis in the right lower leg. Diagnosis of Cushing's syndrome was based on demonstrating hypercortisolism, disturbed circadian rhythms of salivary a cortisol and non-suppressible cortisol by a low dose dexamethasone suppression test (LDST). ACTH and DHEAS levels were low, which confirmed the adrenal origin. CBC was normal and HBA1C was 5.8%. Plasmatic metanephrines and normetanephrines were normal. The venous doppler revealed right saphenous vein thrombosis and the patient was commenced on oral

anticoagulants. Two months later, right laparoscopic adrenalectomy was performed with intra and postoperative glucocorticoid replacement. The pathology report is in progress. Very few cases of lymphoma and Cushing's syndrome are described in literature and some report Cushing's masking the diagnosis of Lymphoma with progression of hematological disease following treatment of Cushing's syndrome. In conclusion, if immunohistochemical analysis for steroidogenesis enzymes expression in neoplastic B-cells will be demonstrated this would require a personalized approach for the succesful management of the patient with Cushing's syndrome.

Radiological characteristics of adrenal incidentalomas followed in the endocrinology department

Prince Ismael Mbossa Lembopo[1], Nassim Essabah Haraj[1], Siham El Aziz[1] & Asma Chadli[1]
[1]Ibn Rochd University Hospital, Endocrinology, Diabetology, Metabolic Diseases, and Nutrition, Casablanca

Introduction
Adrenal incidentaloma refers to an adrenal mass discovered incidentally during imaging for another indication, most commonly through a CT scan. The discovery of an adrenal incidentaloma has become frequent with the use of imaging studies. CT scans play a crucial role in characterizing adrenal incidentalomas, allowing for better management. The aim of the study is to determine the contribution of CT scans in exploring adrenal incidentalomas in patients followed in the endocrinology department.
Patients and Methods
A retrospective descriptive and analytical study was conducted, including all patients seen in consultation or hospitalized in the endocrinology department with adrenal incidentalomas over a period of 5 years (2017-2022). Criteria for determining the nature of the adrenal incidentaloma included histology and the absence of size progression after one year of follow-up. CT scan characteristics for the diagnosis of adrenal incidentalomas included size, spontaneous density (SD), absolute washout (AW), and relative washout (RW). Statistical analysis was performed using Excel 2017.
Results
The study included 43 patients, of whom 59% were women, with a mean age of 48 years. All patients underwent endocrine hormonal assays for adrenal incidentalomas. The size of the mass was less than 40mm in 32 patients and greater than or equal to 40mm in 11 patients. Adrenalectomy was performed in 20 patients, and 23 non-operated patients underwent medical follow-up. Histology revealed adenoma in 11 cases, pheochromocytoma in 2 cases, myelolipoma in 3 cases, lymphoma in 2 cases, and adrenal hyperplasia in 1 case. Adenoma was confirmed histologically, and the size did not change after one year of follow-up in non-operated cases, in 92.4% of adrenal incidentalomas with a size <40 mm, SD ≤ 15 HU, RW $\geq 40\%$, and AW $>60\%$.
Conclusions
Characterizing adrenal incidentalomas with CT scans is a crucial step in the management of these incidentalomas.

Unlocking the metabolic mysteries: exploring metabolic syndrome in primary aldosteronism

Siddiqa Soomauroo[1], Faten Hadjkacem[1], Abdelmuhaymen Missaoui[1], Souhir Maalej[1], Mouna Mnif[1], Mohamed Abid[1] & Nabila Rekik[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Introduction
Primary aldosteronism (PA) is associated with increased prevalence of metabolic disorders such as impaired glucose and lipid metabolism and insulin resistance. Individuals with PA have an increased risk of cardiovascular events. The aim of this study is to determine the characteristics of metabolic syndrome (MS) in patients with PA.
Patients and methods
Retrospective study concerning 40 patients with PA over the period of 10 years from January 2010 to December 2022. The MS was diagnosed according to the worldwide definition of the International Diabetes Federation (IDF).
Findings
The average age of our patients was 55.4 years. There were 16 men and 24 women. Hypertension was present in 39 patients. Severe hypertension was found in 11 cases and resistant hypertension in 4 others. The average Body Mass Index (BMI) was 29.7 kg/m^2. Obesity was documented in 42.5%. It was classified as grade I in the majority of instances. The android distribution was present in 90% of cases. The mean waist circumference (WC) was 102 cm. In terms of lipid profile, dyslipidemia was diagnosed in 30 of our patients, with 7 patients already undergoing treatment. Mixed dyslipidemia was the most common type (35%), followed by isolated low HDL-cholesterol (10%). Among our 40 patients, 16 had diabetes. The exploration of glucose homeostasis diagnosed 9 new cases of impaired glucose tolerance. Metabolic syndrome was present in 82.5% of cases. Among them, 13 patients met all the diagnostic criteria according to the IDF. An analytical study of MS in PA revealed that among anthropometric parameters, only WC was significantly higher in patients with MS ($P=0.005$). Biochemically, triglycerides levels were higher in patients with MS (1.7 vs 0.9 mmol/l; $P=0.002$), while HDL-cholesterol levels were higher in patients without MS (1.1 vs 1.4 mmol/l; $P=0.024$). Bilateral adrenal hyperplasia was the most frequent aetiology of PA among the patients presenting with MS.
Conclusion
Recent studies have shown that MS is more common in hypertensive individuals with PA than in those with essential hypertension. These findings suggest the possibility of aldosterone effects on carbohydrate metabolism through insulin secretion and/or insulin resistance. Indeed, hypokalemia is a factor contributing to decreased insulin production. Additionally, chronic potassium depletion observed in PA is responsible for insulin resistance that persists even after correction of hypokalemia. This implies a direct action of aldosterone on insulin receptors, associated with development of MS.

Association of cognitive-behavioral disorders with a 21-hydroxylase deficiency

Hamza Elfekih[1], Nassim Ben Hadj Slama[1], Amira Yanes[1], Taieb ACH[1], Koussay El Euch[1], Yosra Hasni[1] & Molka Chadli Chaieb[1]
[1]University hospital of Farhat Hached, Endocrinology, Soussa, Tunisia

Introduction
Congenital adrenal hyperplasia encompasses a spectrum of autosomal recessive disorders marked by enzymatic deficiencies in cortisol biosynthesis. The prevailing etiology predominantly involves a deficit in 21-hydroxylase. This pathophysiological state gives rise to a myriad of complications, with acute adrenal insufficiency standing out as the most critical. Nevertheless, it is noteworthy that less-explored are the intricacies of additional complications, particularly those pertaining to the psycho-behavioral domain.
Case présentation
We present the case of a 16-year-old female patient who has been under medical surveillance since early childhood due to the discovery of a 21-hydroxylase block, identified in the context of precocious puberty and virilization. The patient, born of consanguineous parentage, has a a twin brother exhibiting cognitive disorders. The diagnosis of 21-hydroxylase block was established based on elevated levels of 17-hydroxyprogesterone at 10.7 ng/ml. Genetic analysis revealed a heterozygous composite mutation Q318X and duplication of exons 1, 3, 4, 6 inherited from the father, along with exon 8 duplication inherited from the mother. Pituitary imaging, however, showed no abnormalities. The patient was subsequently initiated on appropriate replacement therapy. In addition to the endocrine manifestations, she exhibits psychomotor retardation, language disorders, and challenges in socialization. She has also experienced recurrent major depressive episodes, necessitating ongoing psychiatric management.
Discussion
Deficiency in 21-hydroxylase can manifest as either a salt-wasting or a simple virilizing form. Both forms have the potential to result in cognitive impairment. The relationship between hormones and cognition is intricate and lacks a clear definition. The disturbance of the hypothalamic-pituitary- adrenal axis characteristic of congenital adrenal hyperplasia due to 21-hydroxylase deficiency is likely to affect brain development, yet neuroanatomic work is only beginning. Specific learning disabilities have been rarely reported in congenital adrenal hyperplasia. The impact of hormones on cognition is still not clearly defined, but it is postulated that females with this condition have excess prenatal androgen stimulation, which increases the risk for cognitive impairment. Furthermore, numerous studies have reported a high prevalence of anxiety and depressive disorders among patients with congenital adrenal hyperplasia, notably attributed to challenges in gender identity. Elevated levels of corticotropin-releasing hormone have also been documented in various episodes of melancholic depression. Cognitive and psychiatric disorders should be systematically investigated from the initial diagnosis of congenital adrenal hyperplasia.

When two rare conditions come together

Francisca Leitão, Ana Quítalo, Maria Carlos Cordeiro & Luísa Raimundo
Hospital Garcia de Orta

Introduction
Deficiency of 11-beta hydroxylase (11-HD) accounts for 5% of the causes of congenital adrenal hyperplasia (CAH), with an incidence of 1:100,000. The classic form phenotype consists in an excess of androgens and mineralocorticoids, which clinically translates into hypertension and hypokalaemia. In boys, there may be an increase in penis size, early adrenarche, increased growth velocity, and advancing bone age.
Clinical case
We present a case of a 31-year-old male diagnosed with HCS due to 11-beta-hydroxylase deficiency. At the age of 4, he presented with early penile development (penis 7 cm long) and pubarche, hypertension, with an increase in bone age of 6 years compared to chronological age. At diagnosis, he had an increase in 11-deoxycorticol, 17-hydroxyprogesterone (OHP), and androgens, with low cortisol. A Synacthen test was carried out highlighting the HCS (at 60 minutes cortisol 8.1 mg/dl). The genetic study confirmed the diagnosis, with a reference to his parents and 2 siblings as carriers. Medicated and symptomatically controlled with prednisolone and fludrocortisone. With a personal history of osteoporosis, generalized anxiety, social phobia, and nocturnal facial paresis followed in Rheumatology, Psychiatry, and Neurology, respectively. Medicated with calcium carbonate, D vitamin, and ibandronic acid. At the age of 23, he started manifesting symptoms of decreased libido, loss of appetite, adynamia, epigastralgia, diarrhea, and significant weight loss (14 kg, more than 10% of his weight). Blood tests showed a decrease in dihydroepiandrostenedione sulphate, free and total testosterone. Also, a decreased follicle-stimulating hormone and luteinizing hormone was noted, highlighting hypogonadotropic hypogonadism. Subclinical hypothyroidism was also diagnosed. An upper gastrointestinal endoscopy was performed due to his gastrointestinal complaints, with no alterations. Finally, a magnetic resonance imaging of the sella was also performed to exclude space-occupying lesions, without alterations, and a scrotal ultrasound scan, also normal. He started supplementation with levothyroxine and testosterone. Later, he was admitted to the psychiatry department for anorexia nervosa, indicating hypogonadotropic hypogonadism secondary to eating disorders.
Conclusions
This case highlights the complexity of the overlap between two extremely rare pathologies: HCS due to 11-HD deficiency and anorexia nervosa in men.

Allgrove syndrome: a case report

Ines Mezghani[1], Marrakchi Rim[1], Hadjkacem Faten[2], Boudaya Mariem[1], Jammoussi Kamel[1], Rekik Nabila[2], Abid Mohamed[2] & Turki Mouna[1]
[1]Hedi-Chaker University Hospital, Biochemistry Departement, sfax, Tunisia; [2]Hedi-Chaker University Hospital, Endocrinology Departement, sfax, Tunisia

Introduction
Allgrove syndrome or Triple A (3A) syndrome is a rare autosomal recessive disease characterized by alacrima, esophageal achalasia and adrenocorticotropic hormone-resistant adrenal insufficiency.
Observation
A 3-year-old and 9 months patient, from a consanguineous marriage, consulted for melanoderma, with family history: sisters with an heterozygous mutation of the AAAS gene, two paternal cousins, 5 years and 22 years, followed for autism and profound encephalopathy with epilepsy, respectively. The diagnosis of Allgrove syndrome was based on the association of alacrima confirmed by the Schirmer test, adrenal insufficiency and achalasia following digestive exploration (TOGD and esophageal manometry). The genetic study revealed the IVS14 + 1G > A mutation of the AAAS gene: mutation of intron 14 of the AAAS gene (chromosome 12: 12q13). The child received hydrocortisone and Fludrocortisone. The neurological development was marked by microcephaly at (-3SD), distal wasting with bone deformation (pathological exaggeration of the arch of the foot), facial and bulbar deficiency with a nasal voice. The onset of a growth delay from -0.5 to -2.5 SD, G2 P1 puberty at the age of 14 years 9 months and school failure. The appearance of dysphagia required two esophageal dilations. Macroscopic hematuria appeared at the age of 10 due to calyx microstones.
Conclusions
Allgrove syndrome is a rare, serious and multi-systemic pediatric condition requiring multidisciplinary care and genetic counseling among siblings

Clinical profile of patients with adrenal tumors in a tertiary endocrine center in Kathmandu, Nepal

Ansumali Joshi, Srijana Karmacharya, Puspa Dahal & Rama Rana
Kathmandu Diabetes and Thyroid Centre

Adrenal tumors are not uncommon in endocrine practice. We collected retrospective data from our clinical records of our patients with adrenal tumors from 2021 January to 2023 January. There were a total 20 patients; males 10 (50%) and females 10 (50%). Mean age was 47.4 ± 10.65 years and average BMI was 26.57 ± 4.94. Hypertension was seen in 13 patients (65%) and diabetes in 9 patients (45%). Nonfunctioning adrenal adenomas (NFAAs) were seen in 12 patients (60%) and functioning adenomas seen in 8 patients (40%). Among NFAAs, 9 patients (75%) had left sided, 2 patients (16.6%) had right sided and 1 patient (8.3%) had bilateral adrenal adenomas. All NFAAs were detected as incidentalomas. Mean size of NFAA was 21.92 mm (in greatest dimension). Among patients with NFAAs, 1(8.33%) went for surgery and other 11 patients (91.67%) underwent conservative management. Among functioning adrenal adenomas, 7 patients (87.5%) had left sided and 1 patient (12.5%) had right sided adrenal adenoma. All functioning tumors were unilateral. Pheochromocytoma was seen in 2 patients (10% of all adrenal tumors), aldosterone producing tumor (Conn's syndrome) was seen in 3 patients (15% of all adrenal tumors), cortisol secreting tumor (nonACTH dependent Cushing's syndrome) was seen in 3 patients (15% of all adrenal tumors). Mean size of pheochromocytoma tumors was 35.55 mm (in greatest dimension), aldosterone producing tumors was 14.5mm (in greatest dimension) and cortisol secreting tumors was 26.67mm (in greatest dimension). One patient had MEN 2A syndrome (medullary thyroid carcinoma and pheochromocytoma). Of functioning adrenal adenomas, 6 patients (75 %) went for surgery. All the patients underwent laparoscopic surgery. Cure was achieved in all patients who underwent surgery. One patient with an aldosterone producing tumor was managed with medical treatment (spironolactone) and the patient with MEN 2A syndrome had undergone total thyroidectomy for medullary thyroid carcinoma but died before pheochromocytoma surgery could be done.

Challenges of endocrine hypertension

Tea Khurodze[1], Sopo Javelidze[2], Ana Pruidze[2] & Vitali Vashakidze[2]
[1]David Tvildiani Medical University, Endocrinology, Tbilisi, Georgia; [2]David Tvildiani Medical University, Tbilisi, Georgia

Background
Endocrine pathologies are a common cause of secondary hypertension. Most patients with primary aldosteronism and primary hyperparathyroidism suffer from hypertension. Although the coexistence of parathyroid adenoma and cones syndrome in the same patient is uncommon, the occurrence of these two adenomas at the same time can have significant implications for the patient's clinical presentation, diagnostic evaluation, and treatment approach.
Case Presentation
A 64-year-old Caucasian female was referred by her cardiologist to our clinic due to uncontrolled hypertension for 10-11 years, dyslipidemia and hypokalemia, case-typified resistant hypertension-related target organ damage symptoms, and a history of cardiovascular events. The patient's medical history is remarkable for lithotripsy due to nephrolithiasis in 2017-2018; In 2019 a coronary bypass was performed. History revealed that she was prescribed ace inhibitor in combination with thiazide diuretic and beta blocker for hypertension, atorvastatin for dyslipidemia. In her family history, none of her first-degree relatives had malignancy, her mother died at 50 years of age due to thromboembolism. On her P/E: BP 140/90 mm/hg pulse 90. The laboratory examinations reported: CBC, Urea, Creatinine, OH-vit-D3, cortisol catecholamine and its metabolites in 24 h urine, sodium, thyroid function tests, ACTH, PRL were normal, Potassium 2.0 mmol/l -L, ionized Calcium 1.7 mmol/l -H, Phosphorus: 0.7 mmol/l -L aldosterone level was measured after normalization of potassium level aldosterone 251,11 pg/ml-H, renin 5.91 pg/ml-L/N renin-Aldosterone ratio 40.34-H, Abdominal MRI revealed 1.6 -2.0 cm right adrenal adenoma. Thyroid ultrasound revealed a 22/14/12 mm hypoechogenic nodule at the lower part of the left lobe and a 16/9/7 mm iso echogenic nodular lesion at the lower posterior part of the right lobe. After biochemical confirmation of hyperparathyroidism technetium -99m sestamibi scintigraphy SPECT- CT confirmed the diagnosis of parathyroid adenoma, the mass was adjoined the lower pole of the left lobe of the thyroid gland. Followed by biopsy malignancy was excluded. Subsequent examinations, including densitometry identified osteoporosis. Based on these findings, a diagnosis of primary hyperparathyroidism associated with

aldosterone-secreting adenoma was made. The patient was provided 50 mg of spironolactone daily, BP and potassium were normalized and the patient was operated for parathyroid adenoma. PTH, Ca, and phosphorus normalized after surgery. Blood pressure is controlled with spironolactone, osteoporosis is treated with denosumab, and in 2-3 months adrenalectomy is planned

Conclusion

In this unique case report, we present the clinical details, diagnostic evaluation, and management approach of a rare case involving the coexistence of an adrenal adenoma and a parathyroid adenoma.

DOI: 10.1530/endoabs.99.EP760

Metastatic giant pheochromocytoma and primary hyperparathyroidism: Association or coincidence: about a case report and literature review

Benabdelatif Katia[1], Aicha Lachkhem[1], Abdelkader Yahi[1], Redhouane Longo[2], Ould Kablia Samia[1] & Bensalah Meriem[1]
[1]Endocrinology department, Central Military Hospital, Algiers, Algeria.; [2]Endocrinology department, Regional university Military Hopsital of Oran, Algeria.

Introduction

Pheochromocytomas and paragangliomas (PPGLs) are chromaffin cell tumors that arise from neuroectodermal cells. These tumors are characterized by a very heterogeneous natural history and an unpredictable ability to metastasize. The rate of metastatic disease ranges from lessthan 1% to 79%, depending on tumor site and size, age at diagnosis and genotype.30% are considered to be hereditary. Primary hyperparathyroidism can be associated with PPLGs. We report a case of a metastatic giant pheochromocytoma measuring 15 cm associated to an asymptomatic primary hyperparathyroidism

Case report

64-year-old female, with no significant past medical, family and psychosocial history, admitted for management of a right adrenal lesion measuring 153×100 mm, revealed by deep asthenia, anorexia, weight loss and recurrent *abdominal pain*. Clinical examination reveals an anorexic patient without clinical signs of mineral, androgen or catecholamine tumoral hypersecretion. Screening test for hypertension revealed low blood pressure with a mean of 90/56 mmHg. Biochemical tests revealed a high level of catecholamines (Noradrenaline). Laboratory investigations on three occasions showed a high level on calcium adjusted for albumin (2.67–2.88 mmol/l), parathyroid hormone (102-198 pg/ml) and low phosphor (0.6 mmol/l), which confirm the diagnosis of primary hyperparathyroidism. Neck ultrasound and 99mTc-MIBI scintigraphy revealed a superior right parathyroid adenoma. Morphological exploration revealed a large right adrenal mass measuring 153×100 mm with a suspicious appearance, with liver and lung metastases. MIBG -131 scintigraphy confirms the neuroectodermic tumor of adrenal with pulmonary and hepatic localizations. The patient underwent surgery. The anatomopathological and immunohistochemical study shows an aggressive pheochromocytoma with PASS score 10, expressing synaptophysin and chromogranin A with positive PS100. Unfortunately, she died following surgery.

Conclusion

Metastatic pheochromocytoma and primary hyperparathyroidism are two endocrine entities which can occur in an isolated form or as a part of a syndromic association. The prognosis of metastatic PPGL is heterogeneous, depending on local invasion, associated with a high mortality rate and several complications. Treatments includes medications helping control blood pressure and heart rate, but surgical removal of the tumor is the main curable treatment.

Clinical, biological and anatomopathological profile of pheochromocytomas

Marwa El Arem[1], Bilel Ben Amor[1], Ekram Hajji[1], Sana Abid[1], Ines Bayar[1], Héla Marmouch[2], Hanene Sayadi[2] & Inès Khochteli[3]
[1]Hospital Fatouma Bourguiba, endocrinology, Monastir, Tunisia; [2]Hospital Fatouma Bourguiba, endocrinology, Monastir; [3]Hospital Fatouma Bourguiba, endocrinology

Introduction

Pheochromocytoma is a rare tumour of the adrenal medulla. The aim of our work is to describe the clinical, biological and anatomopathological profile of pheochromocytomas.

Material and method

Retrospective descriptive study carried out in the endocrinology department of the Fattouma Bourguiba University Hospital, Monastir, Tunisia.

Results

Analysis of a series of 13 cases found 9 women and 4 men with an average age of 55.3+/-11 years, 12 patients were hypertensive, 46% of whom had paroxysmal hypertension. The circumstances of discovery were mainly suggestive symptoms ($n=8$), an adrenal incidentaloma ($n=4$) and resistant hypertension ($n=1$). The symptoms described were a Menard's triad (61%), abdominal pain (23.7%) and weight loss (15.3%). The nosological setting was NF1 in two cases and VHL syndrome in one case. The topographical diagnosis was made by abdominal MRI ($n=5$), abdominal CT ($n=5$) and MIBG scintigraphy ($n=2$) with an average size of 5 cm. Methoxylated derivatives were elevated in all patients with a majority increase in normetanephrines with an average level 12 times normal.

Conclusion

The clinical presentation of pheochromocytoma is variable. It should be considered in the presence of any adrenal incidentaloma and resistant hypertension and/or associated with hypokalaemia.

Assessing the Metabolic profile of young healthcare professionals: a cross-sectional study

Zeineb Rekaya, Samir Mekaouer, Meriem Yazidi, Elyes Kamoun, Nadia Khessairi, Ibtissem Oueslati, Fatma Chaker & Melika Chihaoui
La Rabta university hospital, Endocrinology Department, Tunis, Tunisia

Introduction

The prevalence of metabolic syndrome (MS) is constantly increasing, particularly among young individuals with sedentary professions. Identifying individuals with MS is crucial for implementing personalized interventions to prevent cardiovascular events. Our study aimed to assess the metabolic profile of young and healthy healthcare professionals, considering the specific lifestyle linked with their professional roles.

Methods

This cross-sectional observational study, conducted from August 2022 to October 2023, involved 64 young and healthy hospital-based healthcare workers, aged between 18 and 45 years. Each participant underwent a physical examination to determine anthropometric parameters and blood pressure. A fasting biological sample was collected for the analysis of fasting blood glucose and lipid parameters. The diagnosis of metabolic syndrome followed the criteria established by the International Federation of Diabetes (IDF 2009).

Results

The study participants had a mean age of 29.5±7.1 years, with 57% being women and 43% men. 33.8% were overweight, and 13.3% were obese. Smoking was reported by 21.2% of participants. Regular physical activity was reported by 22.2% of participants. Lipid profile analysis revealed total cholesterol at 4.6 mmol/l [4;4.9], Hdl cholesterol at 1.26 mmol/l [1.02;1.41], Triglycerides at 0.89 mmol/l [0.72;1.277], and Ldl cholesterol at 2.82 mmol/l [2.41;3.23]. Android obesity was present in 13.8% of men and 15% of women. The mean systolic blood pressure was 116.3±9.6 mmHg and the mean diastolic blood pressure was 73.5±7.7 mmHg. 7.4% of participants had high triglyceride levels. HypoHdlemia was noted in 31.6% of women and 40% of men. None had fasting glycemia ≥6 mmol/l. The prevalence of metabolic syndrome among all the study participants was 8.8%, with a distribution of 13.8% in men and 5.1% in women.

Conclusion

Despite their young age, the frequency of metabolic disorders among healthcare workers was high in our study. These findings underscore the need for targeted interventions to prevent metabolic and cardiovascular diseases among healthcare professionals.

Adrenal incidentaloma: A case of pheochromocytoma with sub-clinical Cushing's syndrome

Sana Rafi[1], Meryam Alahyane, El Mghari Ghizlane & El Ansari Nawal
Mohammed VI university hospital of Marrakesh, Department of Endocrinology, Diabetes, Metabolic diseases and Nutrition, Marrakesh, Morocco

Background
An adrenal incidentaloma (AI) is defined as an adrenal lesion that is discovered when a radiological study is performed for indications other than suspected adrenal disease. All patients with an AI should be evaluated for endocrine adrenal functioning and malignancy potential features. A combination of pheochromocytoma and Cushing's syndrome in same adrenal gland is extremely rare. We report a case of AI with the evidence of both pheochromocytoma and sub-clinical Cushing's syndrome.
Case report
A 68 year old female patient presented with an acute respiratory SARS-CoV2 infection. To stratify severity and disease extension, a Computed tomography was performed revealing chest ground-glass opacities, as well as a Right adrenal mass measuring 27×26×25 mm, a spontaneous density of 33UH, Absolute Wash out >50%. Left adrenal gland was normal; Without any clinical symptoms or biological hormonal findings suggesting of a functioning adrenal tumor. On endocrine evaluation a year later, the patient remains asymptomatic, however the laboratory data demonstrated 4 times raised 24-h urinary fractionated metanephrines with non-suppressible serum cortisol after 1 mg dexamethasone suppression test. She underwent right-sided adrenalectomy. The Anatomopathologic report confirmed a pheochromocytoma with a pass score at 3; a proliferative KI index of 5%; staining positive for chromogranin and synaptophysin. The Patient was discharged in good clinical condition.
Discussion
There are few case reports suggesting the different etiologies for this association, namely, pheochromocytoma secreting adrenocorticotropin hormone (ACTH) or its precursors, corticomedullary mixed tumors and focal adrenocortical hyperplasia. Pheochromocytoma may secrete various substances in addition to catecholamines. There are few cases reported of Cushing's syndrome due to ACTH-secreting pheochromocytoma. In some of them, there was predominance of hyperpigmentation, hypokalemic alkalosis and evidence of contralateral adrenal gland hyperplasia on imaging, but these features were absent in our case. Mixed tumors involving the cortical and medullary components of the adrenal gland are quite rare. On histochemical staining, patient's tumor was not a corticomedullary mixed tumor, but a pure pheochromocytoma. In some cases adrenocortical hyperplasia resulting from the pheochromocytoma's paracrine stimuli was the source of autonomous cortisol production. As we do not have plasma ACTH levels, this hypothesis could not be completely ruled out.
Conclusions
The clinical aspects of this case suggest the importance of proper pre-operative recognition of the dual hormone secretion from adrenal mass, which, if goes unnoticed could lead to adrenal or hypertensive crisis in perioperative period.

Value of low-dose short synacthen test (1μg) vs high-dose synacthen test (250 μg) for assessment of the adrenal axis

Anastasia Patricia Stanescu-Smocot[1], Vlad George Radulescu[2], Cristina Stancu[2], Dana Manda[2] & Corin Badiu[2]
[1]C.I. Parhon National Institute of Endocrinology, Clinical Endocrinology IV, Bucureşti, Romania; [2]C.I. Parhon National Institute of Endocrinology, Bucureşti, Romania

Introduction
Assessment of adrenal insufficiency (AI) is done routinely through Synacthen test. However, the conventional high dose (250 μg) stimulation is supra-physiological, therefore 1 μg low dose test was developed.
Aim
to investigate the utility of the Low-dose test vs the High-dose test, in patients with suspected central AI, in a tertiary centre of endocrinology, in the National Institute of Endocrinology, Bucharest, Romania.
Material and methods
We performed a retrospective study spanning the period from 2019 to 2023. This study focused on patients presenting diverse disorders leading to central AI. The aetiology was: pituitary adenomas ($n=35$), basal or postsugery, adrenal Cushing after surgery ($n=31$), congenital hypopituitarism ($n=11$), patients previously on corticosteroids ($n=10$), after stopping the GC treatment and oncologic patients under immunotherapy ($n=9$). After basal sampling between 8-10 AM, a dose of synthetic ACTH (Synacthene) was injected iv, 250 μg for high dose and 1 μg for low dose test. Cortisol was sampled at 30 and 60 min.
Results
Among the participants ($n=117$), 36.8 % were male and 63.2 % were female. Complete recovery is considered if serum cortisol levels after stimulation rises over a minimum of 18 μg/dl (12-18 μg/dl is considered incomplete response, values lower than 12 μg/dl is considered diagnostic for AI). Out of the 117 patients 23 (31.9%) were found to have AI in Low-dose testing (cortisol 0' = 6.78 mg/dl ± 4.2, T1 = 16.19 mg/dl ± 8.5, T2 = 16.09 ± 9.04) vs. 4 (cortisol 0' = 11.92 mg/dl ± 6.19, T1 = 31.76 ± 12.45, T2 = 27.46 ± 13.07) (3.3%) in the High-dose test therefore, they required ongoing treatment. Subclinical AI with incomplete response was present in 14 patients, requiring treatment in stress conditions. Among all patients in the low-dose test 10 (13.9 %), respectively 16 (35.6%) in the high-dose test achieved normal adrenal function.
Conclusion
Low dose Synachtene revealed more cases of AI, who required substitution treatment. The findings highlight the need for further research to optimize treatment strategies and improve outcomes for individuals with central hypocorticism.

Evaluation of late-night salivary cortisol diagnostic accuracy for Cushing's syndrome in the clinical setting

Daniela Dadej, Ewelina Szczepanek-Parulska & Marek Ruchała
Poznan University of Medical Sciences, Department of Endocrinology, Metabolism and Internal Medcine, Poznań, Poland

Introduction
The diagnosis of Cushing's syndrome (CS) is often challenging and requires the use of several diagnostic methods. Late-night salivary cortisol (LNSC) offers an easy, non-invasive screening method for CS. However, its availability is still limited and the cut-off values vary widely between laboratories. The aim of this study was to assess the diagnostic value of LNSC for CS in comparison with late-night serum cortisol (LNSerC) and 24-hour urinary free cortisol (UFC). We also aimed to verify the accuracy of manufacturer-provided cut-off value for LNSC.
Methods
Patients with suspected CS hospitalized in our department were retrospectively reviewed. Saliva was collected at 11 p.m. using a Salivette. At the same time blood samples for the determination of serum cortisol were obtained. Additionally, 24-hour urine collection for free cortisol assessment was performed. Salivary cortisol was determined using automated electrochemiluminescence assay - Elecsys Cortisol II (Roche Diagnostics). Upper reference limit for LNSC provided by the manufacturer was 11,3 nmol/l.
Results
A total of 69 patients were included in the study. 19 patients were diagnosed with endogenous CS (pituitary: 10, ectopic: 2, adrenal: 7), among them 2 were already treated and presented normal cortisol values. CS was excluded in the remaining 50 patients. 86% of the cohort were women. The mean age was 45,9, and mean BMI was 29.9 kg/m^2. Obesity was present in 40% of patients. Cortisol concentrations assessed with all analysed methods were significantly higher in patients with active CS compared to patients in whom CS was excluded: salivary cortisol (15 nmol/l vs 2.985 nmol/l, $P<0.001$), serum cortisol (523 nmol/l vs 170 nmol/l, $P<0.001$), and UFC (594.5 nmol/24 h vs 130 nmol/24 h, $P<0.001$). LNSC was not related to sex, BMI, smoking status or oral contraceptive (OC) use (however only 4 patients were using OC). Significant correlations between LNSC and LNSerC ($P<0.001$; $r=0.832$), and UFC ($P<0.001$; $r=0.526$) were identified. ROC curves comparison demonstrated no superiority of any of the analysed methods in the diagnosis of CS (LNSC vs LNSerC $P=0.905$; LNSC vs UFC $P=0.619$; LNSerC vs UFC $P=0.623$). AUC for LNSC was: 0.93043, $P<0.001$, for LNSerC: 0.933258, $P<0.001$, and for UFC: 0.901563, $P<0.001$. The cut-off point 11.3 nmol/l for LNSC provided sensitivity of 88.24% and specificity of 88.46%.
Conclusions
LNSC is a valuable method in the diagnosis of CS providing the accuracy comparable to LNSerC and UFC. Cut-off value provided by the manufacturer offers high accuracy in the diagnosis of CS.

Identification of risk factors and indications for performing an ACTH-Test in cases of suspected adrenal insufficiency

Janine-Marie Eggers[1], Catharina Bullmann[2] & Birgit Harbeck[1]
[1]University Medical Center Hamburg-Eppendorf, III. Department of Medicine, Hamburg, Germany; [2]MVZ Amedes Experts, Endocrinology, Hamburg, Germany

Introduction
Adrenal insufficiency can result in a life-threatening situation if undetected. This pathology is diagnosed by performing an ACTH-Test. Most symptoms like fatigue, loss of weight or arthralgia are rather unspecific. Therefore it is difficult to assess which patients really need an ACTH-Test. Aim of this study was to identify risk factors and indications in order to specify which patients actually require it.
Material and methods
324 patients who received an ACTH-Test from 14th October 2011 to 2nd December 2022 were included. They were compared in terms of gender, age, BMI, blood pressure, symptoms, diagnoses, glucocorticoid medication, laboratory parameters and reasons for testing. A test result was considered as pathological if the basal cortisol level had not increased by at least 100% or >150 ng/ml after 60 minutes despite stimulation with Synacthen. Statistical analysis were executed by using SPSS.
Results
262 of the included patients were female, 61 were male and 1 was transsexual. 87 patients had a pathological test result by definition. No patient with a previously diagnosed hyponatremia had a pathological test result. There was also no significant difference between the test groups for a low sodium value in the laboratory (9.2% (pathological) vs. 8.4% (normal), $P=0.807$). Statistically significant risk factors were myalgia ($P=0.014$), an adrenalectomy ($P=0.014$) and the oral intake of a cortisone-containing drug at time of the test ($P=0.010$), especially of prednisolone ($P=0.029$) and hydrocortisone ($P=0.023$). Statistically significant indications were an elevated ACTH value ($P=0.002$) and a borderline to low cortisol value ($P=0.012$) in the routine laboratory. It was also useful to carry out the test while discontinuing or tapering off hydrocortisone substitution ($P=0.047$).
Conclusions
The patient's symptoms or clinical situation as the only reason for performing an ACTH-Test seems to be too unspecific. Other risk factors or indications like corresponding aberrances in the laboratory parameters should be taken into account.

Primary unilateral macronodular adrenal hyperplasia with concomitant glucocorticoid and androgen excess and KDM1A inactivation

Yasir Elhassan[1], Silke Appenzeller[2], Laura-Sophie Landwehr[2], Juliane Lippert[2], Dillon Popat[3], Lorna C. Gilligan[1], Lida Abdi[3], Edwina Goh[1], Salvador Diaz-Cano[1], Stefan Kircher[2], Susanne Gramlich[2], Robert Sutcliffe[1], Shakila Thangaratinam[1], Li Chan[3], Martin Fassnacht[2], Wiebke Arlt[3] & Cristina L Ronchi[1]
[1]Birmingham, Birmingham, United Kingdom; [2]Würzburg, Würzburg, Germany; [3]London, London, United Kingdom

Background
Primary bilateral macronodular adrenal hyperplasia (PBMAH) is a rare cause of Cushing's syndrome. Primary unilateral macronodular adrenal hyperplasia with concomitant glucocorticoid and androgen excess has never been studied before.
Methods
We investigated a woman with a large, heterogeneous 7 cm adrenal mass (with a radiologically normal contralateral adrenal) and adrenocorticotropic hormone (ACTH)-independent glucocorticoid and androgen excess, a presentation typically suggestive of adrenocortical carcinoma. We undertook detailed histopathological examination in addition to a comprehensive molecular analysis of the resected adrenal mass as well as of the patient and the parent's leukocyte DNA.
Findings
Histopathological examination revealed macronodular adrenal hyperplasia without evidence of malignancy. Interval imaging 24 months after surgery persistently showed normal contralateral adrenal gland. At whole-exome sequencing of four representative nodules, we detected inactivating germline variants p.G46S and p.R269Dfs*7 in *KDM1A*; inactivating *KDM1A* variants have been described in 90% of PBMAH associated with ectopic expression of the gastric inhibitory polypeptide receptor (GIPR) leading to food-dependent Cushing syndrome. Copy number variation analysis demonstrated an additional somatic loss of the *KDM1A* wild-type allele on chromosome 1p36.12 in all nodules. RNA-sequencing on a representative nodule showed low/absent expression of *KDM1A* and a high expression of *GIPR* compared to an available dataset of 52 unilateral sporadic adenomas and 4 normal adrenal glands. Sanger sequencing confirmed germline *KDMIA* p.R269Dfs*7 variant in the father and *KDM1A* p.G46S variant in the mother. Clinical assessment of the parents showed no features of glucocorticoid or androgen excess.
Conclusion
We investigated the first case of primary unilateral macronodular adrenocortical hyperplasia (PUMAH) associated with severe Cushing's syndrome and concomitant androgen excess and suggest pathogenic mechanisms involving *KDM1A*, but without features of food-dependent Cushing's syndrome.

Adrenal lesions do matter in the course of primary aldosteronism: a comparative analysis of Conn's adenoma vs bilateral adrenal hyperplasia

Siddiqa Soomauroo[1], Faten Hadjkacem[1], Ahmad Ridwaan Auckburally[2], Abdelmuhaymen Missaoui[1], Souhir Maalej[1], Wiem Feki[2], Zeinab Mnif[2], Mouna Mnif[1], Mohamed Abid[1] & Nabila Rekik[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Department of Radiology, Sfax, Tunisia

Introduction
Primary aldosteronism (PA) is commonly identified as the main cause of secondary hypertension. It is becoming increasingly wide-spread, affecting between 1 and 30% of people suffering from hypertension. We aim to determine the different characteristics between aldosterone-producing adenoma (APA) and bilateral adrenal hyperplasia (BAH).
Patients and methods
Retrospective descriptive and analytical study concerning 40 patients with PA, collected inthe endocrinology department of the Hedi Chaker University Hospital of Sfax, over the period of 10 years from January 2010 to December 2022. In an endeavour to determine the distinct characteristics of the 2 main aetiologies, we defined 2 groups: the first group APA ($n=17$) and the second group BAH ($n=20$).
Findings
The mean age of our patients was 55.4 years old. The aetiology of PA was dominated by BAH in 20 cases. The sex ratio (M/F) in the group APA was 0.55 whereas in the group BAH, the sex ratio was 1. Statistical analysis between these two groups revealed no significant differences in epidemiological and clinical data, with the exception of asthenia, which was more prominent in the BAH group, with a significant difference (75% vs. 41.2%; $P=0.037$), and fasting blood glucose was significantly higher in the BAH group than in the APA group ($P=0.018$). In terms of hormonal profile, serum aldosterone and renin levels, as well as aldosterone to renin ratio (ARR) were higher in the APA group, but the difference did not reach statistical significance for these parameters. We found no significant difference in the incidence of metabolic syndrome between the 2 groups (APA = 82.4% vs BAH = 80%).
Conclusion
APA is generally observed in individuals between the third and fifth decade of life. The symptoms associated with this entity are generally more severe, with higher blood pressure levels and more pronounced hypokalemia compared with other forms of PA.

Adrenoleucodistrofia ligada al cromosoma X con genética atípica

Rocio Dominguez Rabadan[1], Rossana Manzanares Cordova[2] & Luna Florencio Ojeda[2]
[1]Hospital Juan Ramón Jiménez, Endocrinology, Huelva; [2]Hospital Universitario Juan Ramón Jiménez, Endocrinology, Huelva, Spain

Background
X-linked adrenoleukodystrophy (X-ALD) is a hereditary disease that occurs in boys in childhood and adolescence, with cases being rarer in adulthood. Primary

adrenal insufficiency (PSI) is present in more than 50% of patients and in 10% it is the only manifestation
Case report
24-year-old male, diagnosed with primary adrenal insufficiency as a child. The pathological history included dyslipidemia, obesity, prediabetes and parietospastic gait as possible involvement of the 1st motor neuron. Family history of the index case: Maternal family without any living male, mother had 5 brothers, males who died from vomiting, hyperpigmentation, dehydration. When reviewing his medical history, the etiology of PSI was not identified, so additional tests were requested. Anti-21 hydroxylase (anti-21OH) antibodies were negative and abdominal CT showed a mildly hypoplastic right adrenal gland. Given the negativity of these 2 tests in a man with neurological involvement and a family history, genetic etiology was suspected and very long chain fatty acids (LCGML) in plasma were requested: still pending. The genetic study demonstrated the ABCD1 gene mutation (NM_000033.4). Identified variant: c.355G>C (pAla119Pro). This variant is classified as probably pathogenic because: it is located in a gene where missense-type variants are usually pathogenic; and is described in the ClinVar database (ID: 585356) as a variant of uncertain clinical significance. As of the date of issuance of this report, it has not been described in the scientific literature consulted

Angiomyolipoma of right adrenal gland

Mariyah Ahmed[1], Sheeba Shaikh[2], Aziz Gulamhusein[3], Pedro Oliveira[4] & Safwaan Adam[2,5]
[1]The Christie Hospital, Department of Endocrinology, Manchester, United Kingdom; [2]The Christie Hospital, Department of Endocrinology, Manchester, United Kingdom; [3]The Christie Hospital, Department of Urological Surgery, Manchester, United Kingdom; [4]The Christie Hospital, Department of Pathology, Manchester, United Kingdom; [5]The University of Manchester, Faculty of Biology, Medicine and Health, Manchester, United Kingdom

We describe the case of a 52-year-old female, with a body mass index of 32 kg/m^2 and without significant co-morbid illness who initially presented acutely, with self-resolving abdominal pain. During that admission, an abdominal computed tomography (CT) scan demonstrated a right-sided heterogeneous and contrast enhancing adrenal mass (measuring 59×41 mm) with a 15 mm focus of cystic degeneration. Based on the scan appearances, the patient was suspected as having a phaeochromocytoma and referred to our centre. She did not report any symptoms of catecholamine excess however was found to be hypertensive. Initial blood test screening revealed a diagnosis of type 2 diabetes mellitus (glycated haemoglobin 55 mmol/mol). She underwent biochemical screening for adrenal hormone excess with normal values of plasma metanephrines (<38 pmol/l [0-510]), normetanephrines (233 pmol/l [0-1180]), 3-methoxytyramine (<75 pmol/l [0-180]), aldosterone (161 pmol/l with an aldosterone to renin ratio of 146) and a normal post-overnight dexamethasone suppression test cortisol (<50 nmol/l). On the basis of initial investigations, the patient was worked up for the possibility of a 'non-functioning' phaeochromocytoma and underwent functional imaging with positron emission tomography (PET) scans; she initially underwent a fluorodeoxyglucose (FDG) and then a gallium^{68} dotatoc PET scan. Both PET scans showed moderate-to-high intensity localised tracer uptake and consequently the patient was diagnosed as having a non-functioning phaeochromocytoma. Her hypertension was managed with doxazosin which was uptitrated to achieve consistent normotension. She underwent a right-sided robot-assisted laparoscopic adrenalectomy with an uneventful post operative course. A short synacthen test performed a week after surgery was normal with a peak cortisol of 780 nmol/l (>450). Postoperative histopathology and immunohistochemistry demonstrated features consistent with an epithelioid angiomyolipoma of the adrenal gland, without any evidence of necrosis, mitotic activity or vascular invasion. There was strong positivity for Cathepsin K and alpha smooth muscle actin (SMA) and negativity for Human Melanoma Black 45 (HMB45). Cytokeratins, neuroendocrine markers, CD34 and signal transducer and activator of transcription 6 (STAT6) were also negative. The Ki67 was less than 1%. Our case demonstrates a rare and unusual benign adrenal tumour type which had the preoperative radiological appearances of a phaeochromocytoma. Angiomyolipomas (AMLs) usually consist of smooth muscle cells, adipose tissue, and thick-walled blood vessels and are commonly found in the kidneys. Extrarenal AMLs are rare with the liver being the commonest site. There have been less than 30 cases reported in the English literature for adrenal AML.

Silent yet aggressive: a case of large adrenocortical carcinoma with asymptomatic hypercortisolism

Robu Larisa, Ilona Beatrice Blesneac, Otilia Tarcau, Anca Matei, Laura Teodoriu, Alexandru Florescu & Cristina Preda
Saint Spiridon County Hospital, Iasi, Romania

Introduction
Adrenocortical carcinoma (ACC) is a rare endocrine malignancy arising from the adrenal cortex often with unexpected biological behavior. It can occur at any age, with two peaks of incidence: in the first and between fifth and seventh decades of life. Although ACC are mostly hormonally active, precursors and metabolites may be also produced by dedifferentiated and immature malignant cells.
Case report
We report a rare and challenging case of adrenocortical carcinoma (ACC) in a 40-year-old male with no previous pathological history, presenting with severe abdominal pain, significant weight loss, and hypercortisolism. The patient was admitted to the Endocrinology Clinic for evaluation of an adrenal mass, initially suspected to be an adrenal hematoma of approximately 6 cm based on abdominal CT findings. Clinical examination revealed pale skin, minimal adipose tissue, and a large, hard, painful mass in the right flank. Hormonal evaluation confirmed hypercortisolism, indicated by increased cortisol levels (CLU at 590 mg/dl), a lack of suppression with 1 mg dexamethasone, and only partial suppression with a high-dose dexamethasone test. Notably, DHEAS levels were markedly elevated (>1000 mg/dl), along with increased 17-OH-Progesterone, whereas urinary metanephrines remained normal. The patient also exhibited hypogonadotropic hypogonadism, likely secondary to hypercortisolism. Further imaging with an abdominal CT scan revealed a large retroperitoneal mass centered at the right adrenal lodge, measuring 149/118/168 mm. This mass had heterogeneous components, showing no clear demarcation from adjacent vital structures including the liver, kidney, and inferior vena cava, and exerting a mass effect. Multiple nodular lesions in the right hepatic lobe suggested metastases. A biopsy from the adrenal mass confirmed the diagnosis of adrenocortical carcinoma with a high Ki67 proliferation index of 70-80%. Given the tumor's extensive size, mass effect, and evidence of hepatic metastases, surgical intervention was deemed unfeasible – stage IV. The patient was commenced on Mitotane and protocol-based chemotherapy.
Conclusions
This case of adrenocortical carcinoma exemplifies the unique and complex nature of this malignancy, particularly in its long-term evolution without overt clinical signs of hypercortisolism. Despite the absence of initial symptoms typically associated with hypercortisolism, the patient's condition rapidly deteriorated, underlining the unpredictable and aggressive course of ACC. The long asymptomatic progression of ACC in this patient raises important questions about the underlying mechanisms of tumor growth and hormonal activity, suggesting a potential area for further investigation in the field of endocrine oncology.

The 1-mg overnight low-dose dexamethasone suppression test cut-off in establishing the diagnosis of Cushing's syndrome

Amani Terzi, Ibtissem Oueslati, Yasmine Merhbène, Elyes Kamoun, Cyrine Chehaider, Meriem Yazidi & Melika Chihaoui
La Rabta University Hospital, Department of Endocrinology, Tunisia

Introduction
The 1-mg overnight low-dose dexamethasone suppression test (DST) has been used to screen for mild autonomous cortisol secretion and Cushing's syndrome (CS). The aim of the present study was to determine the DST discriminatory threshold confirming the diagnosis of CS.
Methods
This was a monocentric retrospective study including patients who were admitted to the Department of Endocrinology of La Rabta Hospital, Tunis between 2014 and 2023 for suspicion of CS. All patients underwent 1-mg DST followed by the 4-mg DST. A serum cortisol level <1.8 µg/dl at 08h after DST exclude the diagnosis of CS.
Results
One hundred two patients (69 women and 33 men) were enrolled in this study. Their mean age was 56.6 ± 14.7 years. The diagnosis of CS was confirmed in 63 patients (62%) and ruled out in 39 patients (38%). The mean serum cortisol level after the 1-mg DST was 7.4 ± 6.9 µg/dl in patients with CS and 4.4 ± 4.7 µg/dl in those without CS ($P=0.019$). It was 10.1 ± 8.8 µg/dl in patients with CS clinical features and 4.4 ± 3.3 µg/dl in patients without CS clinical features ($P<$

0.001). The area under the ROC curve of serum cortisol level after the 1- mg DST was 0.726 ($P<0.00$). A cut-off value of 1.8 μg/dl had a sensitivity of 100% and a specificity of 10%. A cut-off value of 10 μg/dl was associated with the diagnosis of Cushing syndrome (Odds Ratio = 4.5, $P=0.034$) with a specificity of 95%. A cut-off value of 24 μg/dl confirmed the diagnosis of CS in 100% of cases.
Conclusion
This study provides evidence that with a higher cutoff for serum cortisol level as 24 μg/dl, the 1-mg DST establishes the diagnosis of CS without the need for other tests.

A middle aged man presented with hypertension and adrenal incidentaloma diagnosed with pheochromocytoma

Mohammad Salah Uddin & Fathi Abourawi
Diana princess of Wales hospital, Endocrinology, Grimsby, United Kingdom

Pheochromocytomas are rare tumors located in the adrenal medulla, that derive from the chromaffin cells and produce catecholamines. They are an uncommon cause of hypertension, and only 50% of the patients present symptoms compatible with this pathology. Here we describe the case of a 67-year-old man who was referred with h/o mild headache, hypertension and adrenal incidentaloma detected by CT abdomen and pelvis which showed 4.5 cm indeterminate nodule in the left adrenal gland. PMH includes T2DM, prostate cancer treated with radical prostatectomy and salvage radiotherapy. His BP was 177/100 mmhg in the clinic and other systemic examinations were unremarkable, no palpable mass was found in neck or abdomen. There was no family history of any adrenal, thyroid, parathyroid or pituitary gland problem. Subsequently, MRI scan of adrenal gland showed 5.5 cm indeterminate nodule in left adrenal gland though in-phase/out-phase sequence couldn't be done. Laboratory studies revealed an elevated plasma non metanephrine of 10,506 pmol/l (normal limit up to 1180), plasma metanephrine level was 272 pmol/l (normal limit up to 272), plasma 3-methoxytyramine was 211 pmol/l (normal limit up to 180). Other blood tests including overnight dexamethasone suppression test, plasma aldosterone and renin ratio, serum calcium, TSH, urea and electrolytes, PSA were in acceptable normal limit. A diagnosis of pheochromocytoma was made and the patient was started on phenoxybenzamine to control his blood pressure with the aim of adding betablocker subsequently. The case has been discussed in adrenal MDT and decided for left sided adrenalectomy after discussion with the patient. He is currently waiting for the left adrenalectomy. This case highlights the importance of having a high index of suspicion to diagnose this rare tumor presented with very subtle clinical findings and adrenal incidentaloma on imaging. Early diagnosis and subsequent interventions with surgery and antihypertensive medications can reduce morbidity and mortality.

Pheochromocytoma with an atypical presentation

Ilir Gjermeni, Irida Kecaj, Ediola Hysa & Ergita Nelaj
University Hospital Center "Mother Teresa", Internal Medicine, Tirana, Albania

Introduction
Pheochromocytoma is a rare tumor of adrenal gland tissue. It results in the release of too much epinephrine and norepinephrine, hormones that control heart rate, metabolism, and blood pressure. The clinical manifestations of patients with pheochromocytoma are diverse, ranging from asymptomatic, paroxysmal hypertension, episodic anxiety to devastating acute heart failure and acute pulmonary edema, which all increase the difficulty of identifying and diagnosing it.
Case presentation
We report the case of a 51-year-old man, with a 4-year history of resistant arterial hypertension, type 2 diabetes mellitus, and post-ischemic stroke. The patient complaints abdominal pain in the right iliac fossa, which is suspected as acute appendicitis, complicated with hypertensive crisis, headache and sweating. Abdominal ultrasound shows a round hypoechoic formation, 29 mm, in the superior pole of right kidney. Computed tomography scan of abdomen shows a dense formation in the right suprarenal gland, 30 x 30 mm, with densification of the surrounding tissue, suspicions for pheochromocytoma. Laboratory tests revealed elevated urinary metanephrine excretion of 1030 mg/24 hours (rate < 375 mg/24 hours) and elevated urinary normetanephrine of 835 mg/24 hours (rate <780 mg/24 hours. Open surgical excision of the pheochromocytoma was performed. The histological analysis of the mass confirmed diagnosis. The symptoms releated to pheochromocytoma were relieved and the blood pressure returned to normal after surgery.
Conclusion
Pheocromocytoma is a rare tumor of the adrenal gland that is responsible for a small percentage of all patients with hypertension. However, it should always be suspected in patients with resistant and unstable hypertension.

Neurofibromatosis type 1: rare cause of pheochromocytoma - a report of 2 cases

Karimi Meryem[1], Hajar Azagouagh[1], Mustapha Asfour[2], Rifai Kaoutar[1], Iraqi Hind[1] & Mohamed Elhassan Gharbi[1]
[1]ibn Sina rabat, Endocrinology, Morocco; [2]Hôpital militaire d'instruction Mohammed V, Endocrinology, Morocco

Introduction
Neurofibromatosis type 1 is a multi-organ genetic disease, commonly occurring with variable severity. Pheochromocytoma is a rare manifestation in NF1, affecting 1-15% of NF1 patients according to studies.
Case Report
We present 2 cases: - Patient 1: 28 years old, with personal history of café au lait spots, cutaneous and subcutaneous neurofibromas, axillary lentigines. Referred for endocrinology consultation due to an adrenal mass discovered during an ultrasound for abdominal pain. Further CT scan revealed right adrenal masses measuring 25*22mm and 39*34mm, with estimated absolute washout of 62% and 37%. Elevated methoxylated derivatives in hormonal assessment. The patient underwent laparoscopic surgery. - Patient 2: 26 years old, with similar personal history. Discovered through a similar presentation as the first patient, adrenal CT scan revealed a tissue mass measuring 50*57*40mm, with tissue density of 49ui. Elevated methoxylated derivatives in hormonal assessment. The patient underwent laparoscopic surgery.
Discussion and Conclusion
In NF1, 80% of pheochromocytomas are asymptomatic, with over half being non-secreting. When secretory, they are often asymptomatic but can become symptomatic acutely, especially during surgical procedures. These findings underscore the importance of screening for pheochromocytoma in the NF1 population around the age of 35 to 40.

Adrenal cavernous hemangioma: a diagnostic challenge

Alberto García Piorno, Isabel Losada Gata, Mónica Gómez-Gordo Hernánz, Gloria Collado González, Marta Pérez Noguero, Ignacio Jiménez Hernando, Alejandra Rivas, Gilberto Pérez Lopez & Laura González Fernández
Gregorio Marañón General University Hospital, Endocrinology, Madrid, Spain

Introduction
Cavernous hemangiomas (CH) are benign vascular tumors that frequently involve the skin, central nervous system or liver. Rarely, they can also affect adrenal glands. Adrenal cavernous hemangiomas are mostly unilateral lesions, typically discovered incidentally on radiological imaging. They generally present in the sixth to seventh decade of life and tend to be asymptomatic and non-functioning tumors. Preoperative differential diagnosis from malignant neoplasms owing to imaging features remains challenging.
Case report
A 58-year-old woman was referred for the evaluation of a left adrenal mass incidentally discovered during an ultrasound conducted for the assessment of acute ureteric colic. The patient was asymptomatic, with no reported headache, palpitations or diaphoresis. Physical examination was unremarkable. A contrast enhanced CT scan of the abdomen revealed a solid exophytic left adrenal mass that measured 4 x 3.5 cm and exhibited heterogeneous contrast enhancement. Imaging characteristics were suggestive of adrenal adenoma with hemorrhagic degeneration. Subsequently, an abdominal magnetic resonance imaging (MIR)

was performed, revealing non-specific features. Tumor functionality was explored through a series of laboratory investigations. Analysis revealed an increase in dopamine and noradrenaline levels in a 24-hour urine sample on a single occasion, which was not confirmed in subsequent assessments. No abnormal hormone levels were detected in blood tests. 123I-Metaiodobenzylguanidine (123I-MIBG) scintigraphy showed absence of radiotracer uptake in the adrenal gland. Given the non-specific radiological findings and the exclusion of functionality, it was decided to monitor the lesion, which remained stable in successive radiological follow-ups. In the latest TC scan, performed 6 years after the initial diagnosis, the adrenal mass exhibited an increase in dimensions to 5 x 5.4 cm. Imaging characteristics were suspicious for adrenal myelolipoma as the tumor displayed macroscopic fat. Additionally, a newly appeared 5 mm focal calcification was observed. Due to diagnostic uncertainty and the observed growth, the patient was offered resection, and a retroperitoneal laparoscopic adrenalectomy was performed. The histopathological examination revealed a benign adrenal cavernous hemangioma with extensive thrombosis. The patient recovered without surgical related complications.
Conclusion
Cavernous adrenal hemangiomas are rare tumors that should be considered in the differential diagnosis for nonfunctioning adrenal incidentalomas. They are radiologically heterogeneous, often presenting as hypodense lesions with variable calcification, macroscopic fat or necrosis. These findings can be common to other adrenal lesions such as angiomyolipoma, pheochromocytoma or adrenal carcinoma. Thus, surgical resection is often required to exclude malignancy and the final diagnosis is largely established after histopathological analysis.

[131I]6ß-iodomethyl-19-norcholesterol SPECT/CT in the localization of cortisol-producing adrenal adenoma

Annamaria Erdei[1], Laura Koroskenyi[1], Eszter Daniel[2], Monika Andrasi[3], Sandor Barna[3] & Endre Nagy[1]
[1]Faculty of Medicine, University of Debrecen, Divison of Endocrinology, Department of Internal Medicine, Debrecen, Hungary; [2]Faculty of Medicine, University of Debrecen, Department of Surgery, Debrecen, Hungary; [3]Faculty of Medicine, University of Debrecen, Department of Nuclear Medicine, Debrecen, Hungary

Introduction
Adrenal scintigraphy using [^{131}I]6ß-iodomethyl-19-norcholesterol has been available since 1975, primarily for the diagnosis of hyperaldosteronism helping to distinguish between unilateral adenoma and bilateral hyperplasia. First line treatment of ACTH-independent form of Cushing syndrome is surgery after localization of the cortisol-producing adrenal tumour.
Case report
A 31-year-old woman has been referred to the endocrine clinic with suspected Cushing syndrome in 2020. Tonsillectomy, lactose intolerance, allergic rhinitis and epilepsy were present in her medical history. She complained of weight gain (30 kg during one year), secondary amenorrhoea, and elevated blood pressure. Physical examination revealed round face, central obesity, oedema on the legs and striae on the skin of the abdomen. Laboratory examinations proved hypercortisolism with suppressed ACTH level. We diagnosed her with hypertension, osteoporosis and impaired glucose tolerance as complications of Cushing syndrome. Adrenal CT showed bilateral adrenal adenomas, with 30 mm diameter in the right side and 17 mm in left side. Iodo-methyl-norcholesterol SPECT/CT proved cortisol-secreting adenoma in the right adrenal gland. Coronavirus pandemic-driven restrictions prevented immediate surgery; this was postponed to an uncertain date in the future. We decided to start metyrapone treatment until surgery, which partially controlled her hypercortisolism. Laparoscopic adrenalectomy in the right side was performed one year later. Histology confirmed cortisol secreting adenoma. After operation, the patient had transient adrenal insufficiency for a few weeks, then normal cortisol levels resumed spontaneously as expected. Clinical features of Cushing syndrome gradually disappeared, her body weight decreased from 126 kg to 78 kg.
Conclusions
In Cushing syndrome with bilateral adrenal lesions, it may be challenging to lateralize the hormone source. Iodo-methyl norcholesterol SPECT/CT is a feasible non-invasive method to localize the cortisol-secreting adrenal adenoma preoperatively.

Administration of high dose vitamin E in female rabbits with hypercholesterolemia increases acutely androgen levels: an animal model study

Ioannis Vlachos[1], Sofia Chatzi[2], Konstantinos Kontzoglou[1] & Georgios Boutzios[2]
[1]National and Kapodistrian University of Athens, Nikolaos Christeas Laboratory of Experimental Surgery and Surgical Research, Medical School, Athens, Greece; [2]National and Kapodistrian University of Athens, Department of Pathophysiology, Medical School, Athens, Greece

Introduction
Only few studies were observed, supporting the hypothesis that the administration of high doses of vitamin E in people with elevated serum total cholesterol levels leads to increased adrenocortical hormone secretion. There are only limited data concerning androgen or estrogen levels. The aim of this study is to investigate the possible effect of Vitamin E on adrenal and sex hormones in rabbits with hypercholesterolemia, as an animal model for the research.
Methods
The study was designed with 4 rabbits, 2 males and 2 females. High cholesterol diet was administered to all subjects for 13 days. When total cholesterol levels were $\geq$597 mg/dl high cholesterol diet was discontinued. We administered vitamin E 1000IU on the study group (1 female and 1 male rabbit, subject 1 and 2 respectively) for 30 days while female subject 3 and male subject 4 did not receive any supplement. Serum samples were tested at baseline when high total cholesterol levels were achieved and 2, 4, 5, 10, 20, 30 after vitamin E supplementation for total cholesterol, SGPT, gGT, estradiol, testosterone, cortisol and DHEA. The animals were then euthanized and were sent for histological examination.
Results
The initial measurements of liver enzymes were: SGPT = 50 IU/l for subject 1, 60 IU/l for subject 2, 47 IU/l for subject 3 and 56 IU/l for subject 4 and gGt = 16 U/l, 20 U/l, 17 U/l, 15 U/l respectively. After vitamin E supplementation SGPT values were 32 IU/l, 35 IU/l, 38 IU/l, 32 IU/l and gGt 6 U/l, 4 U/l, 5 U/l, 4 U/l for each subject respectively. Plasma morning cortisol levels at baseline were 45 mg/dl, 9.49 mg/dl, 1.33 mg/dl, 1.72 mg/dl demonstrating a wide variance in the subsequent measurements, reaching 754 mg/dl for subject 1 on the fifth day of vitamin E administration. Testosterone levels at baseline were 0.0636 ng/dl, 5.58 ng/dl, 0.0933 ng/dl, 5.53 ng/dl and after supplementation 0.0497 ng/dl, 7.49 ng/dl, 0.0783 ng/dl, 6.71 ng/dl. Interestingly, testosterone and DHEA levels increased acutely only in female rabbits, the first day after administration of vitamin E. Estradiol levels at baseline were 13 pg/ml, 8.47 pg/ml, 11.3 pg/ml, 13.2 pg/ml and after supplementation for 30 days 1.84 pg/ml, 11.7 pg/ml, 4.4 pg/ml 4.54 pg/ml.
Conclusions
Administration of high dose vitamin E in female rabbits with hypercholesterolemia increases testosterone and DHEA levels, but not estrogen levels. Further studies are needed to support or verify a claim.

Malignant mesenteric paraganglioma: a case report

Mohamed Samir Merad & Fatiha Mohammedi
Oran, Algeria Oran 1 Ahmed Ben Bella Medical University, Endocrinology and Diabetology departement -Larribere Clinic – university Hospital Dr Benzerdjeb, Oran, Algeria

Introduction
Paragangliomas are neuroendocrine tumors that develop from the paraganglia of the sympathetic and parasympathetic nervous systems. They are benign in approximately 80% of cases and are usually localized. However, in rare situations, they can be malignant, which is defined by the presence of tumor cells in nearby tissues or at a distance (metastases). Most parasymphathetic paragangliomas are located in the skull base and along the vagus and glossopharyngeal nerves, while the majority of sympathetic paragangliomas are found in the belly. Paragangliomas found in the mesentery are extremely rare.
Observation
A 44-year-old man with no previous pathological history arrived with widespread abdominal pain extending to the left shoulder. An abdominal CT scan revealed an intra-abdominal tissue mass, paramedian, on the right below the pancreas, measuring 86/74 mm, with multiple secondary adenopathies, the largest of which was 26 mm. The tumor could not be removed (inoperable tumor), and a biopsy revealed a malignant mesenteric paraganglioma, which is why it was referred to us for care. The patient's general condition was satisfactory, and he was normotensive with no other clinical symptoms suggesting multiple endocrine

neoplasia type 2. In the 24-hour ambulatory blood pressure test, the blood pressure profile was normal, and the ophthalmological examination was normal. Hormonal evaluation: 24-hour plasma and urine methoxylates are normal; calcitonin levels and phosphocalcic assessment are also normal. Extension exploration: a cervico-thoraco-abdomino-pelvic CT scan showed a well-limited (40×10×40 mm) polylobed mesenteric intraperitoneal development with a necrotic segment VII liver nodule measuring 14×13 mm and no bone lesions. MIBG scintigraphy was negative. The patient was later sent to the Oncology Department for combined follow-up, and chemotherapy was advised as palliative treatment.

Conclusion

Non-secreting mesenteric paragangliomas with malignant potential are commonly detected inadvertently and have a poor prognosis.

Norepinephrine-only secreting pheocromocytoma: case report

Elena Dragan
Reteaua Privata de Sanatate Regina Maria, Endocrinology, Bucharest, Romania

Introduction

Pheocromocytomas are catecholamine-secreting tumors that arise from cromaffin cells of the adrenal medulla, probably occurring in less than 0.2% of pacients with hypertension. The objective of this report is to describe a case of norepinephrine-only secreting pheocromocitoma.

Case description

A 43-year-old female pacient presented with hypertension, recent onset diabetes and right adrenal mass measuring 3.5×2.7 cm on a CT scan. Hormonal tests showed normal basal cortizol level, normal cortisol level after 1 mg Dexamethasone test, high levels of aldosterone and renin, elevated normetanephrine levels (12xN) with normal metanephrine levels, high levels of chromogranin A. The normal metanephrine levels with elevated normetanephrine may be a characteristic of VHL syndrome. Thyroid ultrasound, thyroid hormones levels, PTH, calcitonin were normal. Genetic testing for VHL syndrome was made, results being not available for now. The pacient was treated with alpha blockers for several days, the beta-blocking drug was added and she underwent total adrenalectomy. The histological + IHC report confirm benign pheocromocitoma. Postoperative, the pacient had complete resolution of symptoms with normal blood pressure and resolution of diabetes.

Conclusion

A pheocromocytoma is a rare catecholamine secreting tumor. About 30% of pheocromocytomas occur as part of hereditary syndromes. The characteristic of pheocromocytomas associated with VHL syndrome is normetanephrine-only secretion. Genetic testing is important because can set appropriate follow-up and surveillance.

A case of silent giant pheochromocytoma

Sofia-Maria Lider-Burciulescu[1,2], Cristina Stancu[3], Maria Anghel[3], Vlad Radulescu[3] & Corin Badiu[3,4]
[1]Carol Davila University of Medicine and Pharmacy, Endocrinology IV, Bucureşti; [2]"Ana Aslan" National Institute of Geriatrics and Gerontology, Endocrinology, Bucharest, Romania; [3]National Institute of Endocrinology, Endocrinology IV, Bucureşti; [4]Carol Davila University of Medicine and Pharmacy, Endocrinology, Bucureşti

Introduction

Pheochromocytoma is a rare tumor, representing a cause of secondary endocrine hypertension. Traditionally, prior to the widespread availability of imaging investigations, pheochromocytoma was diagnosed based on the triad: headache, palpitations and sweating. Diagnosis is crucial, as 40-50% of pheochromocytoma patients exhibit genetic mutations associated with multiple syndromes, such as MEN2 syndrome, succinate dehydrogenase enzyme mutations, neurofibromatosis type 1 and von Hippel-Lindau syndrome. Management inevitably involves surgery, preceded by appropriate α-blockade. Lifelong monitoring is necessary due to the risk of recurrence and malignancy.

Case description

We present the case of a 50-year-old Caucasian woman, smoker of 30 pack-years, diagnosed with hypertension in 2022 for which she is currently undergoing treatment with Perindopril/Indapamide 5/1.25 mg. The patient describes three hypertensive crises associated with stressful events and hyperhidrosis for the past 3 months. In november 2023 she underwent an abdominal CT scan that revealed a nodularly transformed right adrenal gland, with dimensions of 90/66/81.2 mm, featuring an iodophilic tissue component, cystic areas and several central necrotic areas, suggestive for a giant right adrenal pheochromocytoma. Upon examination, the patient has hyperpigmentation on the anterior thorax, intermittent headache and a blood pressure of 150/98 mmHg. Calcitonin is within normal range. Plasma metanephrines and normetanephrines present values of 1770 pg/ml (>23 UNL) and 4860 pg/ml (>31 UNL), respectively. Markers specific of neuroendocrine tumors are elevated, such as chromogranin A (981 ng/ml; >9.5 UNL) and neuronal specific enolase (19.8 mg/l; >1.5 UNL). Urinary metanephrines and normetanephrines have elevated values of 2600 mg/24 h (>8.5 UNL) and 3900 mg/24 h (>7 UNL), respectively. Urinary 5-HIAA has normal values. The mean blood pressure after ambulatory blood pressure monitoring is 122/80.2 mmHg. Based on these results, the patient underwent surgery after receiving treatment with phenoxybenzamine for 3 weeks. The histopathology report is pending as well as the RET gene analysis.

Discussion

This case describes the management of a patient with giant oligosymptomatic pheochromocytoma. The particularity of the case is given by the large dimensions of the tumor (9 cm) and the unusual clinical picture of the patient.

Caae report of rare hormonally active adrenocortical oncocytoma: two-year follow-up

Khatuna Chakvetadze[1] & tamar shervashidze[2]
[1]JSC Georgian Hospitals- Kutaisi Referral Hospital, Outpatient, Kutaisi, Georgia; [2]David Abuladze Clinic, Outpatient, Tbilisi

Introduction

Adrenocortical oncocytomas, made up of specific epithelial-origin cells, are rare neoplasms, generally without hormonal activity. Most of them are considered to be benign tumors, with the size of generally 4-8 cm and lack of pathognomonic radiological features.

Case Report

This is a 2 year follow up of a 43-year-old woman, who first referred to the endocrinologist in 2021 due to weight gain, resistant arterial hypertension and menstrual irregularities for several years. After 10-years of infertility 7-years ago she delivered a preterm healthy baby-girl. Physical examination revealed cushingoid characteristic features: dorsal cervical fat pad, moon facies, fragile skin and thin extremities. Cushing's syndrome was confirmed by an overnight 1-mg dexamethasone-suppression-test, an elevated free cortisol on a 24-hour urine collection, suppressed ACTH level and low DHEA-S level. Primary hyperaldosteronism was excluded by an oral salt loading test. Urinary metanephrines were normal. HBA1C-6.0%. Abdominal CT and MRI revealed left-sided adrenal heterogeneous lesion measuring 2.3×2.8×2.2 cm with a calcification focus in the periphery. She was also revealed small liver hemangiomas and NAFL-disease. In July 2021 the patient underwent laparoscopic left adrenalectomy. To prevent postoperative adrenal insufficiency, the patient was medicated with hydrocortisone. The operative adrenal gland measured 6×2.5×2.5 cm, with a nodule of 2.5×2.2×2.0 cm of well-defined limits, yellowish. The histological/immunohistochemical analysis revealed the diagnosis of adrenocortical neoplasm with predominance of oncocytic cells in solid-trabecular-structures (adrenocortical oncocytoma), having uncertain malignant potential. The doses of hydrocortisone were tapered slowly and stopped 3 months later. 6,12 and 24 months after surgery her cortisol, DHEA-S, electrolyte levels, HBA1C were normal, without any radiologic evidence of recurrence. In March 2023 she delivered a healthy baby-girl through C-section, without any gynecological or intraoperative complications. She is currently in follow up.

Discussion

Hormonally active adrenocortical oncocytomas are extremely rare tumors, about 17.0% of adrenal oncocytomas may have hormonal activity. By origin oncocytomas are epithelial-tumors composed of large eosinophilic cells, having mitochondria-rich cytoplasm and large nucleoli. The frequency of non-functioning oncocytomas is higher in females. The diagnosis of these neoplasms is mostly based on histological/immunohistochemical analysis. The Lin-Weiss-Bisceglia risk system is used to distinguish malignant oncocytic tumors, with major and minor criteria for differentiation. Small oncocytomas are commonly benign tumors, but in our clinical case oncocytoma expressed with Cushing's syndrome, with its two minor criteria (necrosis and capsular invasion), was classified as having uncertain malignant potential, thus suggesting important prognosis. Two-years close follow-up did not reveal any abnormalities.

EP1092

A rare association of salt-wasting congenital adrenal hyperplasia and type 1 diabetes mellitus

Ahmet Soyer[1], Hatice Aksu[1], Esma Ayrancl[1], Bilge Dibeklioglu[1], Sefika Polat[2], Oya Topaloglu[2], Reyhan Ersoy[2] & Bekir Cakir[2]
[1]Ankara City Hospital, Department of Endocrinology and Metabolism, Turkey; [2]Ankara Yildirim Beyazit University, Department of Endocrinology and Metabolism, Turkey

The co-occurrence of congenital adrenal hyperplasia and type 1 diabetes mellitus (T1DM) is a rare phenomenon in existing literature. The primary cause of congenital adrenal hyperplasia (CAH) is often 21-hydroxylase deficiency (21OHD), a condition associated with the CYP21A2 gene located on chromosome 6p21.3 within the major human leukocyte antigen (HLA) histocompatibility locus. Various gene polymorphisms, particularly in HLA-DQalpha, DQbeta, and DR genes on chromosome 6p21.32, are known to influence the risk of type 1 diabetes. Although the genetic loci for T1DM and 21-OH CAH are close, these conditions typically manifest independently, we present a case involving a man in his 20s who visited the emergency department with symptoms such as nausea, vomiting, headache, fatigue, and excessive sleepiness. This individual had a history of both classic salt-wasting congenital adrenal hyperplasia and type 1 diabetes mellitus. Over the past decade, the patient had experienced recurrent hospitalizations for diabetic ketoacidosis, with recent complications arising from the malfunction of an insulin pump due to technical issues. Initial treatment included insulin infusion, intravenous hydration, and an increased hydrocortisone dose. Once acidosis resolved, the patient transitioned to basal-bolus therapy and resumed insulin pump use. Carb counting was introduced, and dietary adjustments were made. An abdominal computed tomography scan revealed bilaterally thickened adrenal glands, and scrotal ultrasound detected an adrenal rest tumor. The patient was discharged with oral hydrocortisone (30 mg once daily), oral fludrocortisone (0.2 mg once daily), and continued use of an insulin pump. Repeated ketoacidosis episodes were potentially linked to hydrocortisone use, prompting consideration of a connection between T1DM and 21OHD, necessitating further investigation through additional studies.

Metyrapone treatment for mild autonomous cortisol secretion (MACS) - a case report

José Manuel Ruiz-Cánovas[1], Eider Pascual-Corrales[1,2], Estefanía Aracely Achote-Rea[1], Imanol Madrid-Egusquiza[1], María Noelia Sánchez-Ramírez[1], Cindy Anabel Idrobo-Zambrano[1], Carlos García-Regal[1], José María Jiménez-Cassinello[1], Arturo Vega-Beyhart[1] & Marta Araujo-Castro[1,2]
[1]Ramón y Cajal Hospital, Endocrinology and Nutrition, Madrid, Spain; [2]Instituto Ramón y Cajal de Investigación Sanitaria - IRYCIS, Madrid, Spain

A 68-year-old man with history of non-muscle-infiltrating bladder tumor and atrial fibrillation was referred to the Endocrinology Department in November 2020 for a functional study of a left adrenal incidentaloma. Furthermore, the patient had a history of arterial hypertension diagnosed at the age of 45 years, on treatment with 3 drugs (enalapril 20 mg B.I.D., amlodipine 5 mg B.I.D., hydrochlorothiazide 12.5 mg/day), achieving usual blood pressure (BP) levels of 150/90 mmHg. At the first evaluation (November 2020) in the Endocrinology Department, headaches, frequent palpitations and non-weight gain in recent years were reported, BMI of 26 kg/m2 and no specific clinical data of hypercortisolism. Functionality study was requested, after replacing antihypertensive medication for at least 4 weeks with doxazosin 4 mg, obtaining the following results: plasma ACTH <3.8 pg/mL (normal range 7.7-48.8); serum basal cortisol 18.7 mg/dl (normal range: 3.7-19.4); urinary free cortisol (UFC) 75.00 mg/24 h (normal $<$ 140); Late-night salivary cortisol 4.62 nmol/l ($<7,56$); Cortisol after suppression with 1 mg of Dexamethasone 7.10 mg/dl. Aldosterone/renin ratio and metanephrines were normal. HbA1c was 6.1%. In September 2020, non-enhanced CT scan has showed radiological stability of the adrenal lesion with respect to 2018 imaging tests: 41x37mm, oval, sharp-edged, heterogeneous, with majority component of low-density value, compatible with lipid-rich adenoma. The study was extended to norcholesterol scintigraphy, and the findings were consistent with hyperfunctioning left adrenal adenoma. The patient refused adrenalectomy, opting for conservative management. During follow-up, home BP values were around 150/90 mmHg. Glycemic control worsened, HbA1c increasing over 6.5%. Treatment with metformin/empagliflozin was initiated. No osteopenia/osteoporosis was detected. Given patient's refusal of surgery and coexistence of two comorbidities potentially associated with hypercortisolism, one of them poorly controlled, metyrapone treatment (currently off-label) following the Debono protocol was proposed. Upon approval by the hospital pharmacy, metyrapone was started at a night dose of 250 mg. After 2 weeks, BP improved notably, reaching 120/70 mmHg, and amlodipine was suspended. Metyrapone night dose was increased to 500 mg and BP continued falling, so enalapril was discontinued. After 3 months on treatment, pathology tests showed basal cortisol at 15.7 mg/dl; UFC at 31.20 mg/24 h; Late-night salivary cortisol at 3.18 nmol/l ; HbA1c at 6.6%. No secondary side effects were developed. We can conclude that metyrapone is a useful and safe treatment for patients with MACS and associated comorbidities, offering a better control of hypertension.

EP1094

Subclinical hypercortisolism revealed by a resistant hypertension

Nouhaila Essafir, Nada Ait Kassi & Anas Guerboub
Military Hospital Mohammed V Rabat, Endocrinology

Introduction
Hypercortisolism is considered to be a rare condition with an estimated incidence between 0.4 and 2.4 cases per million per year, typically manifests as the clinically and biochemically evident Cushing's syndrome. However, a more subtle form, known as subclinical hypercortisolism (SH) or autonomous cortisol secretion (ACS), poses diagnostic challenges. It is defined as excessive cortisol secretion without the classic manifestations of clinically overt Cushing syndrome.
Case presentation
We report the case of a 33-year-old female patient, who has been followed for secondary amenorrhea, dyslipidemia, and hypertension since the age of 24, controlled with a triple therapy. Given the secondary nature of hypertension, a CT scan was performed, revealing a right adrenal mass measuring 38x19mm with a spontaneous density of 25 HU. A secretory assessment was conducted: 24-h urinary fractionated metanephrines and vanillylmandelic acid levels were measured ruling out pheochromocytoma. Plasma aldosterone/renin ratio was examined to exclude primary aldosteronism. Regarding hypercortisolism, 24-hour urine free cortisol levels were normal. Additionally, the cortisol circadian rhythm was disrupted with a value of 265 ng/ml. The standard dexamethasone suppression test showed an elevated morning cortisol level at 221 ng/ml (**not suppressed**). The morning plasma ACTH concentration was low, less than 3 ng/l. The diagnosis of cortisol adenoma was made, hence the indication for adrenal surgery.
Conclusion
Subclinical hypercortisolism is a relatively newly discussed and understood disease. Unfortunately, it is highly **under-diagnosed** and **under-treated**. Subclinical Cushing's syndrome is described as 'hidden hypercortisolism' since it is typically asymptomatic. Even though, the condition still leads to long-term consequences of cortisol excess (**hypertension, type 2 diabetes, hyperlipidemia and osteoporosis**). The timely diagnosis of such cases allows for appropriate management and prevention of associated complications.

Adrenal insufficiency revealing multifocal tuberculosis

Meryam Alahyane, Sana Rafi, Manar Bari, Ghizlane El Mghari & Nawal El Ansari
Mohammed VI university hospital of Marrakesh, Department of Endocrinology, Diabetes, Metabolic diseases and Nutrition, Marrakesh, Morocco

Background
Multifocal tuberculosis is defined as the involvement of at least two extra-pulmonary sites, with or without pulmonary involvement. The most commonly involved endocrine organ is the adrenal gland. We report a case of adrenal insufficiency revealing multifocal tuberculosis.
Case report
A 65 year old female patient with no context of immunosuppression, presented to emergency department with Consciousness disturbance associated with severe hyponatremia, revealing a primary adrenal crisis confirmed with low plasma cortisol and high ACTH levels. Computed tomography (CT) revealed Bilateral adrenal masses with calcifications measuring 20 mm and 16 mm for the left and the right mass respectively. Both have a spontaneous density of 33 UH, and absolute wash of 27% and 11%. CT chest revealed micronodules in the posterior upper lobe of the left lung, multiple calcification zones and mediastinal lymph nodes. The patient presented also a skin temporal lesion, having the clinical

presentation of tuberculosis lupus. The biopsy showed a giant epithelioid cell granuloma without caseating, with a positivity of Gene-Xpert. HIV serology and viral hepatitis were negative The diagnosis of multifocal tuberculosis including pulmonary, adrenal and skin localisation was established. The symptoms of primary adrenal insufficiency gradually subsided after the initiation of Hydrocortisone replacement in addition to antituberculous therapy.
Discussion
Although autoimmune adrenalitis is the most common cause of primary adrenocortical insufficiency, Tuberculous Addison's disease (TAD) is still common particularly in endemic countries. This condition could be inaugurated by an Addisonian crisis, as it is the case for our patient. Tuberculosis may directly involve the adrenal glands which classically appears after more than 90% of the adrenocortical destruction by tuberculosis. Following Hematogenous and lymphatic dissemination, the adrenal localisation is often not apparent for as many as 10 years after tuberculosis infection. Generally, in the early and active stages of tuberculosis, adrenal glands are enlarged, while long-term disease will have small, atrophic adrenals, and calcification due to degeneration process. Multifocal tuberculosis is a severe form of the disease, usually affecting immunocompromised individuals who already have a pulmonary localization. However, it can also affect immunocompetent subjects with or without pulmonary involvement. It is therefore necessary to systematically carry out an exhaustive assessment of the dissemination of the tuberculosis germ, in order to improve the disease management. Prognosis is often favorable, depending on the type of the disease localisation and the early initiation of anti-tuberculosis drugs.

The complex intersection of congenital adrenal hyperplasia, antiphospholipid syndrome, and infertility: a successful pregnancy journey

Aiste Cemerkaite & Vita Lizdeniene
Lithuania, Lithuanian University of Health Sciences Kaunas Clinics, Kaunas, Lithuania

Congenital Adrenal Hyperplasia (CAH), a genetic adrenal gland disorder, can disrupt hormonal balance, leading to fertility issues in females. Timely interventions, like hormone therapy, are essential for managing fertility concerns and ensuring a safe pregnancy for individuals with CAH. A 28-year-old patient consulted an endocrinologist for a detailed examination due to infertility issues persisting for 2 years. Prior to this, the patient had given birth to a 22-week-old newborn who died within the first day due to infection. During the investigation of infertility causes, 17-OH was incidentally tested despite the absence of hyperandrogenism symptoms (regular menstrual cycle, no hirsutism, no acne). A significantly elevated 17-OH level was found (63.81 nmol/l). Suspecting congenital adrenal hyperplasia, a Synacthen test was performed, but the diagnosis was ruled out (Synacthen test results: 17-OH 0' 11.9 nmol/l, 30' 11.8 nmol/l, 60' 9.06 nmol/l). The patient consulted with a geneticist, and two pathogenic variants of the CYP21A2 gene were identified. Upon repeating the Synacthen test, CAH was diagnosed (Synacthen test results: 17-OH 0' 37.3 nmol/l, 30' 154 nmol/l, 60' 199 nmol/l). Treatment with dexamethasone 0.25 mg/p was prescribed, assisted fertilization was recommended, and the male partner was advised to undergo CYP21A2 mutation screening (not detected). The patient underwent intrauterine insemination, but it was unsuccessful: at 13 weeks, a single embryo reduction was performed, and at 17 weeks, there was a miscarriage of the second fetus. Two days later, with no remaining fetal cardiac activity, an abortion was performed. After the unsuccessful pregnancy, the patient was reevaluated by a geneticist, and antiphospholipid syndrome was confirmed (anti-cardiolipin antibodies (IgM) - 99.96). The patient underwent a second intrauterine insemination and one successfully implanted. Due to CAH, dexamethasone was discontinued, and hydrocortisone 5 mg was started three times a day. Aspirin and low-molecular-weight heparin were prescribed for antiphospholipid syndrome. During pregnancy, the patient consulted with a geneticist again, and it was assessed that the risk of CAH for the fetus was minimal (the fetus is an obligate carrier of one pathogenic variant of the CYP21A2 gene). Chromosomal anomaly testing (PRISCA) was performed with low-risk results. A healthy male newborn was delivered via cesarean section at 38 weeks (APGAR 9). Stress doses of hydrocortisone were administered during delivery, and the postoperative period was uneventful. In conclusion, despite complexities involving congenital adrenal hyperplasia, antiphospholipid syndrome, and infertility, a multidisciplinary approach, including genetic consultations, resulted in the successful delivery of a healthy newborn.

EP1098

Testosterone producing adrenal cortical carcinoma in a post-menopausal woman

Mitra Moazzami, Melanie Lyden & Irina Bancos
Mayo Clinic, Rochester, United States

Introduction
In post-menopausal women, the differential diagnosis of hirsutism caused by testosterone excess includes ovarian and adrenal sources. Bilateral ovarian hyperthecosis is a common cause of testosterone excess in post-menopausal women and the diagnosis is confirmed by histopathological examination of the ovaries. Adrenal tumors causing testosterone excess is exceedingly rare. In fact, most causes of hirsutism secondary to adrenal tumors is due to dehydroepiandrosterone sulfate (DHEAS) and androstenedione excess. Further, the median tumor size of an adrenal cortical carcinoma (ACC) is 10 cm. We present a case of a post-menopausal women with ACC of 1.2 cm with testosterone excess.
Case report
A 60-year-old female presented to the clinic in October 2023 with a two-year history of isolated hirsutism. In September 2022 patient had investigations showing an elevated serum testosterone (172 ng/dl), a normal dehydroepiandrosterone sulfate (DHEAS) of 68 mg/dl, and a normal androstenedione 78 ng/dl. Her local endocrinologist recommended bilateral oophorectomy. Surprisingly, after the oophorectomy, her testosterone levels did not drop (testosterone 138 ng/dl). Pathology of the ovaries were normal. Computed Tomography (CT) of abdomen done showed 1.2 cm right adrenal nodule with unenhanced density of 20 Hounsfield units (HU) and a normal left adrenal. Contrast washout characteristics showed an absolute washout of 61.6% and relative washout of 51.7%. Subsequently, the identified source of testosterone production was suspected to be associated with the adrenal mass. The patient was treated with a right laparoscopic adrenalectomy. Post-operatively, testosterone concentrations dropped. Ultimately, the pathology had features of low-grade ACC which included 6 mitotic figures/50 high power fields (HPFs), Ki-67: 5.13%.
Conclusions
We describe a patient with a testosterone-secreting adrenal mass with findings consistent with a low-grade ACC. The workup of a post-menopausal women with hyperandrogenism includes androgen secreting ovarian or adrenal tumors, Cushing's syndrome or iatrogenesis. The adrenal cortex produces the androgens: DHEAS, androstenedione, and a small amount of testosterone. When only the testosterone level is elevated, it typically indicates an ovarian source. Therefore, isolated elevation of testosterone is rarely due to an adrenal source. Further, most cases of testosterone producing adrenal masses are benign. Moreover, the median size of an ACC is usually 10 cm. Therefore, finding an ACC of 1.2 cm that exclusively secretes testosterone is very rare. This highlights the importance of considering adrenal sources of isolated testosterone secretion.

Gonadal impact of congenital adrenal hyperplasia in adulthood: a follow-up study

Hamdi Frikha[1], Yassmine Abdelkafi[1], Nesrine Dhieb[1], Mouna Elleuch[1], Mahdi Kamoun[1], Thouraya Kamoun[2], Mongia Hachicha[2], mouna mnif[1], Habib Sfar[3], Mohamed Abid[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology; [2]Hedi Chaker University Hospital, Department of Pediatrics; [3]Tahar Sfar University Hospital, Department of Endocrinology

Introduction
Advances in diagnosis and treatment over the years have improved the life expectancy and quality of life for individuals with congenital adrenal hyperplasia (CAH). The inevitable alteration of the hypercortisolism-hyperandrogenism balance with current CAH therapy could be responsible for several anomalies in the gonadotropic axis and compromise fertility. This study aims to investigate this aspect in an aging Tunisian population of patients with CAH.
Methods
A retrospective and descriptive study was conducted on patients with CAH followed at the endocrinology department of Hedi Chaker University Hospital in Sfax.
Results
Twenty-six patients (11 men and 15 women; mean age: 27.4 $\pm$ 8.2 years) were recruited. Evaluation of gonadal function in male subjects showed preserved

Leydig function (Testosterone 5.23 ± 2.34 ng/ml; LH 2.8 ± 1.3 mUI/ml), Sertoli axis abnormalities in 50% of patients (Inhibin B 117.7 ± 75.2 pg/ml), and spermatogenesis abnormalities (Azoospermia = 2, oligoasthenospermia = 1, oligo-astheno-teratospermia = 1). Furthermore, adrenal rest tissue in the testicular tissue (TART) was observed in 6 patients with an ultrasound appearance of vascularized hypoechoic areas. In female subjects, hormonal exploration did not reveal ovarian dysfunction; however, a decrease in follicular reserves, evidenced by a low AMH level, was found in 33% of patients. Additionally, 6 out of 15 patients met at least two diagnostic criteria for polycystic ovary syndrome (PCOS). While infertility was present in only one patient, we observed 4 spontaneous pregnancies in 2 of our patients, resulting in the birth of 2 female newborns without genital anomalies.

Conclusion

The data from our series align with literature findings, although studies on aging CAH populations are infrequent. This underscores the importance of regular monitoring of gonadotropic function in both sexes, especially for the occurrence of TART in men and PCOS in women, which may compromise fertility.

Cardiovascular and cerebrovascular burden associated with primary aldosteronism: a monocentric study

Siddiqa Soomauroo[1], Faten Hadjkacem[1], Abdelmuhaymen Missaoui[1], Ahmad Ridwaan Auckburally[2], Souhir Maalej[1], Wiem Feki[2], Zeinab Mnif[2], Mouna Mnif[1], Mohamed Abid[1] & Nabila Rekik[1]

[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Department of Radiology, Sfax, Tunisia

Introduction

Primary aldosteronism (PA) is commonly identified as the main cause of secondary hypertension. It is becoming increasingly wide-spread, affecting between 1 and 30% of people suffering from hypertension. A prolonged exposure to high aldosterone concentrations has a deleterious effect on cardiovascular tissues and is associated with target organ damage, independently of blood pressure, so a higher risk of cardiovascular events has been reported in patients with primary aldosteronism,

Aim

The aim of this study was to evaluate the prevalence of cardiovascular and cerebrovascular events in patients with PA.

Patients and methods

Retrospective and descriptive study concerning 40 patients with PA, collected in the endocrinology department of the Hedi Chaker University Hospital of Sfax, over the period of 10 years from January 2010 to December 2022.

Results

The average age of our patients was 55.4 years. Fourteen patients had cardiovascular disease consisting of electrical left ventricular hypertrophy and/or hypertrophic cardiomyopathy on transthoracic echocardiogram and/or coronary artery disease. Four patients had cerebrovascular ischemic stroke. Analytical study showed that there was no significant statistical difference between plasma aldosterone concentration (PAC) in patients with and without cardiovascular disease (median PAC = 226 pg/ml vs 199 pg/ml; $P = 0.856$). Similarly, the PAC was higher in patients with cerebrovascular disease but the difference was not significant (median PA: 337 pg/ml vs 207 pg/ml; $P = 0.223$). Twelve out of 40 patients (30%) with cardio and/or cerebrovascular disease had PAC above 200 pg/ml. The evolution of the cardiovascular risk after specific treatment of PA was not carried out in our study.

Conclusion

In addition to the classic role of aldosterone, which acts via the reabsorption of water and sodium in the kidney to induce volume expansion, several studies have shown that aldosterone has direct effects on the vascular system, even in the absence of hypertension. A recent meta-analysis of 31 studies demonstrated that patients with PA had an increased risk of stroke, coronary heart disease and heart failure compared with essential hypertension.

Giant adrenal masses during congenital adrenal hyperplasia: a case report

Hamdi Frikha, Oumeyma Trimeche, Wiem Gherissi, Dhoha Ben Salah, Khouloud Boujelben, Fatma Mnif, Mouna Mnif, Mohamed Abid & Nabila Rekik Majdoub

Hedi Chaker University Hospital, Department of Endocrinology

Introduction

Congenital adrenal hyperplasia (CAH) in its classical form is an early-onset and challenging-to-treat condition with long-term evolution associated with significant morbidity, typically involving metabolism, bone, and gonadal aspects. Through this specific case study, we illustrate one of the rare complications of CAH in adulthood.

Case Report

A 24-year-old patient, born of consanguineous parents, has been monitored since birth for classical virilizing CAH. The patient is treated with suppressive doses of dexamethasone, but due to poor treatment adherence, the disease remains in chronic imbalance (17OHP consistently > 15 ng/ml). An abdominal CT scan conducted to investigate abdominal pain revealed two large bilateral adrenal masses measuring 6 cm (right) and 5.8 cm (left) with loss of the fatty rim. Hormonal assessment did not reveal hormonal hypersecretion. Functional imaging with PET-FDG showed no increased metabolism in relation to the masses, and the extension study was negative. A right adrenalectomy was performed, and pathological examination revealed a benign-looking tumor. Evaluation at 3 months postoperatively showed persistent disease imbalance (17OHP = 57 ng/ml and ACTH > 2000 pg/ml) with a 40% increase in the size of the left adrenal confluent tumor.

Discussion

This case illustrates an unusual complication of CAH with a long course. Prolonged exposure to excess ACTH appears to be the primary etiopathogenic factor for adrenal tumorigenesis in the context of CAH. Malignant transformation and the simultaneous presence of two masses of different histological and functional nature are situations rarely described in the literature but remain plausible in our patient given the rapid increase in size. This concern highlights the importance of careful monitoring.

Clinical features and complication profile of arterial hypertension in patients with primary aldosteronism

Siddiqa Soomauroo[1], Faten Hadjkacem[1], Abdelmuhaymen Missaoui[1], Ahmad Ridwaan Auckburally[2], Souhir Maalej[1], Wiem Feki[2], Zeinab Mnif[2], Mouna Mnif[1], Mohamed Abid[1] & Nabila Rekik[1]

[1]Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Department of Radiology, Sfax, Tunisia

Introduction

Primary aldosteronism (PA) is frequently recognized as the main cause of secondary hypertension. Its prevalence is on the rise, impacting a range of 1 to 30% among individuals with hypertension.

Patients and methods

Retrospective and descriptive study concerning 40 patients with PA, collected in the endocrinology department of the Hedi Chaker University Hospital of Sfax, over the period of 10 years from January 2010 to December 2022.

Results

The average age of our patients was 55.4 years. Among the 40 patients, 39 (16 men and 23 women) presented with hypertension. In 32% of cases, the hypertension was recent, evolving for less than 5 years. Severe hypertension was found in 11 cases and resistant hypertension in 4 others. Ten patients (25.6%) were on at least a triple anti-hypertensive therapy. The therapeutic classes most used were calcium channel blockers prescribed in 25 cases (64.1%), followed by ACE inhibitors in 12 cases (30.8%). The assessment of target organ damage revealed hypertensive retinopathy ($n = 4$), hypertensive cardiopathy ($n = 8$), microalbuminuria ($n = 26$), proteinuria ($n = 3$) and renal failure ($n = 8$). In our study, we noted a statistically significant reduction of antihypertensive drugs in 36 patients who had received treatment, whether by surgery or spironolactone ($P = 0.001$).

Conclusion

Sodium and water retention constitute the primary pathophysiological mechanism behind the elevation of blood pressure in PA. This hypervolemia, combined with other factors, accounts for the nearly constant presence of hypertension in patients with PA. This type of hypertension has no particular semiological features. Its severity is not perfectly correlated with the degree of hyperaldosteronism whereas the prevalence of PA is correlated to the degree of severity of hypertension. Some

studies have reported a prevalence of PA that may exceed 20% in cases of resistant hypertension.

Clinical and biological study of adrenal incidentaloma

Hayfa Farid[1], Taieb ACH[1,2], Asma Ben Abdelkarim[1,2], Hamza Elfekih[1,2], Yosra Hasni[1,2], Amel Maaroufi[1,2] & Molka Chedli Chaieb[1,2]
[1]Farhat-Hached University Hospital, Department of Endocrinology and Diabetology, Sousse, Tunisia; [2]Faculty of Medicine of Sousse, University of Sousse, Tunisia

Introduction
The adrenal incidentaloma is an asymptomatic tumor measuring at least one cm, discovered incidentally during a medical imaging examination. The adrenal incidentaloma continues to grow with technological advances and improved radiological examinations. Any adrenal incidentaloma involves the search for a secretion or malignant character. The objective of our study is to study the clinical, biological and etiological aspects of adrenal incidentalomas.
Patients and Methods
This was a retrospective, descriptive study carried out in an Endocrinology department, on records of patients in whom an adrenal incidentaloma has been discovered. The following parameters were identified: Clinical and biological presentation, etiological profile, diagnosis and therapeutic means.
Results
Our study covered 22 patients: 2 men and 20 women, aged between 29 years and 76 years with an average of 52 ± 14 years. Family history in these patients was familial hypertension in 18 patients (81.8%), 3 had a history of early stroke and 1 had a history of myocardial infarction. Beyond them, 6 patients had type 2 diabetes with an average duration of 4 ± 3 months. Only one patient was smoking and only one was dyslipidemic under statin. Hypertension was found in 12 patients (54.5. Of these patients, 4 had a refractory hypertension (18.2%), 2 had a malignant hypertension (9.1%). The mean systolic blood pressure was 16.1 ± 2.1 mmHg and the average diastolic blood pressure was 9.1 ± 1.3 mmHg. The mean weight of the population was 79.8 ± 15.06 Kg, the mean size of 159.19 ± 7.6 cm, an average BMI of 31.13 kg/m^2; and an average waist of 105 ± 26.6 cm. Biologically, the mean blood glucose was 6.57 mmol/l, the mean serum potassium level was 3.8 ± 0.57 mmol/l. 10 patients had proven hypokalemia. An adrenal-centered scan showed an incidentaloma of an average size of 21.5 ± 19.21 mm. The etiologic diagnosis was a pheochromocytoma in 7 patients (31.8%) attested by an elevation of the metanephrine blocks, clinical and biological hypercorticism in 9 cases (27.3%) including 6 adenomas, 1 case Of adrenal cortex and 2 cases of bilateral adrenal hyperplasia, 4 cases of primary hyperaldosteronism (18.2%). 2 patients had no hormonal secretion. For etiological treatment, 18 patients had unilateral adrenalectomy in (81.8%). 4 patients received medical treatment (18.2%).
Conclusion
The adrenal incidentaloma continues to grow with technological advances and increased abdominal radiological examinations. In the majority of cases, it will be a non-secreting benign adenoma. However, the clinician must ensure that there is no disease requiring specific management by performing a baseline hormonal assessment.

Clinical case: manifestation of primary adrenal insufficiency in Addison's crisis

Justina Bieliauskienė
Lithuania University of Health Sciences, Hospital of Lithuanian University of Health Sciences, Kaunas clinics, Endocrinology department, Kaunas, Lithuania

Introduction
An Addison's crisis is a life-threatening situation that usually results hypotension/hypovolemic shock, nausea or vomiting, fever, loss of consciousness, hyponatremia (Na ≤ 132 mmol/l), hyperkalemia and hypoglycemia.
Case description
33 years old patient was found at home after firefighters broke down the door, with a lot of stomach contents around. The last contact with relatives was a day ago, when the patient complained of fever and vomiting. The patient was unconscious, hypotensive (BP 72/48mmHg), glycemia 5.2 mmol/l, hyperkalemia 6.5 mmol/l, normonatremia 137 mmol/l, increased uremic indicators (creatinine concentration in serum 1439 mcmol/l ; urea 29.3 mmol/l), increased CRB 284.8 mg/l, elevated creatine kinase activity 981 IU/l was found. CT of the head, Ro of the lungs, ultrasound of the abdomen - without changes, and neuroinfection was ruled out. The patient was hospitalized in the intensive care unit, treatment with dexamethasone, infusion and antibiotic therapy was started. Renal replacement therapy was started due to significant uremic indicators. Hyperpigmentation of the patient's skin was observed, so primary adrenal insufficiency was suspected, ACTH was 6.7 pmol/l (n. 1.63 - 14.15 pmol/l) and cortisol in the morning was 25.7 nmol/l (less than 12 hours after dexamethasone injection). After the hypovolemic shock regressed, without administering glucocorticoids for 2 days, the tests were repeated: ACTH - 374.5 pmol/and cortisol - 56.91 nmol/l - primary adrenal insufficiency was confirmed and continuous treatment with hydrocortisone was started, gradually reducing the doses to maintenance doses. In case of a tendency to hyponatremia and hypotension, fludrocortisone was added to hydrocortisone. Renal function and electrolyte imbalance were fully restored, inflammatory indicators normalized. The patient tested for other autoimmune diseases - confirmed chronic autoimmune thyroiditis with euthyroidism. Anti-GAD and anti-IA2 were also positive, but there are currently no data for diabetes. The autoimmune polyglandular syndrome (APS-2) was diagnosed.
Conclusion
In untreated Addison's disease, stress such as trauma, infection, or illness can lead to an Addison's crisis. Immediate treatment with intravenous hydrocortisone is recommended for patients with suspected adrenal crisis without waiting for test results.

Adrenal fusion during renal transplantation: A challenging situation

Rania Dassoufi[1], Eleazar Nyogushima[2], Sana Rafi[2], Ghizlane El Mghari[2] & Nawal El Ansari[2]
[1]CHU Mohamed VI, Endocrinology, Marrakech, Morocco; [2]CHU Mohamed VI, Endocrinology, Morocco

Introduction
Adrenal-renal fusion is a rare entity wherein the capsule of the adrenal gland is fused to the kidney. Generally asymptomatic, it is only in pathological situations or in cases of adrenal or renal resection that this situation can cause problems. Adrenal transplantation has long been studied in rats solely to treat adrenal insufficiency, but no cases of accidental transplantation have been reported. Here, we report a case of adrenal-renal fusion making intraoperative dissection challenging, followed by a renal transplant including adrenal tissue.
Observation
We consulted a 17 years old and obese patient in the nephrology department at Day 1 post renal transplantation with a history of nephropathy for 1 and a half year undergoing haemodialysis at a rate of 2 sessions per week for chronic interstitial nephritis, c complicated by hypertension He received a renal transplant from his sister, complicated peroperatively by the fortuitous discovery of adrenal adhesion to the renal capsule, adrenal tissue was left on the kidney subsequently grafted to the recipient with anastomosis of the graft to the external iliac artery and external iliac vein. Post-operative follow-up was marked by isolated hyperglycemia at 3 g/dl, followed by normoglycemia at daily follow-up. He was put on immunosuppressive prednisolone in decreasing doses up to 50 mg/d, which he is currently taking.
Discussion
Transplantation of adrenal cells is similar to that of a small malignant tumor. Unless it achieves vascularization it will die or remain very small. It is imperative to use a source of a potent angiogenic factor such as FGF 3T3 secreting cells. Overall, in an intact human body, the accidental transplantation of adrenal tissue without preparation or growth factors seems to be doomed to apoptosis.

Modified classification of autoimmune adrenal insufficiency

Nurana Nuralieva, Marina Yukina & Ekaterina Troshina
Endocrinology Research Centre, Moscow, Russian Federation

Objectives
to modify the classification of autoimmune adrenal insufficiency (AAI).
Methods
$n = 8$ patients with early stages (potential and latent) of AAI were included (table 1).
Results
Based on the analysis of clinical and laboratory data of patients, a modified classification of AAI has been developed (table 2).
Conclusion
It is recommended to introduce a modified classification of AAI in clinical practice.

Simultaneous papillary and medullary thyroid carcinoma, primary hyperparathyroidism and ACTH-independent Cushing syndrome- an intriguing puzzle of endocrine disorders

Ana-Iolanda Badita[1], Simona Jercalau[1], Andrei Goldstein[1], Andreea Marcu[1], Oana Stanciulea[2], Anda Dumitrascu[1], Larisa Buduluca[1] & Corin Badiu[1]
[1]C.I. Parhon National Institute of Endocrinology, Bucuresti, Romania; [2]Fundeni Clinical Institute, Bucharest, Romania

Case presentation
A 67-year old diabetic and hypertensive female, with no significant family history, first underwent total thyroidectomy, with a histological and immunohistochemical result of both papillary thyroid carcinoma (PTC) T3Nx stage III and medullary thyroid carcinoma (MTC), with additional radioiodine treatment for PTC, showing excellent response to therapy at follow-ups (stimulated thyroglobulin <0.2 ng/ml, normal CEA and calcitonin). Almost 10 years later, the patient presented for the first time with elevated total serum calcium (12.5 mg/dl) and elevated PTH (82.2 pg/ml). A 99mTc-pertechnetat/99mTc-sestamibi scintigram was performed, showing a left superior parathyroid adenoma, for which she underwent parathyroidectomy, with constant normal PTH and total serum calcium after surgery. At that point, a thorough laboratory and genetic examination was performed. Pheochromocytoma was not confirmed. Screening for genetic mutations of the RET gene for exons 5, 8, 10, 11, 13, 14, 15 and 16 were all negative. Unfortunately, sequencing the entire RET coding region was not possible. During this extensive endocrine evaluation, an abnormal overnight 1 mg dexamethasone suppression test (13.4 mg/dl) raised the possibility of an associated Cushing syndrome. A low ACTH level (1.7 pg/ml) and an elevated midnight plasma cortisol (7.9 mg/dl) confirmed the ACTH-independent Cushing syndrome. The abdominal computed tomography (CT) showed bilateral macronodular adrenal hyperplasia. Adrenal vein sampling not being available at that time in Romania, we carried on with initial left adrenalectomy (being the largest of the two glands). At 6 months postoperative, the patient presented with persistent hypercortisolemia: ACTH = 14.9 pg/ml, basal plasma cortisol = 19.95 mg/dl, midnight plasma cortisol = 9.2 mg/dl, overnight 1 mg dexamethasone suppression test cortisol = 10 mg/dl. The patient had a second adrenalectomy and received prompt glucocorticoid (GC) and mineralocorticoid (MC) substitution. Interestingly, the patient's main complaint was persistent proximal muscle weakness, with persistent cushingoid features, persistent diabetes and hypertension. After gradual withdrawal of GC substitution, a high-dose Synacthen test confirmed residual endogenous glucocorticoid secretion (cortisol at $30' = 27$ mg/dl, $60' = 32$ mg/dl) with a normal 2×2 mg dexamethasone suppression test (0.95 mg/dl). The abdominal CT described an 8 mm nodule most likely a residue of the right adrenal gland.
Conclusion
Our case portrays an interesting association of ACTH-independent Cushing syndrome with normal endogenous cortisol secretion after bilateral adrenalectomy in a patient with prior PTC, MTC and primary hyperparathyroidism (a suspected MEN type 2A without genetic confirmation)- a constellation of rather rare endocrine disorders showcasing the importance of in-depth genetic studies.

Demographic, clinical, and paraclinical features of patients with adrenal incidentaloma

Mariam Mabrouk, Arige Abid, Oueslati Ibtissem, Elyes Kamoun, Faten Cherchir, Meriem Yazidi & Chihaoui Melika
RABTA Hospital, Endocrinology, Tunis, Tunisia

Introduction
Adrenal incidentalomas (AI) are adrenal masses detected on imaging performed for reasons other than suspected adrenal disease. It is important to categorize whether the mass is a functioning or non-functioning incidentalomas to determine the appropriate management and follow-up. The aim of this study was to assess demographic, clinical, and paraclinical features of patients with AI.

(Abstract EP1165) Table 1. Characteristics of patients

An additional diagnostic criterion. It is advisable to conduct the study only in women aged 18-40 years.[2]
At the onset of the disease.[3]
With a long course of the disease.

Methods
This was a monocentric retrospective study including 155 patients with adrenal incidentaloma (AI) followed up at the department of endocrinology of la Rabta university hospital in Tunis between 2015 and 2022. Clinical and paraclinical data were collected from patients medical files. Patients with missing data were excluded.
Results
There were 103 women and 52 men with a sex-ratio of 1.98. The mean age at the diagnosis was 52 + 12.7 years (range: 20-84). Past medical history included obesity (8.8%), hypertension (53.5%), diabetes (11.8%), dyslipidemia (5.3%), and urolithiasis (4.1%). AI was unilateral in 80.6% of cases (56.2% on the right) and bilateral in 11.6% of cases. The mean initial size at diagnosis was 21.4 ± 16.8 mm (range: 7 – 130). The AI size was ≥ 40 mm in 7% of cases. AI were homogeneous in 80% of case. The mean spontaneous density value was 9.5 HU (interquartile interval: -2 and 14). Endocrine investigation revealed that 47.7 % of patients had nonfunctional tumors, 35.5% had primary hyperaldosteronism, 11.6% had Cushing's syndrome, 4.5% had pheochromocytoma, and 0.6% had coexisting autonomous cortisol secretion and pheochromocytoma. Bilateral AI (17.6% vs 6.2%, $P=0.027$, Odds Ratio = 3.23, 95%-confidence interval: 1.09-9.58) and heterogeneous tumors (26% vs 8.6%, $P=0.004$, Odds Ratio: 1.73, 95% confidence interval: 1.27-2.36) were more frequently functional than unilateral and homogeneous ones.
Conclusions
Our results showed that AI were more frequent in women than in men. They were unilateral, homogeneous, measuring less than 40 mm, and functional in the majority of cases. It is therefore important to explore all adrenal incidentalomas for an appropriate management.

Testicular adrenal rests in a patient with congenital adrenal hyperplasia: a case report and literature review

Hind Ouakrim, Fatiha Ettalibi, Sana Rafi, Ghizlane El Mghari & Nawal El Mghari
Chu Mohamed Vi Marrakesh - Drh, Marrakech, Morocco

Introduction
Congenital adrenal hyperplasia (CAH) is a group of rare inherited autosomal recessive disorders, CAH is caused by a mutation in the CYP21A2 gene that leads to a deficiency of 21-hydroxylase (CYP21), due to CYP21A2 gene mutations. Testicular adrenal rest tumors (T-ARTs) is a rare kind of benign tumor in the testis, which occurs mainly secondary to congenital adrenal hyperplasia (CAH). We report a rare case of bilateral TART in a patient with CAH whose diagnosis was revealed by precocious puberty.
Case report
The 7-year-old patient was referred to early puberty. Clinical examination revealed advanced stature, and Tanner stage G5P5. Additionally, a heterogeneous mass in the left testicle was identified. The bone age was assessed as 17 years. Cortisol and ACTH levels were 3.02 µg/dl and 365.0 ng/l, respectively. Gonadotropin hormones (FSHus and LH) were suppressed, while testosterone was elevated at 9,74 ng/dl. Cytogenetic analysis revealed a 46XY karyotype. Testicular ultrasound showed increased size with heterogeneous echostructure, suggestive of intratesticular adrenal inclusions. A diagnosis of congenital adrenal hyperplasia complicated by early puberty with testicular adrenal inclusions was established. Treatment involved progressive administration of hydrocortisone up to 40 mg/day, followed by monitoring with a 17OHP level of 775.9 nmol/l. Subsequent testicular ultrasound revealed multiple nodular formations, measuring 32×20×38.6 mm on the right and 40×24.4×54 mm on the left, likely related to an adrenal testicular inclusion. The patient was then treated with dexamethasone at a dose of 1 mg/day.
Discussion
TARTs are a complication in males affected by congenital adrenal hyperplasia (CAH), boasting an average prevalence of 40%. They stand out as the primary cause of infertility among male CAH patients. TARTs manifest during childhood, their prevalence surges during puberty and adulthood. Distinguishing between TARTs and Leydig cell tumors proves challenging. TART occurrence in individuals without CAH is exceedingly rare. TARTs exhibit characteristics of both adrenal and testicular origins, suggesting a pluripotent cell type as their source. While ACTH emerges as a pivotal stimulating factor in TART development among CAH patients, additional unidentified factors contribute to this process.
Conclusion
Patients diagnosed with congenital adrenal hyperplasia should undergo routine scrotal ultrasound examinations from childhood. If testicular nodules are detected, the most likely diagnosis is TART, especially in prepubertal boys with bilateral involvement, poor compliance to replacement therapy, and suggestive echo-Doppler appearance. It is crucial to optimize replacement therapy and conduct regular ultrasound follow-ups to observe the regression of anomalies, confirming the diagnosis.

Congenital adrenal hyperplasia: Cardiometabolic and bone outcomes

Hamdi Frikha[1], Nesrine Dhieb[1], Hana Charfi[1], Dhoha Ben Salah[1], Mahdi Kamoun[1], Thouraya Kamoun[2], Mongia Hachicha[2], Mouna Mnif[1], Habib Sfar[3], mouna elleuch[1], Mohamed Abid[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology; [2]Hedi Chaker University Hospital, Department of Pediatrics; [3]Tahar Sfar University Hospital, Department of Endocrinology

Introduction
Congenital adrenal hyperplasia (CAH) is an autosomal recessive disorder affecting adrenal steroid synthesis. Its treatment aims to achieve a balance between optimal glucocorticoid replacement and normal androgen levels. The long-term outcomes of this condition are poorly studied. The objective of this study is to evaluate the impact of CAH due to 21-hydroxylase deficiency on final height (FH), bone metabolism, and cardiometabolic risk in a Tunisian cohort.
Methods
A retrospective and descriptive bicentric study was conducted on patients with CAH followed at the endocrinology department of Hedi Chaker University Hospital in Sfax and the endocrinology department of Tahar Sfar University Hospital in Mahdia.
Results
Twenty-six patients (11 men and 15 women; mean age: 27.4 ± 8.2 years) were recruited. The mean FH was 159.5 ± 9.7 cm. Twenty-one patients (80.7%) had an FH below the target height. Ten patients (38.4%) had bone demineralization. Eight patients (30.7%) were obese. Lipid profile abnormalities and glucose metabolism disorders were detected in 10 (38.4%) and 5 (19.2%) patients, respectively. Seven patients (27%) had carbohydrate intolerance. Ambulatory blood pressure monitoring revealed abnormalities in 6 patients (23%). An increase in carotid intima-media thickness was observed in 14 patients (53.8%).
Conclusion
Patients with CAH are at risk of cardiometabolic and bone complications. The latter is attributed in various studies to iatrogenic hypercorticism. Regular follow-up, optimization of treatment, early lifestyle interventions, and evaluation of bone mineralization are necessary.

EP1192

Case of amenorrhea in identical twin sisters. late-onset congenital adrenal hyperplasia (?)

Naia Lataria
Academician Bochorishvili Clinic, Endocrinology, Tbilisi, Georgia

Overview
Congenital adrenal hyperplasia is a group of autosomal recessive disorders. In the presented case we will evaluate milder form of the disease, also referred as, non-Classical''. Prevalence of CAH is 1-9/100000. In 90-95% of cases, CAH is caused by a mutation in the *CYP21A2* gene located on chromosome 6p21.3
Presented case
16-year-old girl came to our clinic with amenorrhea, she had her last menstrual cycle 1 year ago. No signs of hirsutism and/or acne. She had gained 10 kg since February. Her BMI was 26.4 kg/m^2. After evaluating, she had elevated insulin resistance index, vitamin D deficiency and elevated 17(OH) progesterone - 4.135 ng/ml. DHEAs, LH, FSH, Free Testosterone, Estradiol, Prolactin in normal range Metformin 1000 mg and Vitamin D3 4000 IU and 17(OH)progesterone measurement after ACTH stimulation for the verification of non-Classical congenital adrenal hyperplasia had been prescribed. She came again, in December, with her identical twin sister, both with amenorrhea. Sister N2 had normal weight. DHEAs, LH, FSH, Free Testosterone, Estradiol, Prolactin in normal range as well as in sister N1. 17(OH)progesterone was measured again in twin sisters. Sister N1, had 17(OH)Progesterone – 2.83 ng/ml, Sister N.2 had 17(OH)Progesterone - 2.78 ng/ml. In February 2023 ACTH stimulation test with Synacthen was performed: Sister N1: Cortisol basal – 711 nmol/l 17(OH) Progesterone T0 – 8.2 nmol/l Cortisol in 30 minutes – 978 nmol/l 17(OH)Progesterone T60 – 11.1 nmol/l Cortisol in 1 hour – 1131.38 nmol/l Sister N2: Cortisol basal – 583 nmol/l 17(OH)Progesterone T0 – 8.7 nmol/l Cortisol in 30 minutes – 878 nmol/l 17(OH)Progesterone T60 – 9.2 nmol/l Cortisol in 1 hour – 1017.70 nmol/l Prescription and recommendation: In sister N1 case, her test result is equivocal, CAH is not

excluded so urine steroid profile and genotyping was recommended. In sister N2 case, CAH was excluded. Oral contraceptives were prescribed for menstrual cycle management in both sisters.
Conclusion
It is important to evaluate NCCAH in all girls/women with menstrual abnormalities, hirsutism and acne for right diagnose and treatment of infertility.

Precocious puberty: a case report
Omaima Hammami[1], Ines Mezghani[1], Rim Marrakchi[1], Souhir Maalej[2], Faten Hajkacem[2], Mariem Boudaya[1], Kamel Jammoussi[1], Nabila Rekik[2], Mohamed Abid[2] & Mouna Turki[1]
[1]Hedi Chaker University Hospital, Biochemistry Departement, sfax, Tunisia; [2]Hedi Chaker University Hospital, Endocrinolgy Departement, sfax, Tunisia

Introduction
Precocious puberty is characterized by the onset of signs of puberty before the usual age and can be caused by various etiologies. Congenital adrenal hyperplasia represents a rare cause of precocious puberty. Our aim was to report a case of a child with precocious puberty.
Observation
A 4-year-old and 11 months patient, from a consanguineous marriage, hospitalized in the endocrinology department for precocious puberty. The clinical examination found a child in good general condition, a bone age of 13 years, a stature advancement of +1 standard deviations (SD) and the presence of a dysmorphic syndrome including a rounded forehead, an enlarged nose, almond-shaped eyes, micrognathism, retrognatism, slight hypotelorism, and bilateral ulna valgus. The hormonal assessment shows a high testosterone level of 3.25 nmol/l. The 17-OH progesterone was highly elevated (20 ng/ml), cortisol at 8 a.m: 51.3 ng/mL, FSH: 0.6 mIU/ml, LH is low, less than 0.1 mIU /ml, androstenedione was elevated to 0.11 ng/mL and SDHEA was increased to 7.58 µg/mL. The diagnosis of congenital adrenal hyperplasia linked to a 21 OH adrenal enzyme block was made, the genetic study is in progress and the patient received hydrocortisone at a reducing dose of 10 mg/m^2/day, divided into 2 taken.
Conclusion
congenital adrenal hyperplasia due to enzymatic block represents a complex clinical cause that requires a careful diagnostic and therapeutic approach. This disorder, although rare, can lead to early manifestations of puberty, posing significant challenges for healthcare professionals.

Adrenal insufficiency in allgrove syndrome:a case report
Hajar Azagouagh, Karimi Meryem, Nawal Moussaid, Rifai Kaoutar, Iraqi Hind & Mohamed Elhassan Gharbi
CHU IBN SINA, Endocrinology, Rabat

Introduction
Allgrove syndrome or triple A syndrome is a rare genetic disorder of autosomal recessive inheritance combining in its complete form: esophageal achalasia, alacrymia and adrenal insufficiency.
Observation
Patient aged 16, 3rd of 4 siblings from a consanguineous marriage, followed for allograve Sd with megaesophagus operated on in 2016, alacrymia with artificial tears and neurological impairment. As part of the follow-up of his pathology, an 8-hour cortisolaemia was performed, showing low cortisolaemia with high ACTH. The patient was started on hydrocortisone 30 mg and received several therapeutic education sessions. Genetic counseling of siblings was requested.
Discussion and conclusion
Allgrove syndrome is a rare disorder (97 published cases) of autosomal recessive inheritance, characterized by adrenal insufficiency with isolated glucocorticoid deficiency, achalasia, alacrymia, autonomic dysfunction and neurodegeneration. The gene responsible for the disease, located on chromosome 12, codes for the ALADIN protein (for alacrima-achalasia-adrenal insufficiency neurologic disorder). The exact role of this protein in Triple A syndrome is not yet known. The incidence of the condition is unknown and difficult to determine, due to the clinical variant of the disease and the infant mortality due to attacks of adrenal insufficiency, hence the importance of a careful anamnesis in search of a history of mortality in siblings. Allgrove affects both males and females, regardless of race (rational sex = 1). Achalasia and alacrymia are the first signs of the disease and may appear from birth, whereas adrenal insufficiency attacks may be discovered in adulthood, during the 2nd decade, or may never appear at all, which justifies regular monitoring and the importance of genetic counseling in siblings.

EP1215

Addison's disease presented as a persistent hyperkaliemia in a patient with diabetic ketosis and autoimmune polyendocrine syndrome type 2 (APS-2). a case report and review of literature
Marjeta Kermaj, Dorina Ylli, Violeta Hoxha, Klodiana Poshi & Agron Ylli
[1]UHC "Mother Tereza", Endocrinology, Tirana, Albania

Introduction
APS-2 is the most common autoimmune polyendocrine syndrome. It is characterized by the presence of various endocrine-related diseases, such as autoimmune thyroid disease, type 1 diabetes mellitus, Addison's disease, primary hypogonadism, and, in rarer cases, hypoparathyroidism or hypopituitarism.
Case report
Our patient is a 38-year-old female with a medical history of type 1 diabetes mellitus (DMT1) for 13 years, Hashimoto's thyroiditis 2 years later (euthyroid under treatment with levothyroxine), and newly diagnosed Addison's disease. The patient presented to the emergency room with symptoms of diabetic ketosis, including vomiting and general body weakness. Additionally, the patient had noticed recently, darkening of the skin on her face and palms. The patient's initial assessment revealed elevated glycaemia and ketones in urine, confirming the diabetic ketosis diagnosis. However, what caught the attention of the medical team was the persistence of hyperkalaemia, despite following the appropriate treatment for diabetic ketosis. Further investigation, including laboratory tests, showed normal level of TSH and Ft4 but high levels of adrenocorticotropic hormone (ACTH) and low level of cortisolemia, confirmed the presence of Addison's disease. With the initiation of hydrocortisone treatment, the situation improved. A week later, the patient discharged the hospital in a good general health condition with diagnoses: Autoimmune poliglandular syndrome Type 2 (DMT1, Hashimoto's thyroiditis and Addison's disease) under hormone replacement therapy.
Conclusion
Addison's disease can present with hyperkalaemia due to adrenal insufficiency. Our case highlights the vital importance of recognizing and managing coexisting autoimmune endocrine disorders in patients with DMT1, as they can significantly impact a patient's clinical presentation and treatment approach.

Primary aldosteronism: clinical presentation and management about 2 cases
Ahmed Boukhalfa, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Mohamed VI University Hospital Center, Marrakech, Morocco, Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakesh, Morocco

Introduction
Primary aldosteronism (PA) is widely recognized as the most common form of secondary hypertension (1). PA, also known as Conn syndrome, is a group of pathological conditions associated with an aldosterone secretion inappropriate for sodium intake, that is relatively autonomous from renin–angiotensin system activity and potassium levels.
Clinical Case 1
Thirty two year-old patient, diagnosed since 11 months with arterial hypertension with peaks reaching 18 of systolic. The patient reported intermittent headaches and a recent weight gain of 7 kg. Clinically, we noted blood pressure at 15/8 cmhg, acanthosis nigricans and Buffalo hump. Biological tests revealed: normal kidney function, urinary methoxylate derivatives and urinary free cortisol were negative, Aldosterone:1318 pmol/l, Rénine: 6,3 mUI/l, Aldosterone to Rénine Ratio (ARR) very high at 209. Abdominal CT scan showed nodular left adrenal formation, well-limited rounding, < 10 of spontaneous density measuring 22*18 mm. The patient underwent left adrenalectomy, anatomopathological study was in favor of an adrenocortical adenoma. Evolution was marked by the normalization of blood pressure.

Clinical Case 2
Fifty six year-old patient, diagnosed since 1 year with arterial hypertension, wich despite triple antihypertensive therapy, remained poorly controlled. The patient reported fatigability with muscle cramps. Clinically, we noted high BP at 16/9 cmhg. Biological tests revealed: kidney faillure with 13 ml/mn of creatinine clearance, chronic hypokalemia, Aldosterone to Rénine Ratio (ARR) was superior than 70. Abdominal CT scan showed nodular left adrenal formation, measuring 25 mm. The patient underwent left adrenalectomy, anatomopathological study was in favor of an adrenocortical adenoma.
Discussion
Prevalence of PA varies from 6 to 18 %. While the majority of cases of PA are sporadic, four forms of autosomal-dominant inheritance have been described: familial hyperaldosteronism types I to IV. Severe or resistant hypertension, association with hypokalemia represent conditions which requires screening for PA. The Aldosterone -to-Renine Ratio has higher sensitivity than other measures. Antihypertensive drugs that can be maintained during exploration include alpha-blockers and calcium channel blockers ideally long-acting and non-dihydropyridine antagonists (2). Treatment of PA amis at preventing or correcting hypertension, hypokalemia and target organ damage. Spironolactone controls hypertension and hypokalemia and may prevent postoperatve hypoaldosteronism. Partial adrenalectomy and non-surgical ablation have no proven avantage over total adrenalectomy.
Conclusion
PA is one of the most frequent causes of secondary hypertension. Prevention requires screening for hypertensive patients, to enable specific medical or surgical management to avoid cardiovascular morbidity and mortality.
Key words primary aldosteronism, ARR, adenoma.

Involvement of age, obesity and genetic polymorphisms in the increment of 25(OH)D levels after 12-month treatment with calcifediol and cholecalciferol

Esteban Jódar[1,2], Paula Arranz-Gutiérrez[3] & Jose Luis Perez-Castrillon[4,5]
[1]Department of Endocrinology and Nutrition, Quirón Salud Madrid and Ruber Juan Bravo University Hospitals, Madrid, Spain; [2]Universidad Europea de Madrid, Madrid, Spain.; [3]Department of Research, Development and Innovation, FAES FARMA, Leioa, Bizkaia, Spain.; [4]Department of Internal Medicine, Hospital Universitario Río Hortega, Valladolid, Spain.; [5]School of Medicine, Universidad de Valladolid, Valladolid, Spain.

Introduction
Vitamin D deficiency is a prevalent condition worldwide. Low serum 25(OH)D levels are associated with several diseases, being age and obesity strongly related to hypovitaminosis D. In addition, several genetic variants have also been associated with lower and/or higher 25(OH)D levels.
Objective
We aimed to assess the potential influence of age, BMI, waist circumference and genetic variants on the efficacy of 12-month treatment with calcifediol compared to cholecalciferol in postmenopausal women with vitamin D deficiency. Genetic influence on 25(OH)D modulation was assessed studying 14 polymorphisms linked to VDR and vitamin D metabolism.
Methodology
This was a long-term, phase III-IV, double blind, randomized, controlled, multicenter clinical trial including postmenopausal women with basal 25(OH)D levels <20 ng/ml treated monthly with calcifediol (0.266 mg, $n=101$) or cholecalciferol (0.625 mg, $n=98$). Subgroup analyses were performed using ANOVA analysis if there was no baseline effect of the response variable; otherwise, ANCOVA analysis was used. In both cases, Weighted Least Squares (WLS) was considered if the assumptions of the model were not met. Polymorphisms were analyzed using a multivariate mixed model approach.
Results
Change in 25(OH)D levels from baseline to month 12 was significantly affected by BMI in patients treated with cholecalciferol (ANOVA $P=0.0177$; ANCOVA $P=0.0068$), whereas no significant differences were observed when treated with calcifediol ($P=0.4582$). Accordingly, abdominal circumference ≥ 80 cm produced lower 25(OH)D increments in cholecalciferol group (ANOVA $P=0.0259$; ANCOVA $P=0.0274$; WLS $P=0.0871$), but not in calcifediol group ($P=0.6899$). When results were analyzed among three different age subgroups (<65;65-74; >74 years), no differences in efficacy were observed for any of the treatments tested. Modulation of 25(OH)D levels according to genotype (PP population) shows certain association for *GC* and *VDR* in cholecalciferol group and for *CYP2R1* in calcifediol group. *CYP2R1*, that encodes 25-hydroxilase, shows that the less frequent allele of this polymorphism is linked to higher 25(OH)D levels in the calcifediol group. In the cholecalciferol group, the polymorphism rs7041 (*GC*) and rs2228570 (*VDR*) under recessive models shows a lower response due to its effect on the transporter protein and a lower affinity of the active metabolite on the receptor. These results suggest pharmacogenetic differences between calcifediol and cholecalciferol.
Conclusion
Increments on 25(OH)D levels after calcifediol treatment are independent of patients age and BMI, whereas cholecalciferol treatment shows a lower rise in 25(OH)D levels in obese patients. Pharmacogenetic differences between calcifediol and cholecalciferol were observed, although their clinical relevance remains unclear.

Novel germline variant of CDC73 identified during screening for familial primary hyperparathyroidism

Andreea Muntean[1], Isabel Mazarico Altisent[1], Ismael Capel Flores[1], Laia Casamitjana Espuña[1], Alba Hernández Lázaro[1], Santiago Barcons Vilaplana[2], Xavier Guirao Garriga[2], Neus Baena Diez[3], Ana Romero Gregori[1], Berta Bella Burgos[4], Valeria Arsentales Montalva[1], Judith Jover Gornall[1] & Mercedes Rigla Cros[1]
[1]Endocrinology and Nutrition Department, Parc Taulí University Hospital, Institut d'Investigació i Innovació Parc Taulí (I3PT), Sabadell, Barcelona, Spain; [2]Surgery Department, Parc Taulí University Hospital, Institut d'Investigació i Innovació Parc Taulí (I3PT), Sabadell, Barcelona, Spain; [3]Genetic Department, Parc Taulí University Hospital, Institut d'Investigació i Innovació Parc Taulí (I3PT), Sabadell, Barcelona, Spain; [4]Pathology Department, Parc Taulí University Hospital, Institut d'Investigació i Innovació Parc Taulí (I3PT), Sabadell, Barcelona, Spain

Background
Hyperparathyroidism jaw-tumor syndrome (HPT-JT) is a rare and under-diagnosed cause of familial primary hyperparathyroidism (incidence $<$ 1/1000000). It is caused by a pathogenic variant in the *CDC73* (or *HRPT2*) gene that encodes parafibromin. Patients with HPT-JT have a 15–20% risk of developing parathyroid carcinoma. Other related conditions are jaw tumors in 30% of cases, kidney abnormalities in 15% of cases, and uterine tumors in 50% of cases.
Case report
A 21-year-old woman with bipolar disorder undergoing lithium treatment referred from psychiatry due to hypercalcemia. Primary hyperparathyroidism was diagnosed, with PTH 125 pg/ml, and Ca 11.3 mg/dl. Imaging tests located a lesion in the upper left parathyroid. Because the patient had a sister with two parathyroid adenomas, uterine polyps, and giant cell bone tumors, a genetic study (for suspicion of familial hyperparathyroidism) was conducted. The genetic study identified a heterozygous frameshift variant *CDC73* c.110del, p.(Lys37Argfs*72) , not previously described, classified as likely pathogenic. The patient underwent parathyroidectomy, and the pathology report defined the lesion as parathyroid adenoma. Additionally, the patient presented uterine polyps with benign characteristics, no malformations of the urinary system, and currently is awaiting a mandibular imaging study. A segregation study was performed, whereas genetic studies are pending for the remaining siblings and parents, as well as additional tests to identify conditions related to the mutation. Two siblings had primary hyperparathyroidism (diagnosed at 19 years in both cases) and underwent surgery. Pathology studies showed parathyroid adenoma in one case, and atypical parathyroid tumor in the other (this case presented with severe hypercalcemia and ECG abnormalities, which required admission into the Critical Care Unit); three siblings showed benign uterine polyps, and one sibling had giant cell bone tumors in the lower extremities. No urinary system malformations nor jaw tumors were identified so far in the family.
Conclusion
Performing a genetic screening for familial hyperparathyroidism and segregation studies in suspected cases lies in providing early diagnosis and treatment for parathyroid tumors, as well as identifying potential conditions associated with HPT-JT syndrome. These conditions may limit the functionality of patients and pose a life-threatening risk if not identified and treated promptly.

EP26

Involvement of the vitamin D receptor gene in children with growth hormone deficiency

Mariana Ryznychuk[1,2] & Olena Bolshova[3]
[1]Bukovinian State Medical University, Department of Pediatrics and Medical Genetic, Chernivtsi; [2], Ukraine; [3]Institute of Endocrinology and Metabolism named after V.P. Commissioner of the National Academy of Sciences of Ukraine, Department of Pediatric Endocrine Pathology, Kiev, Ukraine

Introduction
Polymorphisms of genes involved in the growth process are an important cause of growth hormone deficiency (isolated form). Isolated growth hormone deficiency can be caused by genetic defects in about 10% of patients, in 34% of cases it is a consequence of familial pathology, and 4% are sporadic cases. The nuclear receptor for vitamin D mediates most of the biological functions of this vitamin. It belongs to the steroid hormone receptor family, the gene for which (vitamin D receptor — VDR) is locatedon chromosome 12q13.1.
Aim
To study the TaqI polymorphism of the VDR gene in children with GH-deficiency.
Material and methods
Determination of the TaqI polymorphism of the VDR gene (rs731236) was performed in 36 prepubertal GHD children by polymerase chain reaction followed by analysis of the length of the restriction fragments when detected by agarose gel electrophoresis.
Results
In the group of patients with GHD, the proportion of heterozygotes for T/C TaqI polymorphism of the VDR gene (rs731236) is 1.28 times higher than among healthy individuals. There were 0.68 and 0.90 times fewer patients carrying T/T and C/C genotypes than in the control group. The presence of a homozygous TT genotype increases the risk of developing GHD, but not significantly (odds ratio (OR) = 1.89, 95% confidence interval (CI) 0.66–5.39; $P = 0.23$), and the presence of a homozygous CC genotype is protective (OR = 0.75, 95% CI 0.17–3.22; $P = 0.70$). When analyzing alleles in patients with GHD, the following data were obtained: carriage of the T allele for the polymorphic loci TaqI rs731236 of the VDR gene is associated with the risk of GHD (OR = 1.24, 95% CI 0.65–2.36; $P = 0.52$) but not significantly. The ratio of allele (pT = 0.554, qC = 0.446) frequencies practically does not differ from1:1, which indicates the preservation of allele frequencies in the Ukrainian population.
Conclusions
A significant number of GHD children (55.56%) have heterozygous T/C genotype of TaqI polymorphism (rs731236) against the background of significantly lower levels of IGF-1 and stimulated GH in comparison with these indicators in children carrying homozygous C/C genotype. Hypovitaminosis D was detected in all patients with somatotropic insufficiency: deficiency - in children with homozygous T/T genotype (42.08 ± 15.70 nmol/l), and vitamin D deficiency - in carriers of heterozygous T/C genotype (56.24 ± 18.60 nmol/l) and homozygous C/C genotype (68.25 ± 16.87 nmol/l).

The usefulness of 18F-choline PET/CT in patients with negative findings on 99mTc-sestamibi SPECT/CT in Locating Hyperfunctioning Parathyroid Glands in Primary Hyperparathyroidism

Ante Mandic[1], Ivana Kraljevic[2,3], Tanja Skoric Polovina[2], Karin Zibar Tomsic[2], Tina Dusek[2,3], Annemarie Balasko[2], Mirsala Solak[2] & Darko Kastelan[2,3]
[1]University Clinical Hospital Mostar, Department of Endocrinology, Mostar, Bosnia and Herzegovina; [2]University Hospital Centre Zagreb, Zagreb, Croatia; [3]School of Medicine, University of Zagreb, Zagreb, Croatia

Objective
This study aimed to investigate the diagnostic performance of ^{18}F-choline PET/CT in patients with negative or inconclusive results of ^{99m}Tc-sestamibi SPECT/CT in locating hyperfunctioning parathyroid tissue in primary hyperparathyroidism patients.
Methods
We conducted a retrospective study involving patients who were operated on due to primary hyperparathyroidism from April 2019 to March 2022. The analysis focused on patients undergoing ^{18}F-choline PET/CT scan due to previously negative or inconclusive findings on ^{99m}Tc-sestamibi SPECT/CT in order to localize a hyperfunctioning parathyroid gland(s). Pathohistological reports were used as a reference standard for the assessment of imaging results.
Results
The study included 29 patients (23 (79.3%) females), with a mean age of 56.3 years (range 25–74). Pathohistological analysis revealed 36 glands. The detection rate of ^{18}F-choline PET/CT in per lesion analysis was 88.9% (95% CI 70.8–97.7).
Conclusion
The results of our study showed the significant usefulness of ^{18}F-choline PET/CT in patients with negative or inconclusive results of ^{99m}Tc-sestamibi SPECT/CT in accurately locating hyperfunctioning parathyroid glands in primary hyperparathyroidism patients.

Predictive factors of early postoperative hypocalcemia in patients with secondary hyperparathyroidism undergoing parathyroidectomy

Mezri Sameh[1], chaima zitouni[1], Wadii Thabet[2] & akkari khemaies[1]
[1]Principal Military Hospital, ENT, Tunis, Tunisia; [2]Taher Sfar Hospital, ENT, Mahdia, Tunisia

Introduction
Secondary hyperparathyroidism is the main disorder of mineral and bone metabolism associated with chronic kidney disease. This disorder is characterized by hypersecretion of parathyroid hormone (PTH). Given the high cost and unavailability of calcimimetics, surgery remains a good alternative. In the immediate postoperative period after parathyroidectomy, hypocalcemia is common and close monitoring is critical.
Objective
The aim of our work was to evaluate the surgical results of parathyroidectomy in terms of efficacy and postoperative hypocalcemia.
Methods
This is a retrospective study including 45 patients operated on in our department during the period from 2010 to 2023. The analytical study evaluated the predictive criteria of hypocalcemia after surgery.
Results
The mean age of our patients was 46 years with a sex ratio of 1.5. The mean preoperative PTH level was 2030 ng/l. The mean preoperative corrected serum calcium level was 2.4 mmol/. Twenty-five patients underwent subtotal parathyroidectomy (7/8). Fifteen patients had selective parathyroidectomy (3/4) and five of them underwent selective surgery. According to KDOQI 2003 criteria, the surgical success rate was 87%. The mean postoperative PTH level was 202 ng/l. Subtotal parathyroidectomy provided the best surgical success rates. In our study, 38 patients developed postoperative hypocalcemia. It was severe in 47% of cases. Among them, 13 patients developed Hungry Bone syndrome. Alkaline phosphatase level > 500 IU/l and preoperative hypocalcemia were respectively the main factors predicting postoperative hypocalcemia.
Conclusion
In our study, preoperative serum alkaline phosphatase and calcium concentrations were found to be predictors of postoperative hypocalcemia in patients with secondary hyperthyroidism who underwent parathyroidectomy. These variables may help clinicians identify patients undergoing hemodialysis who are at higher risk of hypocalcemia following parathyroid surgery and thus monitor them more closely during the postoperative period. Such high-risk patients may benefit from postoperative calcium and vitamin D supplementation.

Primary hyperparathyroidism in pregnant women: experience of a specialized centre

Ekaterina Bibik[1], Anna Eremkina[1], Svetlana Vorotnikova[2] & Natalia Mokrysheva[3]
[1]Endocrinology Research Centre, Parathyroid pathology and mineral disorders, Moscow; [2]Endocrinology Research Centre, Endocrinopathies and pregnancy, Moscow; [3]Endocrinology Research Centre, Moscow

Background
Primary hyperparathyroidism (PHPT) during pregnancy is rare and often unrecognized. Most of these patients are asymptomatic or have nonspecific complaints but some of them can present with classical symptoms of PHPT and even with severe complications of pregnancy as preeclampsia, miscarriage, preterm labor etc. The incidence of maternal complications is approximately 67%, poor fetal outcomes, including stillbirth and intrauterine growth retardation

may reach 80%. Therefore, PHPT in pregnancy requires close monitoring of the multidisciplinary team.
Aim
We present a case series of PHPT in pregnancy.
Results
We managed 15 young women (median age 32 [28; 37] years), who were referred to our Centre at 21 [17; 24] weeks gestation (min 16, max 34) and only one in the early postpartum period. Two of them had *MEN1* mutation. The main laboratory features of PHPT were: iPTH 133.1 pg/ml [84.5; 232.7], albumin-adjusted serum calcium 2.87 mmol/l [2.74; 2.90], 24-h urinary calcium 10.8 mmol [6.3; 12.8]. The most common PHPT complication was nephrolithiasis (67%), among non-classical complications - hypertension (13%) and gestational diabetes (20%). 6 women received conservative treatment (group 1), because of mild disease ($n=3$) , patient's withdrawal ($n=1$) or high risks of preterm labor ($n=2$), and 9 people (group 2) underwent parathyroidectomy (PTE). The calcium and iPTH levels were comparable in both groups (for all $P>0.05$). A conservative management in all cases included low-calcium diet and oral rehydration. One patient from group 1 received cinacalcet 30 mg for 4 weeks before delivery and another one from group 2 for 2 weeks before PTE with a positive effect on serum calcium level in both cases. One patient underwent emergency C-section because of preeclampsia. In all cases a selective PTE was performed at 22 [18; 25] weeks followed by parathyroid adenoma confirmation. The total frequency of fetal/newborn complications was 50% in the group 1 and 22% in the group 2, among them hypocalcemia ($n=1$), congenital pneumonia ($n=2$), intrauterine fetal death in twins ($n=1$) were observed. In a single case (group 2) after successful PTE surgical abortion was carried out at 21 weeks gestation because congenital heart defect had been detected.
Conclusion
Surgical approach seems more beneficial for pregnant patients with symptomatic PHPT. PTE performed during the second trimester resulted in good outcomes. Mild forms of the disease can be managed conservatively with low-calcium diet and optimal oral hydration.

Impact of bodycomposition on bone mineral density: beyond BMI

Sofia Lopes, Cátia Araújo, Mafalda Martins Ferreira, Luísa Ruas, Carla Baptista, patrícia oliveira, Dírcea Rodrigues & Isabel Paiva
Coimbra Hospital and Universitary Centre, Endocrinology, Diabetes and Metabolism, Coimbra, Portugal

Introduction
The interaction between obesity and bone metabolism is complex and not fully understood. Historically, higher body weight was considered to be protective against osteoporosis. This association has affected clinical practice: body mass index (BMI) is one of the variables included in Fracture Risk Assessment Tool (FRAX), where a higher BMI leads to a lower fracture risk. Despite this association between bone mineral density (BMD) and body weight, it is not clear whether it prevails for higher BMI values, or which components of body composition are responsible for this correlation. The aim of our study was to evaluate the impact of BMI and body composition on BMD in patients with obesity.
Methods
Cross-sectional study including patients with obesity from a tertiary hospital. To assess BMD, T-score value was used for postmenopausal women or men aged 50 or over; Z-score value for the remaining patients. Body composition was assessed by bioimpedance and DEXA.
Results
A total of 30 patients were included, 80% female, mean age of 45 ± 11 years. Mean BMI was 42.1 ± 5.9 kg/m^2 (70% in class III obesity). Mean fat mass percentage was 51.9 ± 10.6% and 47.8 ± 5.9%, as measured through bioimpedance and DEXA, respectively. There was no significant correlation between BMI and BMD ($P=0.251$). There was a negative correlation between total body BMD and body fat mass percentage assessed by bioimpedance ($r=$-0.423; $P=0.040$) and by DEXA ($r=$-0.730; $P=0.003$). Femoral neck BMD was negative and weakly correlated with body fat mass percentage assessed by DEXA ($r=$-0.455; $P=0.022$). Although there was no significant correlation between visceral adipose tissue and total body BMD ($P=0.097$), there was a negative and weak correlation between visceral adipose tissue index and femoral neck BMD ($r=$-0.448; $P=0.025$).
Conclusions
Our study challenges the belief that obesity is protective against osteoporosis, suggesting that increased fat mass should act as a red flag for the development of osteoporosis. The exact mechanism for the effects of obesity on bone health remains unclear. Several mechanisms have been proposed: accelerated senescence in stromal stem cells; increased inflammation (especially visceral adiposity, due to associated low-grade chronic systemic inflammation); replacement of osteoblasts by adipocytes in bone marrow; mutations in the obesity-associated genes leading to bone fragility. In our study, fat mass had a negative impact on femoral neck BMD, suggesting that body fat may selectively affect cortical rather than trabecular bone. The effects of fat mass on skeletal strength might be site dependent.

Risk of osteoporotic fractures among patients with thyroid cancer: a nationwide population-based study

Eun Kyung Lee[1], Eu Jeong Ku[2], Won Sang Yoo[3], Yu Been Hwang[4], Subin Jang[4], Jooyoung Lee[4], Shinje Moon[5], Hwa Young Ahn[6] & Young Joo Park[7]
[1]National Cancer Center, Center for Thyroid Cancer, Department of Internal Medicine, Goyang; [2]Seoul National University Hospital Healthcare System Gangnam Center; [3]Dankook University College of Medicine; [4]Chung-Ang University College of Statistics; [5]Hallym University College of Medicine; [6]Chung-Ang University College of Medicine; [7]Seoul National University College of Medicine

Background
The association between thyroid cancer and skeletal outcomes has not been thoroughly investigated. We aimed to investigate the risk of osteoporotic fractures in patients with thyroid cancer compared with a matched control group.
Methods
This retrospective cohort study included 2,514 patients with thyroid cancer and 75,420 matched controls from the Korean National Health Insurance Service-National Sample Cohort (NHIS-NSC, 2006-2019). Rates of osteoporotic fractures were analysed and associations with levothyroxine dose were evaluated.
Results
Patients with thyroid cancer had a significantly lower risk of fracture compared with the control group (hazard ratio [HR] 0.81, 95% confidence interval [CI]: 0.69 to 0.94, $P=0.006$). The group diagnosed with thyroid cancer after the age of 50 (older cancer group) had a significantly lower risk of fractures compared with the control group (HR: 0.72, 95% CI: 0.6 to 0.85, $P<0.001$), especially for spine fractures (HR: 0.66, 95% CI: 0.51 to 0.85, $P=0.001$). The older cancer group started osteoporosis treatment earlier than the control group (65.5 ± 7.5 vs 67.3 ± 7.6 years, $P<0.001$). In addition, a lower dose of levothyroxine was associated with a lower risk of fracture.
Conclusions
In the actual clinical setting, the risk of fracture in women diagnosed with thyroid cancer after the age of 50 years was lower than in the control group, which is interpreted as a phenomenon caused by more proactive osteoporosis treatment in postmenopausal women with thyroid cancer.

Young osteoporosis - factors affecting the course of T-score: a 3-year follow-up of the German register young osteoporosis

Ashley Macline Wandji[1], Clara Kühner[1], Veronika Koeppen-Ursic[2], Mandy Warda[3], Alexander Defèr[3], Marion Bogatsch-Gis[1], Katharina Pfeifer[1] & Vanadin Seifert-Klauss[1]
[1]Klinikum rechts der Isar der Technischen Universität München, Interdisziplinäres Osteoporosezentrum, Munich, Germany; [2]Klinikum Freising, Abteilung für Orthopädie und Unfallchirurgie, Freising, Germany; [3]DVO - Osteoporose Register, Dresden, Germany

Background
Osteoporosis is a disease usually associated with postmenopausal women and men over sixty. Little is known about the long-term course of early-onset osteoporosis and the factors affecting fracture risk and bone density(T-score).
Objectives
Factors that cause osteoporosis or aggravate its progression in younger patients are less studied than in older patients. Data are lacking on treatment choice, adherence and effectiveness. Our study group pursues this topic in the current follow-up of the Register Young Osteoporosis.
Methods
Women $\leq$50 yrs. and men $\leq$60 yrs. at the time of diagnosis who presented to our outpatient clinic, were recruited into the Register Young Osteoporosis, a sub-

register of the German Osteoporosis register in cooperation with the DVO (Dachverband Osteologie e.V). After written informed consent, information about bone mineral density (BMD), fractures, personal medical and family history were recorded in the register. For the follow-up, a questionnaire on the course of osteoporosis and its management (BMD, fractures, osteoporosis medication, risk factors) was sent to patients with records of at least 2 DXA-measurements. T-scores of participants who had been followed for at least 3 years were analyzed for change over time in relation to sex, medication use, fracture history, weight and (in women) menopause.

Results

72 (54,96%) out of 131 responded to the questionnaires, 46 (63,89%) women and 26 (36,11%) men. At the time of diagnosis, mean age was 35 ± 8 years in women and 47 ± 11 years in men. Vitamin D supplementation was associated with an increase in lumbar spine (LS) T-scores in both men ($P = 0{,}031$) and women ($P = 0{,}050$). 19/26 men received specific osteoporosis medication, they had lower baseline T-scores (LS:-3,1, total hip(TH):-2,0) than those who did not. 23/26 men had a positive fracture history. A significant improvement in LS T-scores ($P = 0{,}045$) was seen in men who received medication. Average baseline T-score in women with osteoporosis medication was LS:-2,8, TH:-2,0. 34/46 women had a positive fracture history. Those who received medication had lower T-scores (LS:-2,8, TH:-1,9) than fractured women who didńt. Premenopausal women (30/46) presented a higher increase in LS T-scores ($P = 0{,}041$), compared to postmenopausal women (16/46). Premenopausal women showed a significant increase in LS T-scores ($P = 0{,}015$). A significant decrease in TH T-scores ($P = 0{,}006$) was seen in underweight women (BMI < 18,5).

Conclusions

Vitamin D supplementation, osteoporosis medication, as well as fracture history, weight and (in women) menopause are influential in the management of young osteoporosis patients. Multicentre participation in the registry should be enhanced.

EP116

Ectopic mediastinal parathyroid adenoma: Diagnostic and therapeutic difficulties across three cases

Gorgi Khaoula, Echchad Lamya, Cheibetta Zakaria, Rifai Kaoutar, Iraqi Hinde & Gharbi Mohamed El Hassan
Ibn Sina University Hospital, Endocrinology, Morocco

Introduction

Primary hyperparathyroidism (PHPT) represents a prevalent medical condition frequently characterized by asymptomatic manifestations. The etiology of PHPT is predominantly attributed to parathyroid adenomas, accounting for 85% of cases, with 10% demonstrating ectopic localization. The prevalence of asymptomatic presentation poses distinctive challenges in both diagnostic and therapeutic realms, necessitating a nuanced approach to effectively address the complexities associated with this pathology.

Observation

In a series of challenging cases, a 54-year-old female patient, previously treated twice for primary hyperparathyroidism (PHPT), underwent left upper parathyroidectomy and mediastinal ectopic parathyroid resection. A decade later, she reappeared with hypercalcemia, elevated PTH, low phosphoremia, and increased 24-hour calciuria. Despite normal ultrasound and cervicothoracic CT results, sestamibi scintigraphy revealed a mediastinal ectopic parathyroid focus. Another case involved a 59-year-old female with primary hyperparathyroidism who underwent parathyroidectomy for a left inferior polar parathyroid lesion. Despite persistent hypercalcemia, elevated PTH, and abnormal 24-hour calciuria, cervical ultrasound and cervicothoracic CT scans showed no abnormalities. However, sestamibi scintigraphy indicated anterior mediastinal ectopy. Additionally, a 68-year-old male patient, post-parathyroidectomy for primary ectopic posterior mediastinal hyperparathyroidism, presented with disrupted phosphocalcic balance. Despite inconclusive results from cervical ultrasound, cervicothoracic CT, and MIBI scintigraphy, a PET scan confirmed posterior mediastinal fixation. In all three cases, thorough investigations for other components of multiple endocrine neoplasia (NEM) yielded negative results, and our patients experienced positive outcomes following surgical resection of the ectopic focus. The anatomopathological study consistently favored the diagnosis of a mediastinal ectopic parathyroid adenoma, highlighting the diagnostic challenges and successful outcomes achieved through advanced imaging-guided interventions in recurrent hyperparathyroidism.

Discussion & Conclusion

The ectopic parathyroid adenoma is a an important cause of refreactory abd recurrent hyperparathyroidism. The mediastinal location of ectopic parathyroid tissue, though relatively rare in contrast to cervical localizations, present distinctive diagnostic and therapeutic challenges. Optimal management entails a meticulous imaging assessment, a pivotal prerequisite for determining precise anatomical localization. This intricate mapping is imperative for devising an exact therapeutic strategy tailored to the unique characteristics of this parathyroid adenoma manifestation.

83 cases of primary hyperparathyroidism: insights and observations

Gorgi Khaoula[1], Errahali yassine[2], Tadaloui Abderahmane[2], Lamya Echchad[1], Rifai Kaoutar[1], Iraqi Hinde[1] & Gharbi Mohamed El Hassan[1]
[1]Ibn Sina University Hospital, Endocrinology, Rabat, Morocco; [2]Mohamed V Military training hospital, Endocrinology, rabat, Morocco

Introduction

Primary hyperparathyroidism (PHPT) is a common endocrine disease secondary to autonomous hypersecretion of parathyroid hormone (PTH) by one or more parathyroid glands. It is a predominantly female disease and most often asymptomatic. Its positive diagnosis is purely biological. Its curative treatment is surgical.

Patients & methods

This retrospective descriptive study encompasses 83 patients who were hospitalized and longitudinally monitored for primary hyperparathyroidism. The study was conducted at the Endocrinology Department of the Ibn Sina University Hospital of Rabat and the Endocrinology Department of the Mohamed V Military Training Hospital. The observational period spans seven years, from 2015 to 2022.

Results

The mean age of our patient cohort was 53.27 ± 16.862 years, with a predominant representation of females accounting for 90.4% of cases. Clinical presentations exhibited variability, notably characterized by osteoarticular manifestations in 65.6% of cases, urinary signs in 10.8%, and general signs in 36.1%. Primary hyperparathyroidism remained asymptomatic in 39.7% of cases. The average blood calcium level was 122.8 ± 21.4 mg/l, with normal levels observed in 9.6% of cases. Parathyroid hormone (PTH) was elevated in all cases, demonstrating a mean level of 261.7 ± 186.8 pg/ml. Cervical ultrasound, conducted in all patients, exhibited a sensitivity of 89.1%, while 64 patients underwent MIBI scintigraphy, achieving a sensitivity of 92%. Management of primary hyperparathyroidism revolves around addressing hypercalcemia, with surgical intervention implemented when indicated. Surgical treatment was undertaken in 79 patients, constituting 95.18% of cases. Anatomopathological examination revealed parathyroid adenoma as the predominant finding in 81.92% of cases. The anatomopathological study showed a parathyroid adenoma in 81.92% of cases.

Discussion & Conclusion

Our study substantiates the observed predominance of primary hyperparathyroidism in females. It emphasizes the significance of routinely assessing serum calcium levels, especially in women aged over 50, to enable early detection of PHPT at its asymptomatic phase. This proactive approach aims to prevent complications that pose risks to vital prognosis and mitigate the onset of renal and skeletal complications.

Unusual presentation of parathyroid carcinoma

Ricardo Fonseca, Catarina Roque, Ana Sofia Osório & Sofia Castro Oliveira
Hospital Fernando Fonseca, Endocrinology, Amadora, Portugal

Background

Parathyroid carcinoma is a rare cause of primary hyperparathyroidism. There's an overlap between benign and malignant disease clinical presentation, but the presence of very high calcium levels (> 14 mg/dl), markedly raised levels of PTH, palpable neck mass or severe bone/kidney disease is more common in parathyroid carcinoma. We present a case of primary hyperparathyroidism due to a parathyroid carcinoma, with unusual presentation.

Case

A 75 years-old male was referred to the Endocrinology department to evaluate hypercalcemia, identified during the study of alithiasic acute pancreatitis. The patient had a previous history of pre-Diabetes, arterial hypertension and chronic kidney disease. During the previous hospitalization, a pancreatic mass and pelvis bone lesions were noticed in the abdominal CT. A FDG-PET was performed, with uptake

at both locations. There was a suspicion of pancreatic malignant disease, with bone metastasis, but the bone biopsy was compatible with brown tumors and the pancreatic mass biopsy was benign. Laboratory tests showed a calcium level at presentation of 12.9 mg/dl (8.8-10.2), with a phosphate of 2.4 mg/dl (2.5-4.5), PTH level of 357 pg/ml (normal range 15-65) and an estimated glomerular filtration rate of 38 ml/min/1.73 m^2. After vigorous hydration and intravenous Pamidronate, a reduction of calcium to basal levels of 10.6 – 11.4 mg/dl was noticed in the following months. Primary hyperparathyroidism was assumed, with bone disease (brown tumors at pelvis) and kidney disease (lithiasis and chronic kidney disease). Cervical ultrasonography and CT showed a mixed nodule with 34×24×22 mm at the inferior pole of right thyroid lobe, concordant with sestamibi scintigraphy result. The patient had selective parathyroidectomy with a low normal intraoperative PTH level. Postoperatively, the patient had a low normal calcium/hypocalcemia, corrected with calcitriol and oral calcium. Histology was malignant (parathyroid carcinoma). Two years after surgery, the patient has normal calcium and phosphate and a secondary hyperparathyroidism due chronic kidney disease (latest laboratory results: calcium 9.2, phosphate 3.2, PTH 75, glomerular filtration rate of 28 ml/min/1.73m^2) without signs of recurrence of the disease.

Discussion

Parathyroid carcinoma is a challenging entity, with various clinical presentations. In our case, calcium level at presentation (12.9 mg/dl), basal calcium after bisphosphonates (10.6-11.4) and PTH levels were not suspicious of malignant disease. However, the patient had severe target organ involvement – chronic kidney disease, lithiasis, brown pelvis tumors and acute pancreatitis – that are more frequent in malignant disease.

EP150

Role of MEN1 mutation on postoperative outcomes in patients with Multiple Endocrine Neoplasia type 1-related primary hyperparathyroidism: a single center experience

Laura Pierotti1[1], Elena Pardi[1], Chiara Sardella[2], Simone Della Valentina[1], Anna Dal Lago[1], Paolo Piaggi[3], Maria Adelaide Caligo[4], Gabriele Materazzi[5] & Cetani Filomena[2]
[1]University of Pisa, Department of Clinical and Experimental Medicine, Pisa, Italy; [2]University of Pisa, Unit of Endocrinology, Pisa, Italy; [3]University of Pisa, Department of Information Engineering, Pisa, Italy; [4]University of Pisa, Laboratory of Molecular Genetics, Pisa, Italy; [5]University of Pisa, Department of Surgical, Medical and Molecular Pathology and Critical Area, Pisa, Italy

Subtotal parathyroidectomy (PTX) is considered the surgery of choice for patients with MEN1, because it optimally balances the risk of recurrence/persistence against surgical complications. Notably, MEN1 patients negative at the genetic test (*MEN1*-negative) seem to exhibit distinct clinical characteristics compared to their mutated counterparts (*MEN1*-positive). Therefore, we hypothesized that these patients may also have a different surgical outcome. The objective of our retrospective study, conducted at our Endocrine Unit from January 1993 to January 2023, was to compare the rate of remission, persistence, and recurrence of primary hyperparathyroidism (PHPT) in *MEN1*-positive and *MEN1*-negative patients according to different surgical procedures. We evaluated 101 MEN1 patients undergoing PTX, including 80 *MEN1*-positive and 21 *MEN1*-negative patients. The diagnosis of MEN1 occurred in 29 (28.7%) cases post-surgery (69% in *MEN1*-positive and 31% in *MEN1*-negative patients). Patients underwent several types of surgery: total PTX ($n=4$), subtotal PTX ($n=48$), PTX with cervical exploration ($n=12$), simple PTX ($n=37$); none of the *MEN1*-negative group underwent total or subtotal PTX. No significant difference was observed between the two groups in terms of remission rate (38.8 % vs 50%, $P=0.37$), persistence (32.5% cs. 28.6% $P=0.9$) and recurrence (28.7% vs 23.8% $P=0.16$). The median time to remission and recurrence was 84 (41-120) and 72 (36-120) months in *MEN1*-positive and 36 (12-36) and 36 (12-24) months in *MEN1*-negative respectively. By excluding patients who underwent total and subtotal PTX, we found a significantly higher rate of remission in *MEN1*-negative compared to *MEN1*-positive patients (50 % vs 10.7 %, $P=0.007$). We found a significantly higher rate of recurrence in *MEN1*-positive than in *MEN1*-negative patients (54% vs 20% $P=0.01$). No difference was found in the persistence rate between the two groups (35.7% vs 30% $P=0.9$). When including only patients who had simple PTX we observed a significant higher remission in MEN1-negative compared to MEN1 positive patients (35.7% vs 0%; $P=0.0087$). No difference in term of the rate of persistence (41% vs 36% $P=0.7$) and recurrence (59% vs 28%; $P=0.09$) was found between the two groups. Thirteen patients (12.7%) ($n=11$ subtotal, $n=2$ total PTX), all belonging to *MEN1*-genetic positive patients, developed a chronic post-surgical hypoparathyroidism. Only one patient, belonging to MEN1-positive group, developed permanent laryngeal palsy. According to our results, MEN1-negative patients might benefit from bilateral cervical neck exploration with selective removal of the pathological glands. This surgery could present a good trade-off between risk of recurrence/persistence and surgical complications.

Exploring complications associated with primary hyperparathyroidism: findings from an 83-case study

Gorgi Khaoula[1], Errahali Yassine[2], Lamya Echchad[1], Moktar Mohamed[1], Rifai Kaoutar[1], Iraqi Hinde[1] & Gharbi Mohamed El Hassan[1]
[1]Ibn Sina University Hospital, Endocrinology, Rabat, Morocco; [2]Mohamed V Military training hospital, Endocrinology, Rabat, Morocco

Introduction

Primary hyperparathyroidism (PHPT) is a common endocrinopathy caused by inappropriate PTH secretion by the parathyroid glands, which leads to alterations in phosphocalcic metabolism. The aim of our study is to determine the prevalence of complications of PHPT.

Materials and Methods

Retrospective descriptive study of 83 patients with primary hyperparathyroidism collected over a period of 07 years (between 2015 and 2022) in the endocrinology department at the Ibn Sina University Hospital of Rabat and in the endocrinology department of the Mohamed V training military hospital, Clinical and paraclinical parameters were collected from patient records.

Results

Our series encompasses 83 patients, with an average age of 53.27 years (range: 11-85), notably demonstrating a pronounced female predominance in 90.4% of cases. Functional manifestations were diverse, with 65.6% presenting with bone-related symptoms, 10.8% exhibiting urinary signs, 15.7% displaying digestive symptoms, 10.8% manifesting cardiovascular issues, and 6.5% experiencing neuropsychological and neuromuscular symptoms, along with a 6% incidence of QT interval shortening. Complications observed were widespread, with 48.2% exhibiting bone-related complications, encompassing fractures in 14.5% of cases and brown tumors in 9.6%. Bone densitometry, performed in 85.5% of cases, revealed osteoporosis in 33.7% and osteopenia in 20.5%. Additionally, digestive complications accounted for 4.8%, with two cases of pancreatitis, while renal complications were observed in 10% of cases. This comprehensive analysis provides a detailed overview of the clinical spectrum and complications associated with primary hyperparathyroidism in our patient cohort.

>Discussion & Conclusion

Primary hyperparathyroidism emerges as a disorder characterized by the inappropriate secretion of parathyroid hormone, consequently leading to hypercalcemia. Typically discovered incidentally due to elevated serum calcium levels or, less frequently, in the context of complications such as osteoporosis or, more rarely, digestive issues like pancreatitis. The clinical ramifications of PHPT are primarily associated with chronic hypercalcemia, hypercalciuria, or hyperparathormonemia. Within the skeletal system, excess parathyroid hormone fosters heightened bone resorption, suppressing osteoblastic activity while augmenting the osteoclast pool. This imbalance contributes to significant bone remodeling, reduced bone mineral density, and subsequently, the development of osteoporosis and bone fractures. In the renal system, there is an increase in tubular reabsorption of calcium and urinary excretion of phosphates, resulting in hypercalciuria. This elevated urinary calcium excretion can predispose individuals to episodes of renal lithiasis (20%) or, less commonly, nephrocalcinosis. The intricate interplay between parathyroid hormone, calcium metabolism, and renal function underscores the multifaceted clinical consequences of primary hyperparathyroidism.

Features of vitamin D metabolism during normal pregnancy

Ilana Katsobashvili, Ekaterina Pigarova, Svetlana Vorotnikova, Ekaterina Bibik & Larisa Dzeranova
Endocrinology Research Center, Moskva, Russian Federation

Introduction

Vitamin D plays an important role in the regulation of the mother-placenta-fetus systemensuring normal growth, weight and development of the fetus, reducing the risks of gestational diabetes mellitus, eclampsia and preterm labor. There is insufficient data in the literature on the vitamin D metabolic pathways in pregnant women, and the available results require confirmation using more accurate methods of determination.

Objective
To study of vitamin D metabolism peculiarities in normal pregnancy in comparison with a control group of healthy female patients.
Methods
Two groups of patients participated in the study: group 1- pregnant patients ($n=20$) from 18 to 45 years of age with gestational age from week 9 to 13; group 2 - healthy female patients ($n=19$) who underwent blood sampling for vitamin D metabolites to determine total 25(OH)D by immunochemiluminescence assay and 25(OH)D3, 3-epi-25(OH)D3, 24,25(OH)2D3, 1,25(OH)2D3 by high-performance liquid chromatography with mass spectrometric detection (HPLC-MS/MS).
Results
In group 1, the following results were obtained: total 25(OH)D, 26.1 ng/ml [17.4; 37.3], 25(OH)D3, 25.6 ng/ml [17.4; 37.3], 3-epi-25(OH)D3, 1.8 ng/ml [1.1; 3.2], 1,25(OH)D3, 33.4 pg/ml [16.1; 46.0], 24,25(OH)D3, 0.8 ng/ml [0.4; 1.5]. In group 2: total 25(OH)D - 16.7 ng/ml [13.5; 27.2], 25(OH)D3 - 19.5 ng/ml [14.0; 27.0], 3-epi- 25(OH)D3 - 1.1 ng/ml [0.75; 1.47], 1,25(OH)D3 - 38.8 pg/ml [34.0; 46.4], 24,25(OH)D3 - 1.5 ng/ml [0.82; 2.69]. For the above parameters, statistically significantly higher levels in the pregnancy group were obtained for total 25(OH)D ($P=0.02$) and 3-epi-25(OH)D3 ($P=0.002$). The ratio of 1,25(OH)D3/25(OH)D3 metabolites, reflecting 1-alpha-hydroxylase activity, was 0.00132 ng/ml [0.00067; 0.00206] vs 0.0021 ng/ml [0.00153; 0.00264] ($P=0.02$); the 25(OH)D3/24,25(OH)D3 ratio reflecting 24-hydroxylase activity was 24.1 ng/ml [18.6; 60.7] vs 11.6 ng/ml [10.9; 17.6], $P=0,003$, and the 3-epi-25(OH) D3/25(OH)D3 ratio reflecting 3-epimerase activity, 0.08 ng/ml [0.07; 0.10] vs 0.05 ng/ml [0.05; 0.6], $P=0.0004$, for group 1 and group 2, respectively.
Conclusions
The data obtained indicate that in the first trimester of pregnancy the epimerization of vitamin D increases, which raises the levels of this metabolite in the blood. A decrease in activation and increase in deactivation of vitamin D in pregnant women was also observed, which reflects the ratios of metabolites that characterize these processes.

The relationship between bone mineral density, vitamin d level and sleep quality in postmenopausal women with osteoporosis

Emir Avşar[1], Selda Celik[2], Hande Peynirci[3], Feride Taşkın Yılmaz[4] & Gülden Anataca[5]
[1]Yeditepe University, Faculty of Health Sciences, Department of Nursing, Turkey; [2]University of Health Sciences, Hamidiye Faculty of Nursing, Department of Internal Medicine Nursing, Turkey; [3]University of Health Sciences, Kanuni Sultan Suleyman Training and Research Hospital, Department of Endocrinology and Metabolic Diseases, Turkey; [4]Sakarya University of Applied Sciences, Faculty of Health Sciences, Department of Nursing, Turkey; [5]University of Health Sciences, Kanuni Sultan Suleyman Training and Research Hospital, Department of Diabetes Nursing, Turkey

Introduction
Osteoporosis is a skeletal disease characterized by decreased bone mineral density and destruction of the microarchitecture of bone structure. This study was conducted to determine the relationship between bone mineral density, vitamin D level and sleep quality in female patients with osteoporosis.
Material and Method
This descriptive correlational study included a total of 318 women diagnosed with osteoporosis. The data were collected using a patient identification form, including items for plasma vitamin D level and bone mineral density score obtained by DXA method, and the Pittsburgh Sleep Quality Index (PSQI). The data were analyzed using parametric and non-parametric tests according to whether they had normal distribution.
Results
The mean age of the women was 56.49 ± 5.68 years and their femoral neck T mean score, an indicator of bone mineral density, was -2.94 ± 0.31. Only 6.3% of the women had adequate vitamin D levels. In addition, according to their PSQI scores, 85.8% of the women had poor sleep quality. In the study, no significant difference was found between the women's bone mineral densities and vitamin D levels according to sleep quality ($P>0.05$). However, there was a weak negative correlation between the duration of osteoporosis and sleep quality ($P<0.05$).
Conclusion
The majority of the women diagnosed with osteoporosis had poor sleep quality. There was no association between vitamin D level, bone mineral density and sleep quality, but the duration of osteoporosis was negatively associated with sleep quality. Accordingly, it may be recommended to provide education and counseling to postmenopausal women diagnosed with osteoporosis on issues such as sunbathing, vitamin D and calcium preparation intake, weight control and non-pharmacological treatment approaches by making necessary individual-specific plans to improve sleep quality.

Keywords: Osteoporosis; bone mineral density, vitamin D; sleep quality.

Romosozumab therapy after parathyroidectomy for osteoporosis caused by primary hyperaparathyroidism: two case reports

Saya Takebe, Yasufumi Seki, Kaoru Yamashita, Noriyoshi Takano, Kananko Bokuda, Daisuke Watanabe, Satoshi morimoto & Atsuhiro Ichihara
Tokyo Women's Medical University, Department of Endocrinology and Hypertension, Tokyo, Japan

Background
Primary hyperparathyroidism (PHPT) reduces bone mineral density (BMD), leading to secondary osteoporosis. While parathyroidectomy has been reported to increase BMD, the efficacy of medical therapy for PHPT-induced osteoporosis after parathyroidectomy remains uncertain. Herein, we report two PHPT cases with osteoporosis, where romosozumab, an anti-sclerostin monoclonal antibody, increased BMDs after parathyroidectomy.
Case 1
A 67-year-old woman was admitted to our department with mild hypercalcemia (10.2 mg/dl) and elevated PTH levels. She was diagnosed with osteoporosis at the age of 55 and had taken 0.75 μg eldecalcitol and 60 mg raloxifene for six months before admission. Serum calcium (reference, 8.5-9.9) and intact PTH (reference, 15-65) were 9.4 mg/dl and 110 pg/ml, respectively. Echography and ^{99m}Tc-sestamibi (MIBI) scintigraphy revealed a 9 mm-sized parathyroid gland behind the left lobe of the thyroid. Dual-energy X-ray absorptiometry (DXA) indicated reduced BMDs with T-scores of -4.0 in the lumbar spine and -5.4 in the 33% radius. She was diagnosed with PHPT and underwent parathyroidectomy. Raloxifene was replaced with 210 mg/month of subcutaneous romosozumab 5 years after the surgery. The 12-month romosozumab therapy increased T-scores from -5.6 to -2.1 in the lumber spine and from -5.6 to -5.4 in the 33% radius.
Case 2
A 64-year-old woman with a history of urolithiasis was admitted with mild hypercalcemia (11.0 mg/dl) and elevated PTH levels. She had taken 20 mg of bazedoxifene and 0.25 μg of alfacalcidol since her diagnosis of osteoporosis at the age of 60. Serum calcium and intact PTH levels after cessation of alfacalcidol were 10.3 mg/dl and 161 pg/ml, respectively. Echography and ^{99m}Tc-MIBI scintigraphy revealed a 20 mm-sized parathyroid gland below the right lower pole of the thyroid. DXA scans indicated reduced BMDs with T-scores of -4.1 in the lumbar spine and -4.9 in the 33% radius. She was diagnosed with PHPT and underwent parathyroidectomy, followed by a 12-month romosozumab therapy. The romosozumab treatment increased T-scores to -2.8 in the lumbar spine and -4.9 in the 33% radius.
Discussion
We present two cases of PHPT with osteoporosis, which demonstrated improved BMDs by romosozumab therapy after parathyroidectomy, especially in the lumbar spine. The absence of prior bisphosphonate treatment may enhance the effect of romosozumab on BMDs. Our cases suggest romosozumab as a potential postoperative therapy for PHPT-induced osteoporosis.

9-year remission of severe primary hyperparathyroidism after high-dose cinacalcet treatment: case report

Michal Krcma
University Hospital, Diabetes & Endocrine unit, Pilsen, Czech Republic

Introduction
Parathyroid adenomas with marked hypercalcemia need in most of cases surgical treatment. Calcimimetic treatment is usually a bridging therapy to correct hypercalcemia (in combination with other approaches, e.q. bisphosphonates). We describe case of conservative treatment in a patient in whom surgical therapy was not possible due to severe acute pancreatitis and where a high dose of calcimimetics led to clinical, laboratory and graphic remission with the possibility of discontinuation of treatment.
Case report
A 64-year-old lady was admitted to our hospital for severe acute pancreatitis, triggered with hypercalcemia in primary hyperparathyroidism (iPTH 740 ng/l; Ca

3.4 mmol/l). Hypercalcemia was corrected with intravenous bisphosphonate and during very complicated and prolonged disease (from July to November) with impossibility of surgery it was necessary to proceed to treatment with high dose of cinacalcet (up to 180 mg three times a day). Initial graphic examinations (sonography, CT) showed a probable 10mm adenoma of the right lower parathyroid gland; in the acute condition we did not perform functional imaging. After resolution of pancreatitis, ^{99m}TC MIBI scintigraphy was performed, but the enlarged parathyroid gland (with same size) appeared to be inactive. We gradually reduced the dose of cinacalcet while controlling calcemia and managed to discontinue the treatment within 6 months. Further scintigraphy one month after discontinuation of treatment showed no accumulation of the isotope. In the next two years, calcemia and PTH levels remained normal. Further scintigraphy showed a reduction parathyroid adenoma to 5mm (corresponding sonographic finding) and physiological isotope accumulation. The patient remains under follow-up in our endocrinology outpatient clinic (also for secondary - post-pancreatic diabetes requiring insulin therapy) and over the next six years, she continues to have physiological calcium metabolism with adequate parathyroid hormone levels, need for D-vitamin replacement and osteopenia.

Discussion

A case report of parathyroid apoplexy followed by hypocalcemia as a consequence of cinacalcet administration is described in the literature. It is not clear whether our patient's case was a consequence of supramaximal treatment with cinacalcet or a result of a generally severe, months-long condition that could have led to ischemia of the adenoma. In any case, there was a remission of primary hyperparathyroidism lasting many years.

Introduction

Autosomal dominant hypocalcemia (ADH) type 1 is a rare form of hypoparathyroidism, caused by heterozygous, inherited or de novo, activating mutations in the *CASR*. CASR is also expressed in the kidney and activating mutations lead to decreased calcium renal absorption. Activating mutations in the CasR, inhibits salt transport, leading to Bartteŕs syndrome (BS) type V which can co-exist with ADH1. Chronic myeloid leukemia (Cml) is characterized by the clonal hyperproliferation of immature blood cells. Recently, CaSR has been raised as a targetable factor in Aml progression, however, data on its role in Cml are scarce.

Clinical presentation

33-year-old man was referred to the outpatient for poorly controlled hypoparathyroidism along with hypomagnesemia, and mild hypokalemia and dehydration. His hypoparathyroidism was diagnosed on the second day of birth. The patient presented nephrolithiasis and basal ganglia calcification. In 2020, he was also diagnosed with Cml. He was treated with calcium carbonate, alfacalcidol, cholocalciferol, hydroclorothiazide. He also received dasatinib for the Cml. At the outpatient, rhPTH was initiated along with magnesium supplements leading to reduction of the alfacalcidol and calcium supplements and to a better control of hypocalcemia and hypercalciuria. NGS was performed and demonstrated a genetic change (c.2486A>G) in exon 7 of the *CaSR*. The patient had a heterozygous substitution of adenine (TAT) for guanine (TGT) at codon 829.

Discussion

This is the third case of the specific mutation. In one case, mild Bartter V syndrome was also co-exist. The clinical presentations and onset timing of BS phenotype differ according to the type of mutation. Moreover, BS phenotype can differ between patients who have the same *CaSR* mutation, deteriorating the loss of water and predisposing to hypokalemia to varying extent. Of interest, this is the second case presenting with ADH1 and Cml. In the first reported case, severe hypocalcemia was triggered by imatinib leading to the diagnosis of underlying ADH1. CaSR has been found to modulate intracellular levels of Ca2+ and consequently calcium-dependent protein kinases which coordinate several signaling pathways (i.e. P-ERK and b-catenin) which are crucial to Cml malignant transformation in the same manner as *BCR-ABL* does. Conclusively,1)in Cml patients treated with TKIs and presented with severe hypocalcemia, the possible existence of ADH1 may need to be investigated, 2) a potential role *CASR* activating mutations in the pathogenesis and progress of Cml merits investigation.

Outcomes of parathyroidectomy in patients with primary hyperparathyroidism

Sameh Mezri[1], chaima zitouni[1], Wadii Thabet[2] & Khemaies Akkari[1]
[1]Principal Military Hospital, ENT, Tunis, Tunisia; [2]Taher Sfar Hospital, ENT, Tunis, Tunisia

Introduction

Hyperparathyroidism is the clinical and biological manifestation of excessive and inappropriate parathyroid hormone (PTH) production. It is the third most common endocrinopathy. It is often secondary to a single adenoma (80%). Occasionally, it may be a multi-glandular disease (15-18%). Treatment is surgical.

Objective

the aim is to evaluate therapeutic results after surgery for primary hyperparathyroidism.

Method

This is a retrospective study including 84 patients operated on for primary hyperparathyroidism in our department over a period from 2015 to 2023.

Results

The mean age of our patients was 49 years, with a clear female predominance. Patients presented osteoarticular signs in 60% of cases, renal signs in 29%, digestive signs in 15% and neuropsychic signs in 5%. Hyperparathyroidism was discovered incidentally on biology data in 32% of patients (27 cases). Mean calcemia was 2.8 mmol/l. Normocalcic forms were noted in 8.4% of cases. Malignant hypercalcemia was noted in 5.9% of cases. Hypovitaminosis D was found in 48% of cases. The mean PTH level was 411µg/l. Postoperatively, the rate of improvement in osteoarticular signs, renal signs, digestive signs and neuropsychic signs was 62%, 58%, 54% and 75% respectively. We noted normalization of PTH levels within 72 hours of surgery in 90.5% of cases. Failure was noted in 6 cases. This failure was related to incomplete surgery for a triple adenoma in 1 case, hyperplasia in 3 cases, glandular ectopy in 1 case and multiple endocrine neoplasia in 1 case.

Conclusion

Parathyroidectomy is the only curative treatment option available in primary hyperparathyroidism with high cure rates. This surgery can reduce symptoms and prevent further complications.

Hyperparathyroidism: secondary to myeloma or concomitant association

Hind Ouakrim, neima hassan, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Chu Mohamed Vi Marrakesh - Drh, Marrakech, Morocco

Introduction

Hyperparathyroidism is a pathological condition characterized by the excessive secretion of parathyroid hormone (PTH), resulting from the hyperactivity of one

or more parathyroid glands. This condition can manifest as primary, secondary, or tertiary hyperparathyroidism. However, determining the primary or tertiary origin of hyperparathyroidism can pose challenges in certain complex situations. In this report, we present a clinical case where identifying the primary or tertiary origin of hyperparathyroidism remains intricate.
Case Report
A 50-year-old patient with a three-year history of multiple myeloma complicated by end-stage renal failure requiring hemodialysis was diagnosed with hyperparathyroidism during routine medical follow-up. Despite maintaining a normal phosphocalcic balance, the patient reported diffuse bone pain and a general decline in health, with no other associated symptoms observed during the clinical examination. Sestamibi-Tc99 scintigraphy revealed three focal retentions of MIBI-Tc99m: one behind the upper right pole measuring 5.7×4.6 mm, one behind the lower right pole measuring 5.9×4.3 mm, and one behind the lower left pole measuring 5.6×4.8 mm. These findings suggested the presence of pathological parathyroid tissues, without any identified ectopic focus. Subsequently, the patient was referred for subtotal parathyroidectomy.
Discussion
Multiple myeloma is a hematologic malignancy characterized by osteolytic bone destruction resulting from increased osteoclastic resorption without a corresponding increase in bone formation. This process contributes significantly to the morbidity and mortality in multiple myeloma patients, leading to symptoms such as bone pain, diffuse osteopenia, focal lytic lesions, pathologic fractures, spinal cord compression, and hypercalcemia. Kidney failure, a common complication of multiple myeloma, can give rise to secondary and tertiary hyperparathyroidism. While both multiple myeloma (MM) and primary hyperparathyroidism (PHPT) are common causes of hypercalcemia, the simultaneous occurrence of these two pathologic processes in a single patient is exceedingly rare. Literature suggests that monoclonal gammopathies are more prevalent in patients with PHPT than in the general population, highlighting the importance of screening for monoclonal gammopathy in patients with PHPT. In the presented case, the patient had a history of kidney failure secondary to MM and presented with hyperparathyroidism. Sestamibi scintigraphy revealed hyperplasia of the parathyroid glands, consistent with both tertiary and primary hyperparathyroidism.
Conclusion
In cases where the origin of hyperparathyroidism remains challenging to determine, particularly when associated with multiple myeloma, careful consideration and further investigation are warranted. The coexistence of primary hyperparathyroidism with multiple myeloma represents a rare presentation, emphasizing the need for a thorough examination and comprehensive assessment.

Hypercalcemia caused by advanced chronic liver disease without malignancy: a rare entity
Nauman Jadoon
NHS Greater Glasgow & Clyde, Endocrinology, Glasgow, United Kingdom

Background and Aims
Hypercalcemia in patients with advanced chronic liver disease (CLD) without hepatic neoplasia is a rarely reported and poorly understood entity. CLD is usually associated with hypocalcaemia because of hypoalbuminemia. Hypercalcemia on the other hand is extremely rare and needs meticulous ruling out of other causes.
Methods
Here a case of 55-year-old male with hypercalcemia who had chronic liver disease in the absence of malignancy, is presented.
Results
A 55-year-old male who was admitted with jaundice, weight loss and hypercalcaemia. He had a calcium that peaked at 3.34 with a suppressed PTH (<0.4). Labs revealed worsening liver enzymes. Total bilirubin peaked around 9 days, at 149 umol/l, before starting to trend down. He had extensive evaluation of hypercalcemia. He had an urgent CTCAP to look for malignancy which found new diagnosis of liver cirrhosis with multi nodular liver and features of portal hypertension. Focal hepatic abnormality was difficult to exclude with the background of cirrhosis. He went onto have an MRI on which there were no discrete focal liver lesions although there was decompensation with ascites not seen on the first scan few days prior. His vitamin D was low, ruling out parathyroid adenoma or vitamin D toxicity. AFP and ACE levels were normal, as was TSH and T4, ruling out malignancy and hyperthyroidism as aetiology. Normal renal function ruled out renal aetiology for hypercalcemia. There was no evidence of granulomatous disease. He had raised IgG 21.2 but normal immunoglobulins. Serum electrophoresis and urine BJP were negative. No paraprotein detected, no urinary free light chains. After extensive work-up, no cause was found, and he was treated with IV fluids and given an IV infusion of bisphosphonate.
Conclusions
Hypercalcemia caused by advanced chronic liver disease in the absence of malignancy is a rare condition. It is a diagnosis of exclusion and responds well to bisphosphonate treatment, leading to resolution of hypercalcemia and prevention of further debility.

Early puberty and abnormal bone health: a comprehensive review
Ashraf Soliman, Nada Alaaraj, Fawzia Alyafei, Noor Hamed & Shayma Mohamed
Hamad General Hospital, Pediatric Endocrinology, Doha, Qatar

Introduction
The relationship between early puberty and abnormal bone health has garnered significant research attention, with varying outcomes.
Objectives
This review systematically examines studies up to March 2023 to determine whether early puberty is associated with abnormal bone health, specifically low bone mineral density (BMD), osteopenia, and osteoporosis. We analyze and summarize research articles ($n=25$) to elucidate the potential link between early puberty and the occurrence of abnormal bone health, particularly low BMD, osteopenia, and osteoporosis.
Results
Peak Bone Mass and Pubertal Timing: Peak bone mass (PBM), a critical determinant of osteoporosis risk and fractures, shares similarities with pubertal timing in terms of physiological variability and genetic influence. Factors influencing pubertal timing also affect bone acquisition. Fetal and infancy exposure to nutrients like vitamin D, calcium, and protein influence both traits. The Gothenburg Osteoporosis and Obesity Determinants study shows a negative association between age at peak height velocity (PHV) and bone density in young adult men. Using National Health and Nutrition Examination Survey (NHANES) data, a study reveals that an age of menarche ≥ 16 years is associated with lower lumbar spine (LS) BMD, even after adjusting for confounding factors. This suggests that late menarche may increase the risk of lumbar osteoporotic fractures. A large study on Swedish men finds that late pubertal timing is associated with increased adult fracture risk. Age at peak height velocity (PHV) predicts fractures, independent of factors like birth weight, childhood BMI, and adult height. Girls with idiopathic central precocious puberty (CPP) show increased bone mineral density, but this advantage wanes when corrected for bone age. GnRH agonist treatment seems to have no detrimental effect on bone mineral density. Longitudinal studies on British participants suggest that male participants gain bone density faster than females. Late pubertal age is associated with persistently lower bone mineral density in both genders. Studies analyzing GnRH agonist treatment in children with CPP reveal mixed results. While some suggest a reversible reduction in bone mineral density during treatment, others find restoration of bone mass after cessation of therapy.
Conclusion
Overall, this review highlights the complex relationship between early puberty and abnormal bone health. While some studies indicate associations between early puberty and decreased bone health, others emphasize the potential for recovery post-treatment cessation. Further research is necessary to fully elucidate the impact of early puberty on bone health, especially in the context of preventative measures for osteoporosis and fractures.

EP331

Denosumab therapy in diffuse sclerosing osteomyelitis – a case report
Mona Vahidi Rad, Samir Ahmed, Michael Whitaker & Aditi Kumar
Mayo Clinic, Endocrinology, diabetes and metabolism, Scottsdale, United States

Introduction
Diffuse sclerosing osteomyelitis (DSO) of the jaw is a chronic and rare condition that can present with recurrent and severe jaw pain and mandibular swelling. The treatment of this condition can often be quite challenging. We present a patient with mandibular DSO who had significant improvement in jaw pain with denosumab injections.
Clinical Case
A 23-year-old female presented with left mandible pain for 4 years. Her symptoms started after a blunt trauma to her jaw. Based on clinical features and

CT scan findings, she was diagnosed with chronic non-infectious osteomyelitis of the jaw. She was treated with oral appliances, trigger point injections, analgesics, anti-inflammatory medications, and oral steroids but only had minimal and temporary resolution in her pain. She was seen in endocrinology clinic and received denosumab which resulted in significant improvement and about 50% reducation in jaw pain. A second injection of denosumab was given 6 months later with continued improvement in her symptoms. Repeat imaging after denosumab injections revealed stable thickening and sclerotic signal changes in the body and angle of the left mandible corresponding to chronic osteomyelitis, without additional osseous abnormalities.

Discussion

There have been several medical and surgical options proposed to treat DSO. The typical medical treatment options include anti-inflammatory drugs, intravenous or oral antibiotics, corticosteroids, and analgesics for pain control. The medical treatment might often require several months and may not provide adequate pain control. There have been limited number of reports of using antiresorptive medications including bisphosphonates and denosumab to control pain and inflammatory activity in DSO. These antiresorptive treatments can potentially reduce pain and swelling via direct inhibition of the osteoclast activity that plays an important role in pathogenesis of DSO. Our patient with DSO experienced significant pain relief after denosumab injections. Given the potential risk of medication related osteonecrosis of the jaw (MRONJ) with antiresorptives, denosumab has the advantage of having a shorter half-life in bone compared with bisphosphonates thus decreasing the duration of risk for MRONJ.

Conclusion

Denosumab may be a promising treatment option for pain control in DSO. Additional studies are needed to further study the effects of denosumab and its roles in treatment of DSO.

EP333

Bone mineral density in women with breast cancer receiving adjuvant aromatase inhibitors and anti-resorptive treatment – healthy living after breast cancer

Rasmus Jansen[1], Djordje Marina[1], Simone Diedrichsen Marstrand[1], Michael Andersson[2], August Nielsen[1], Kristian Buch Larsen[1] & Peter Schwarz[1,3]

[1]Department of Endocrinology and Metabolism, Rigshospitalet, Copenhagen, Denmark; [2]Department of Oncology, Centre for Cancer and Organ Diseases, Rigshospitalet, Copenhagen, Denmark; [3]Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark

Introduction

Aromatase inhibitors, such as Letrozole or Exemestane, are often used as adjuvant treatment for post-menopausal breast cancer. However, they are known to reduce bone mineral density (BMD). Furthermore, breast cancer patients often undergo chemotherapy with drugs associated to BMD loss by themselves. Therefore, patients treated for breast cancer are subject to a considerable risk of BMD loss, and to alleviate this the treatments are normally combined with an anti-resorptive agent such as zoledronic acid or denosumab. These drugs have proven effective at stopping BMD loss during breast cancer treatment in several trials. A current oncological protocol is to use adjuvant i.v. zoledronic acid 4 mg every 6 months for 4 years while patients undergo treatment with aromatase inhibitors. We have investigated a group of women with breast cancer undergoing this protocol regime in a regular, clinical setting with the aim of determining whether all-cause BMD loss can be halted and/or reversed in an average, unselected population of women with early post-menopausal breast cancer.

Methods

A prospective study of BMD changes in post-menopausal women with breast cancer undergoing adjuvant treatment with aromatase inhibitors and anti-resorptive treatment in a clinical setting. We are currently following this cohort of women from diagnosis to finalized aromatase inhibitor treatment, and data presented here represent an interim analysis after two years of aromatase inhibitor treatment.

Results

A total of 79 women with a mean age of 59.4 years ($\pm$6.0) was included. BMD was measured by DXA-scan at baseline, after 12 months and after 24 months. In this interim analysis we found that adjuvant antiresorptive treatment significantly increases BMD after 12 months in all sites; in lumbar spine from 0.920 to 0.975 g/cm^2 ($P<0.001$), in total hip from 0.828 to 0.851 g/cm^2 ($P=0.006$) and in femoral neck from 0.704 to 0.725 g/cm^2 ($P=0.005$). All three sites remained significantly increased compared to baseline after 24 months ($P<0.001$ at lumbar spine; $P=0.017$ at total hip; $P=0.045$ at femoral neck).

Conclusion

Adjuvant treatment with anti-resorptive drugs can, in a short time, significantly improve BMD in women treated for early breast cancer with chemotherapy and aromatase inhibitors, in normal clinical practice.

Bone disorders in oncological patients treated with Immune-Checkpoint Inhibitors (ICIs)

Vasiliki Siampanopoulou[1], Anna Angelousi[1], George Lyrarakis[2], Athina Karampela[1], Petros Papalexis[1], Alexandros Lafioniatis[1], Chrysoula Mytareli[1], Elisavet Tasouli[1], Dimitrios Ziogas[2], Evanthia Kassi[3,4] & Helen Gogas[2]

[1]Unit of Endocrinology, First Department of Internal Medicine, Laiko General Hospital, National and Kapodistrian University of Athens, Athens, Greece; [2]First Department of Internal Medicine, Laiko General Hospital, National and Kapodistrian University of Athens, Athens, Greece; [3]Unit of Endocrinology, First Department of Propaedeutic and Internal Medicine, Laikon General Hospital, National and Kapodistrian University of Athens, Athens, Greece; [4]Department of Biological Chemistry, Medical School, National and Kapodistrian University of Athens, Athens, Greece

Background

The use of immune checkpoint inhibitors (ICIs) has been lately established as a promising and effective treatment in several solid malignancies. Endocrine-related adverse effects are common, however their effects on bone metabolism is unknown.

Methods

We retrospectively investigated the prevalence of bone-related complications in patients undergoing or completing treatment with ICIs. Epidemiological and clinical data from the medical files of 72 patients treated mainly for melanoma (90.2%) were recorded. Bone health metrics were determined by Dual Energy X-ray Absorptiometry (DEXA) scans and biochemical markers.

Results

In this study, a total of 72 patients were included, with a female to male ratio (54% vs 46%) and a mean age of 59.2 years for women and 64.8 years for men. Monotherapy with ICIs was administered in 48.6% of the cases, with nivolumab being the most common type (36.1%). Sequential and/or combination treatments were also administrated in 26.3% of the patients, including chemotherapy + ICI (9.8%), sequential ICIs (8.3%), Interferon A + ICI (4.1%) and Tyrosine Kinase Inhibitors (TKIs) + ICIs (4.1%). DEXA scans revealed normal bone density in 48.6% of the cases, osteopenia in 36.1% and osteoporosis in 15.2%. In all cases, bone density data were acquired in a mean time of 22.7 months post-ICI initiation. It should be noted that the patients with osteopenia or osteoporosis had no prior personal history of bone disease and did not receive any antiosteoporotic medication. No osteoporotic fractures were reported in any of our patients. Mean osteocalcin (BGP) levels in patients with osteoporosis and osteopenia were statistically significantly higher compared to those with normal DEXA [28 $\pm$ 11.6 ng/ml (p-value$=0.016$) and 22.8 $\pm$ 9.1 ng/ml (p-value$=0.013$) accordingly, vs 16.4 $\pm$ 9.8 ng/ml (p-value$=0.315$)].

Conclusions

Our findings suggest that bone health issues have a significant prevalence among oncological patients treated with ICI irrespective of the treatment schemes. Bone health is a parameter that should not be underestimated in oncological patients.

DOI: 10.1530/endoabs.99.EP334

Trabecular bone score and specific bone turnover markers in high-dose glucocorticoid therapy among individuals with graves' orbitopathy

Lukasz Gojny, Justyna Kuliczkowska-Płaksej, Aleksandra Jawiarczyk-Przybyłowska, Jowita Halupczok-Żyła & Marek Bolanowski

Wroclaw Medical University, Department of Endocrinology, Diabetes and Isotope Therapy, Wrocław, Poland

The Trabecular Bone Score (TBS) has recently been developed through the grayscale textural analysis of Dual-Energy X-ray Absorptiometry (DXA) images. Due to its capability to evaluate the microarchitectural texture of bone, TBS proves valuable in the assessment of bone quality. While the clinical relevance of TBS has been partially confirmed in relation to hormonal disorders, there is currently a lack of precise data regarding its application during specific phases of treatment for individuals with Graves' Orbitopathy (GO) undergoing high-dose glucocorticoid (GS) therapy. The objective of this investigation was to assess the utility of TBS testing and specific bone turnover markers at various stages of GO treatment. This evaluation aimed to identify their practical value in routine clinical practice. Between 2020 and 2023, the study focused on a cohort of 47 patients experiencing active moderate-to-severe GO who underwent treatment with intravenous methylprednisolone (MP). Within a subset of 29 patients treated from 2020 to 2022, the study evaluated the therapeutic effects on TBS, Lumbar Spine Bone Mineral Density (LS BMD), and Femoral Neck Bone Mineral Density (FN BMD). Another subgroup consisting of 42 patients treated during the

same period underwent an assessment of therapy impact on specific markers, including sclerostin (SCL), osteoprotegerin (OPG), osteocalcin (OC), and N-terminal telopeptide of type I collagen (NTX). BMS and TBS assessments were conducted immediately prior to the initiation of treatment and two months following the administration of the final dose of MP. Measurements of bone turnover markers were taken at the onset of treatment, preceding the sixth MP dose, subsequent to the 12th MP dose, and two months post the final MP dose. Within the cohort receiving treatment, statistically notable alterations in LS BMD and TBS were identified, showing a rise of 3% and 0.7%, respectively. Furthermore, within the subset of patients undergoing marker assessments, a decline in the average concentrations of SCL, OPG, NTX was noted, along with an increase in OC concentration. The findings from the conducted study indicate that BMD TBS exhibit comparable responses to high-dose corticosteroid therapy in individuals with thyroid orbitopathy. It has been verified that the use of MP in the treatment of thyroid orbitopathy leads to alterations in the rate of bone turnover. Given these observations, patients undergoing planned or ongoing MP therapy necessitate continual clinical assessment and enhanced diagnostic scrutiny to evaluate the risk of osteoporotic fractures and implement suitable preventive measures.

Association between reduced physical activity and 10-years risk of fracture in postmenopausal women with osteopenia/osteoporosis

Aikaterini Andreadi[1,2], Alessandro Minasi[1], Ilenia D'Ippolito[1], Maria Romano[1], Valeria Ruotolo[1], Marco Meloni[1,2], Francesco Maria Iafrate[1], Flavio Pozzi[1], Alfonso Bellia[1,2] & Davide Lauro[1,2]
[1]Policlinico Tor Vergata Hospital, Unit of Endocrinology and Diabetology, Rome, Italy; [2]University of Rome Tor Vergata, Department of Systems Medicine, Section of Endocrinology and Metabolic Diseases, Rome, Italy

We conducted a cross-sectional analysis on a sample of postmenopausal women ($n=88$, aged 66 ± 5 years) attending the osteoporosis outpatient service of our University Hospital between September and October 2023. All patients underwent physical examination and Dual Energy X-ray Absorptiometry (GE HealthCare-Lunar) scans at lumbar spine and hip level. 10-years risk of major osteoporotic fracture was assessed with the FRAX® algorithm. Level of physical activity was assessed by the International Physical Activity Questionnaire (IPAQ) - Short Form, whereas adherence to Mediterranean diet was evaluated by the Medi-Lite score. Associations were tested using logistic regression analysis, with dichotomic variables entered as follows: 10-years fracture risk $>20\%$ vs $<20\%$; being overweight/obese (BMI ≥25) vs normal weight (BMI ≤25); low level of physical activity (IPAQ class 3) vs moderate/high level (IPAQ class 1 or 2); low adherence to Mediterranean diet (Medi-Lite score <6) vs moderate/high adherence (Medi-Lite score 7-18). The majority of women had osteopenia (47%) or osteoporosis (41%) according to relative T-Score reference range. None reported a history of fracture. More than 90% of the patients were on anti-resorptive therapy (bisphosphonates, denosumab) and/or vitamin D supplementation, as appropriate. Approximately one-third of the patients (27.3%) were overweight or obese according to BMI (≥25). BMI ≥25 was significantly associated with having a 10-years risk of fracture higher than 20%, irrespective of age and concomitant medications (OR 1.28; 1.11-2.72, $P=0.038$). Being physical inactive according to IPAQ was significantly associated with having a 10-years risk of fracture higher than 20%, irrespective of age, concomitant medications and class of BMI (OR 1.76; 1.22-3.01, $P=0.004$), whereas no significant association were seen between adherence to Mediterranean diet and 10-years risk of fracture (OR 1.12; 0.76-1.91, $P=0.42$). Low level of physical activity assessed with a standardized self-administered questionnaire (IPAQ) turns out to be significantly related with a 10-years major osteoporotic fracture risk higher than 20% in an unselected group of post-menopausal women with osteopenia/osteoporosis. This relationship may be independent of body weight and adherence to Mediterranean diet. Since assessment of physical activity is currently not included in the FRAX® algorithm, these preliminary results deserve to be confirmed/better addresses in a broader population of post-menopausal women.

Pediatric case of autosomal dominant hypocalcaemia type 2 (ADH2) due to GNA11 gene mutation

Nada Akad[1,2], Maria Christina Ungureanu[1,2], Ana Tofan[3], Ioana Vasiliu[1,4] & Otilia-Andreea Tarcau[2]
[1]Universitatea de Medicină şi Farmacie "Grigore T. Popa" din Iaşi, Iaşi, Romania; [2]Saint Spiridon County Hospital, Iaşi, Romania; [3]Arcadia - Spitale şi Centre Medicale, Iaşi, Romania; [4]Saint Mary Emergency Children Hospital, Iaşi, Romania

Introduction
Autosomal Dominant Hypocalcemia (ADH) presents with low calcium and high phosphorus levels due to hypoparathyroidism. It is categorized into type 1, resulting from gain-of-function mutations in the calcium-sensing receptor (CASR), and type 2, caused by activating mutations in GNA11, a key mediator in CASR signaling. Our contribution involves reporting a rare case of pediatric ADH 2.
Case presentation
We present the case of a 9-year-old boy who first addressed the Department of Endocrinology Iasi to investigate short stature and low Body Mass Index (BMI) (Height at -2.89SD and BMI at - 4.46SD) and persistently low levels of calcium and PTH**.** In his medical background, we highlight the diagnosis of gut dysbiosis at the age of 6. It is important to mention that the older brother and the father experience chronic hypocalcemia, the father suffering from clinical manifestations of hypocalcemia. Hormonal and biochemical assessment eliminated the possibility of adrenal and thyroid dysfunction. Regarding somatotropic axis, the baseline values of GH and IGF1 were low with no adequate stimulation of GH when stimulated with arginine. Low IGF1 may be in the context of malnutrition, but this does not explain GH deficiency. HrGH treatment was initiated with height improving to -1.93SD in 18 months. Because of the alteration in phosphate-calcium balance, genetic testing was done. It was identified a heterozygous mutation of the GNA11 gene, c.178c>t (p.arg60cys), responsible for the development of ADH2. Treatment with calcitriol was underwent for 18 months. Calciuria begun to rise, and together with the elevated phosphates and the absence of symptoms lead to the therapeutic decision to stop calcitriol considering the risk of renal lithiasis and calcification of basal nuclei.
Discussion
The protein produced of GNA11 gene is the alfa subunit of G11 protein that functions alongside CASR in calcium regulation. The activating mutation of GNA11 is accountable of developing ADH2. Data from literature show that ADH2 is associated with a milder phenotype in terms of hypocalcemia and it is rarely associated with hypomagnesemia or hypercalciuria, possibly because CASR couples with proteins other than G11 in the kidney. ADH2 patients present more often short stature, implying that GNA11 plays a role in skeletal growth, and calcifications of the basal ganglia. The treatment is not recommended in asymptomatic patients.
Conclusion
Although genetic disorders are not a common cause of hypoparathyroidism, accurate diagnosis of the underlying genetic etiology is essential, affecting treatment goals, comorbidity screening, and family planning.

Elevated parathyroid hormone is not enough to make the diagnosis

Yordan Vlahov[1], Boyana Trifonova[1], Ralitsa Mekova[1], Antoniya Nikolova[1], Radina Ivanova[2], Gabriela Mateva[3], Pavel Bochev[3] & Anna-Maria Borissova[1]
[1]University Hospital Sofiamed, Sofia, Bul, Clinic of Endocrinology, Sofia, Bulgaria; [2]Medical University, Sofia, Bulgaria, Department of Pathology, Sofia, Bulgaria; [3]Acibadem City Clinic UMBAL mladost, Clinic of nuclear medicine, Sofia, Bulgaria

PTH increases calcium uptake from bone, tubular calcium reabsorption and renal phosphate excretion, and by stimulating 1α-OH vitamin D hydroxylase in the kidney increases production of 1,25(OH)2D.
Aim
To differentiate and characterize the various diseases associated with an increase in PTH in the material of the Endocrinology Clinic, Sofiamed University Hospital for 3 years.
Material
167 patients with elevated PTH were examined, 145 (87.3%) women and 21 (12.7%) men, with an average age of 62.01 ± 12.73 years (36-85 years). Patients are divided into two groups: 1. with Primary Hyperparathyroidism (PHPT), n-77; 2. with Secondary Hyperparathyroidism (SHPT), consisting of three subgroups - 2.1. with vitamin D deficiency (n-31) 2.2. with CKD stage 3-4 (n-39); 2.3. with CKD stage 5 (n-20).
Methods
Standard biochemical and hormonal studies of the mineral exchange, neckultrasonography, Spect-CT and fine needle puncture biopsy in 23% (38/167) of the patients.

Results
The oldest were the patients with SHPT with CKD pre-dialysis, and the youngest were the CKD patients on chroniodialysis compared to the other groups, $P<0.001$. The serum calcium was significantly higher in patients with PHPT, $P<0.001$. The serum level of phosphorus was significantly lowest in patients with PHPT and significantly highest in patients with SHPT on chroniodialysis, $P<0.001$. The same group also had a significantly higher level of alkaline phosphatase compared to patients with PHPT, $P<0.001$. PTH was significantly higher in patients with SHPT on chroniodialysis, $P<0.001$, and patients with PHPT had a significantly higher level of PTH only against patients with vitamin D deficiency, $P<0.001$. In chronodialysis SHPT group, eGFR was significantly lowest vs the other groups, $P<0.001$. There is a significant direct inverse relationship between the levels of 25(OH)D and PTH in patients with SHPT with CKD pre-dialysis and vitamin D deficiency. There is no dependence of PTH on the level of 25(OH)D in the other two groups - with PHPT and with SHPT of chroniodialysis due to the non-participation of vitamin D in the pathogenesis of both diseases. A significant correlation of eGFR/PTH is present in patients with CKD pre-dialysis, and it is absent in patients with PHPT and group with vitamin D deficiency.
Conclusion
Hyperparathyroidism requires complex investigations carried out by a highly specialized team with sufficient experience for correct diagnostic and subsequent therapeutic assessment.

Linear growth and response to GH therapy in short children with normal vs low IGF1 level and normal BMI at presentation

Ashraf Soliman, Fawzia Alyafei, Nada Alaaraj, Noor Hamed & Shayma Mohamed
Hamad General Hospital, Pediatric Endocrinology, Doha, Qatar

We conducted a longitudinal study on 95 children presented to pediatric clinic with short stature. Children were classified to low IGF1 (IGF1SDS <-1) ($n=25$) and normal IGF1 (IGF1SDS >-1) ($n=70$) and treated with human GH (0.03: 0.05 mg/kg/day) for 2 years. Anthropometrics data (HtSDS, difference from mid-parental height SDS (MPHSD), BMISDS, bone age and IGF1 level were studied for 2 years.
Results
At presentation, the age, bone age, HtSDS and Growth velocity (GV) did not differ significantly among the 2 groups. The peak GH response to provocation was lower in the low IGF1. Children with low IGF1 had lower BMI vs those with normal IGF1. GH stimulation using clonidine showed that 10/25 (40%) of patients with low IGF1 have GH deficiency (Peak <7) while 23/70 (32.8%) of patients with normal IGF1 had low peak GH to provocation (not significant). The IGF1/GH peak ratio was significantly higher in the normal IGF1 group vs the low IGF1 group (higher response of IGF1 for their peak level of GH). After an average of 2 years of GH therapy (0.03 -0.05 mg/kg/day), The IGF1 SDS increased significantly in both groups with higher levels in the normal IGF1 group. the HtSDS increased significantly in both groups ($P<0.01$) however, the increment was significantly higher in the Low IGF1 group (+1.2 SD) vs the normal IGF1 group (+0.74 SD).
Conclusion
Our data confirms good growth response to GH therapy and increment in IGF-1SDS in both low and normal IGF1 level with better growth response in the low IGF1 group.

Tumour-induced osteomalacia secondary to a toe mesenchymal tumour – a case report

Charlotte Choo & Nikhel Sachdev
Singapore General Hospital, Endocrinology, Singapore, Singapore

Tumour-Induced Osteomalacia (TIO) is a rare paraneoplastic syndrome that is often underdiagnosed given its non-specific manifestations. A 64-year-old Chinese male presented with chest discomfort and generalized weakness. He was treated for symptomatic iron deficiency anaemia, with two units of blood transfusion given his low haemoglobin of 6.1 g/dl; no intravenous iron replacement was given. Concurrently, laboratory results revealed a low phosphate level of 0.4 mmol/l [reference range: 0.94-1.50 mmol/l], requiring aggressive intravenous and oral phosphate replacements. Past medical history was significant for atrial fibrillation, dilated cardiomyopathy with an ejection fraction of 37%, myositis on mycophenolate mofetil, and glucocorticoid-induced osteoporosis – presently on drug holiday after three years of alendronate. There was no previous history of hypophosphataemia. On subsequent follow-up, he remained persistently hypophosphataemic (0.34-0.4 mmol/l). He had no symptoms to suggest gastrointestinal losses. His calcium and renal function were normal at 2.15 mmol/l [reference range 2.09-2.46 mmol/l] and 32 pmol/l [reference range 37-75 pmol/l] respectively. iPTH was mildly elevated 9.6 mmol/l [reference range 1.30 – 7.60 pmol/l], possibly contributed by Vitamin D insufficiency (21 ng/ml). In light of persistent hypophosphataemia, 24-hour urinary phosphate studies were pursued. The fractional excretion of phosphate of 32.9%, and the ratio of tubular maximum reabsorption rate of phosphate to glomerular filtration rate (TmP/GFR) of 0.43 mmol/l for a corresponding low phosphate reading of 0.76 nmol/l suggested renal phosphate loss. He had no syndromic features and has no family history of abnormal phosphate metabolism or skeletal disorders. Examination did not reveal palpable lymph nodes or masses, and was otherwise systemically unremarkable. Fibroblast growth factor 23 (FGF-23) was elevated at 102 pg/ml [reference range ≤59 pg/ml]. 1,25-Dihydroxyvitamin D was normal. Following the suspicion for TIO; ^{68}Ga-DOTATATE PET/CT was performed with tracer-avidity localising to the left big toe. This was confirmed subsequently on magnetic resonance imaging as an ill-defined 1.2 x 0.5 x 1.2 cm^3 T1 w/T2w hypointense, heterogeneously enhancing lesion at the lateral aspect of the hallux proximal phalanx. He was given phosphate, colecalciferol and calcitriol replacements and eventually underwent excision of the left big toe soft tissue tumour. Histology yielded monomorphic ovoid tumour cells, consistent with a phosphaturic mesenchymal tumour. Post-operatively, serum phosphate normalized as did FGF-23 to 24 pg/ml. This patient's insidious presentation of muscle weakness was initially perceived to be from symptomatic anaemia. His persistent hypophosphataemia led to an eventual diagnosis of TIO, with no overt clinical findings, highlighting the challenges in the diagnosis of TIO.

Introduction
Traditionally, obesity is thought to exert a positive impact on bone mineral density (BMD). However, the effect of adipose tissue on bone health is under investigation. Trabecular bone score (TBS) is a measure of bone texture, providing information on bone quality and microarchitecture, independently of BMD. Lower values of TBS indicate a worsening in bone quality and amplify fracture risk. Herein, we aimed to investigate the association of body composition and bone quality as evaluated by lumbar spine TBS.
Methods
We included 83 subjects (69 women and 14 men) with a mean age of 62.38years ± 10.48. There was no history of secondary osteoporosis, neither received anti-osteoporotic drugs. Body composition and lumbar spine TBS were evaluated by dual-energy X-ray absorptiometry (DXA). To determine the associations among the variables of interest linear regression analysis was performed (Stata Corp (2017)).
Results
Our analysis demonstrated that total fat mass is negatively associated with TBS ($P<0.01$). Moreover, total lean mass is positively correlated with TBS. Extending our analysis to examine the association of visceral adipose tissue (VAT) mass and arm fat mass with TBS, we demonstrated that VAT mass is negatively associated with TBS ($P<0.05$). Furthermore, we found that right and left arm fat mass, each one or combined, associated negatively with TBS ($P<0.05$), even after adjustment for age and weight. Each right and left arm lean mass or combined were positively associated with TBS reaching statistical significance ($P<0.1$).
Conclusions
Our study provide evidence that total fat and in specific VAT negatively impacts bone quality as it is estimated by TBS. It is known that VAT is the main source of proinflammatory adipocytokines provoking low grade inflammation that has potentially a negative impact on bone quality. We also showed for the first time that the body composition of the arms is correlated with the bone quality of lumbar spine, possibly underscoring the importance of the physical exercise of the upper part of the body in the bone quality of vertebrae.

The effect of denosumab treatment on metabolic and inflammatory parameters in postmenopausal osteoporosis

Gizem Gok, Aysen Akalin & Goknur Yorulmaz
Eskisehir Osmangazi University, Meselik Campus, Endocrinology, Turkey

Denosumab is a monoclonal antibody against RANKL used in the treatment of postmenopausal osteoporosis. RANK/RANKL/OPG cycle is effective on both immune system and osteoporosis. Some RANK mutations are associated with hypogammaglobulinaemia. There are studies suggesting that the RANK/RANKL pathway may mediate the development of insulin resistance and hepatosteatosis. However, the clinical effects of denosumab on inflammation and immunity are not well known. In this study, we aimed to investigate the effects of denosumab treatment on metabolic and inflammatory parameters. In our study, 30 patients who were over 50 years of age, had been in menopause for at least one year, had a lumbar vertebra or hip T score of -2.5 or below in bone mineral density measurement, or had a history of fragility fracture, and were unable to use or did not respond to other treatments, who applied to the outpatient clinics or were followed up in the wards of our hospital between November 2021 and March 2023 were included. Patients received 60 mg subcutaneous denosumab and standard doses of calcium and vitamin supplementation (1g elemental calcium + 880IU vitamin D3). Complete blood count, neutrophil/lymphocyte ratio, erithrocyte sedimentation rate (ESR), CRP, fibrinogen, ferritin, procalcitonin, D-dimer, homocysteine, fasting blood glucose, insulin, HOMA-IR, LDL, HDL, triglyceride, lipoprotein (a), calcium, albumin, phosphorus, parathormone, alkaline phosphatase parameters were evaluated retrospectively before and 1 month after treatment. In our study, no significant difference was found between the metabolic parameters analysed before and after denosumab administration ($P>0.05$). A significant decrease was found in calcium ($P=0.003$), phosphorus ($P<0.001$) and albumin ($P=0.005$) levels. A statistically significant increase was found in parathormone levels ($P<0.001$). Leukocyte ($P=0,042$), neutrophil ($P=0,042$) and monocyte ($P=0,034$) values before and after denosumab treatment showed a significant decrease. In our study, it was found that short term denosumab treatment had no effect on metabolic parameters. But it has been shown that it may have an effect on immune system responses and inflammation by reducing nerutrophil and monocyte levels.

Hyperparathyroidism in patients with acute fragility fractures

Anamarija Zrilic Vrkljan[1], Mirna Hrabar[1], Jelena Andric[1], Jelena Jaksic[2] & Vlatka Pandzic Jaksic[1]
[1]University hospital Dubrava, Department of Endocrinology, Diabetes, Metabolism and Clinical Pharmacology, Zagreb, Croatia; [2]School of Medicine, University od Zagreb

Background
An acute fragility fracture is considered a 'bone attack,' necessitating prompt treatment of osteoporosis. Standard clinical practice involves assessing the patient's clinical status, comorbidities, and secondary causes of osteoporosis, influencing the choice between osteoanabolic or antiresorptive therapy. Normocalcemic hyperparathyroidism is common among fragility fracture patients. While it is commonly associated with vitamin D deficiency and chronic kidney disease, this study aims to investigate other variables that may also influence parathyroid hormone (PTH) levels.
Methods
Within the Fracture Liaison Service, we retrospectively studied 249 consecutive patients aged 50 and above with no prior anti-osteoporotic therapy, hospitalized for acute fragility fractures (hip, vertebra, distal forearm, humerus, pelvis). Participants were categorized into two groups based on normal or high PTH levels, excluding those with typical primary hyperparathyroidism. We analyzed the prevalence of secondary causes of osteoporosis (vitamin D deficiency, chronic kidney disease, premature menopause, hyperthyroidism, malabsorption, monoclonal gammopathy, use of corticosteroids, aromatase inhibitors, and chemotherapy), as well as the presence of diabetes and malignancies. We also collected data on serum creatinine, albumin, calcium, phosphorus, 25-hydroxy vitamin D, leukocytes, and CRP, and calcium in urine samples.
Results
Among all participants, 91 (36.5%) had high PTH, and 158 (63.5%) had normal PTH levels. Patients with high PTH were older, less likely to receive vitamin D supplementation before the fracture, and showed a higher prevalence of aggregated secondary causes of osteoporosis and diabetes ($p\leq0.01$). Secondary causes of osteoporosis, excluding hyperparathyroidism and chronic kidney disease, were more common in the normal PTH group ($P<0.01$). No difference in malignant disease presence was observed between groups. The high PTH group had significantly higher creatinine but lower albumin, albumin-corrected calcium, phosphorus, urine calcium, and 25-hydroxy vitamin D ($P<0.05$). CRP at admission was also significantly higher in this group ($P=0.028$), while leukocyte count showed no difference. In the multiple regression model, PTH levels were independently predicted by higher creatinine, lower 25-hydroxy vitamin D, albumin-corrected serum calcium, urine calcium, and phosphorus. Diabetes, female gender, and advanced age entered as independent predictors of PTH too ($R2=0.37$).
Conclusion
Hyperparathyroidism often prevents or postpones timely osteoanabolic therapy after fragility fractures. It is essential to recognize bone metabolism markers beyond the conventional ones that impact elevated PTH levels and to intervene accordingly. The modest proportion of variance explained by standard laboratory and clinical parameters in our model suggests the presence of other unknown variables influencing PTH levels, emphasizing the need for further investigation.

Differences of bone mineralization in individuals with klinefelter syndrome compared to hypogonadotropic hypogonadism under long-term testosterone replacement therapy

Roza Sabia[1], Nina Fischer[2], Felix Wüste[2], Gisa Ufer[2], Lena Rauschek[2], Martin Heni[2], Martin Wagner[2] & Burkhard Manfras[2]
[1]Ulm University Medical Center, Department of endocrinology diabetes and metabolic diseases, Ulm, Germany; [2], Ulm, Germany

Introduction
Klinefelter syndrome has been associated with decreased bone density most likely due to testosterone deficiency. Furthermore, a negative effect of long-lasting follicle-stimulating hormone (FSH) excess (starting from puberty) on trabecular bone has been suggested. Other endocrine mechanisms, such as global Leydig cell dysfunction, higher oestradiol levels, altered 25-OH vitamin D levels, and genetic aspects related to the supernumerary X chromosome might be involved. An increased risk for vertebral fractures has been reported as a complication of Klinefelter syndrome despite testosterone replacement therapy.
Objective
This study aimed to investigate bone health in a cohort of individuals with Klinefelter syndrome (KS) compared to patients with hypogonadotropic hypogonadism (HH) considering the influence of testosterone replacement therapy.
Methods
Ten individuals with known KS (23-78 years) and 15 individuals with HH (33-87 years) were submitted in regard to metabolic markers, bone density (BMD), bone formation markers (alkaline phosphatase and osteocalcin), a bone turnover marker (beta-crosslinks) and 25-OH vitamin D levels. BMD was measured by dual-energy X-ray absorptiometry (DXA) and expressed as T-scores. Nine of the KS individuals and 14 of the HH patients administered testosterone replacement therapy. Serum levels of testosterone, FSH, 25-OH vitamin D and bone markers were measured by commercial immunoassays in a routine clinical laboratory.
Results
All but one individual treated with exogenous testosterone had a bone mineral density within the normal range. Patients with KS had higher FSH concentrations ($P=0.0043$) but testosterone levels were comparable. The T-score of bone mineral density was found to be lower in lumbar spine than in the femoral neck in KS patients. In contrast, in HH individuals T-score of bone mineral density of lumbar spine was similar to T-scores of the femoral neck, demonstrating a difference in bone mineralization of the lumbar spine in KS vs HH ($P=0.04$). Bone formation biomarkers (alkaline phosphatase, osteocalcin) and the bone turnover biomarker were comparable between groups.
Conclusions
Despite comparable bone markers, we found significantly lower lumbar spine bone mineralization in patients with Klinefelter syndrome compared to hypogonadotropic hypogonadism under long-term testosterone replacement therapy. The underlying mechanism of this observation remains to be identified but may explain the previously reported increased risk of individuals with Klinefelter syndrome for vertebral fractures.

A tertiary center experience on denosumab treatment

Alexandra Balasa[1], Andreea Manole[1], Ramona Dobre[1,2], Madalina Sorohan[1,2] & Catalina Poiana[1,2]
[1]National Institute of Endocrinology "C.I. Parhon", Bucharest, Romania; [2]University of Medicine and Pharmacy "Carol Davila", Bucharest, Romania

Background
Osteoporosis is a chronic metabolic bone disease, highly prevalent in the elderly population, especially in postmenopausal women. Denosumab is a potent anti-resorptive drug, which can be used as an initial therapy or as an alternative therapy in the treatment of osteoporosis.
Objective
We aimed to analyze the characteristics of patients, the evolution of bone mass density (BMD) and trabecular bone score (TBS) and the factors associated with fragility fractures, all under treatment with Denosumab.
Methods
Between Nov 2013 and Nov 2023, 1375 patients were diagnosed with osteoporosis in our center, of which 184 patients received treatment with Denosumab and we had follow up for 81 patients, which included osteodensitometric (DXA scan) evaluation before and after the treatment with Denosumab and radiological vertebral fracture assessment.
Results
The patients had a mean age of 72 years, 98.8% women (97.5% postmenopausal), with an average BMI of 25.31 kg/m^2, 95% had an osteodensitometric score of osteoporosis and the median period of therapy with Denosumab was 3 years. The batch had an average lumbar spine T score of -3 DS and a TBS value of 1.235. Under Denosumab therapy, BMD increased at the level of all segments, the increase being statistically significant at the lumbar spine and the hip. Twenty-eight percent of patients presented secondary causes of osteoporosis: Hyperthyroidism (9.9%), diabetes 7.4%, hyperthyroidism (4.9%), acromegaly (2.5%), glucocorticoids therapy (2.5%), and hypogonadism (1.2%). We detected a history of old fragility fractures in 78% of the patients, the most common being vertebral fractures (48%). Before undergoing treatment with Denosumab 92% underwent treatment with bisphosphonates, 14.8% also with teriparatide and only 2% were treatment naive. Ten percent of patients suffered a fragility fracture during Denosumab therapy. We performed a comparative analysis of the group according to the occurrence of fragility fractures during Denosumab treatment and observed that patients with new fractures on therapy had significantly lower TBS at follow up and had a history of old hip fractures.
Conclusions
Fracture prevention is the main treatment goal in osteoporosis, as the fractures can be debilitating and can increase the likelihood of death. Denosumab has clear indications for osteoporotic patients and it is an effective treatment, that leads to substantial increases in bone mass. The potential for fractures to occur upon treatment, especially at patients with a history of old hip fractures and those who have lower TBS at follow-up, as seen in our study, requires close-up management.

Maternal vitamin d supplementation during pregnancy and lactation: effects on maternal and infantile vitamin d status

Ashraf Soliman, Fawzia Alyafei, Nada Alaaraj, Noor Hamed, Shayma Mohamed & Maya Itani
Hamad General Hospital, Doha, Qatar

This review assessed recent literature (RCTs, longitudinal studies, meta-analyses) from the past decade via PubMed, Google Scholar, and Scopus to gauge the impact of prenatal and postnatal vitamin D (VD) supplementation on maternal and infantile vitamin D status.
Results
We analyzed 12 studies ($n=6253$ mothers). In a prospective interventional study involving 80 women who received two doses of VD injections (600,000 IU/ml each), 60% of women displayed unsatisfactory VD levels despite high-dose treatment. A randomized study of 180 women at 27 weeks' gestation explored different vitamin D supplementation strategies: a single oral dose of 200,000 IU VD, a daily supplement of 800 IU VD from 27 weeks until delivery, and a no-treatment group. Supplemented groups exhibited significantly higher 25-hydroxyvitamin D (25OHD) levels and lower secondary hyperparathyroidism instances. Cord blood 25OHD levels significantly increased with maternal supplementation. Maternal supplementation during lactation elevated infant serum 25OHD levels, with higher doses proving more effective in boosting infantile 25OHD. Maternal supplementation with 50 μg VD_3/d during gestation safeguarded 98% of unsupplemented breastfed infants from VDD (<30 nmol/l) for at least 8 weeks. In comparison, 10 or 25 μg VD/d protected only 57% and 84% of infants, respectively. Maternal VD supplementation dosages displayed nonlinear effects on maternal and infantile 25OHD concentrations. High doses (≥ 6000 IU/day) effectively rectified VDD in both mothers and infants. A maternal dose of 6400 IU/day surpassed the 400 and 2,400 IU doses in achieving VD sufficiency. A longitudinal study involving 6-month maternal supplementation with 6000 IU resulted in 96% of mothers attaining adequate serum 25(OH) D levels (≥ 50 nmol/l), compared to 52% for those on 600 IU ($P<0.0001$). Infants born to mothers on 600 IU, supplemented with 400 IU vitamin D3, displayed slightly higher serum 25OHD levels compared to those born to mothers on 6000 IU alone. Among Arab women randomized at 12-16 weeks' gestation, supplementation with 400, 2000, and 4000 IU/d VD3 demonstrated that higher maternal doses were more effective in increasing maternal and infant 25OHD levels. In another study, maternal supplementation with 4000 IU of vitamin D during lactation resulted in adequate serum vitamin D levels in $>90\%$ of infants.
Conclusion
For breast-fed infants, a recommended dose is 400 IU vitamin D3/day. Alternatively, maternal supplementation with 4000 to 6,400 IU vitamin D3/day during pregnancy and lactation can augment breast milk's vitamin D content, offering a practical choice.

Distinctive features of primary hyperparathyroidism in multiple endocrine neoplasia type 2a: a series of five cases

Gorgi Khaoula[1], Echchad Lamya[1], Rifai Kaoutar[1], Iraqi Hinde[1] & Gharbi Mohamed El Hassan[2]
[1]Ibn Sina University Hospital, Rabat, Morocco; [2]Ibn Sina University Hospital, Endocrinology, Rabat, Morocco

Introduction
Multiple endocrine neoplasia type 2A (MEN2A) is a rare genetic condition characterized by medullary thyroid cancer (MTC), often accompanied by primary hyperparathyroidism (PHPT) in 20% to 30% of cases which is usually detected while investigating other issues and is not commonly the initial indicator of the condition. This study aims to describe the specific features of primary hyperparathyroidism (PHPT) in MEN2A, providing insights into its distinct characteristics for a better understanding of this complex endocrine disorder.
Subjects and methods
This retrospective and descriptive study covers a period of seven years and focuses on the clinical data of five individuals with Multiple Endocrine Neoplasia Type 2A (NEM2A) due to genetic alterations in the RET gene. The study was conducted at the Department of Endocrinology, Diabetology, and Metabolic Diseases at Ibn Sina University Hospital of Rabat, Morocco.
Results
The average age at diagnosis of PHPT was 26.8 years. Renal lithiasis was observed in only one patient, and another presented with a fracture. The parathyroid hormone (PTH) level was notably elevated, measuring 182.2 pg/ml (normal range: 8-76), and the mean serum calcium level was 101.2 mg/l (normal range: 85-105). Parathyroid ultrasound revealed lesions in all patients, leading to surgical intervention in each case. The surgical approach involved the excision of one to three parathyroids.
Discussion & Conclusion
Our study elucidates the frequent manifestation of primary hyperparathyroidism (PHPT) in individuals diagnosed with Multiple Endocrine Neoplasia Type 2A (NEM2A). PHPT is commonly identified during lesion assessments, serving as an incidental rather than a primary diagnostic indicator. Noteworthy is the frequent observation of normocalcemic presentations, potentially attributed to prevalent vitamin D deficiencies in contemporary populations. The adoption of systematic screening protocols proves instrumental in achieving early detection, thus contributing to a more favorable prognosis and timely therapeutic interventions in the context of NEM2A-associated primary hyperparathyroidism.

Assessment of vitamin d status in patients with primary hyperparathyroidism: implications for clinical management

Gorgi Khaoula[1], Errahali Yassine[2], Echchad Lamya[1], Rifai Kaoutar[1], Iraqi Hinde[1] & Gharbi Mohamed El Hassan[1]
[1]Ibn Sina University Hospital, Endocrinology, Rabat, Morocco; [2]Mohamed V Military training hospital, Endocrinology, Rabat, Morocco

Introduction
Primary hyperparathyroidism is frequently accompanied by low vitamin D levels. This study aims to assess the vitamin D status of patients diagnosed with primary hyperparathyroidism, with a focus on determining the prevalence of insufficient and deficient 25(OH) D levels in this patient population.
Patients and Methods
Conducted as a retrospective study over a 7-year period (2015-2022), our research was carried out at the endocrinology-diabetology department of CHU IBN SINA RABAT and the Mohamed V military hospital in Rabat. The study concentrated on patients hospitalized for primary hyperparathyroidism, analyzing their vitamin D levels.
Results
A total of 63 patients, with an average age of 55.8 years, were included in the study. Systematic measurement of vitamin D levels revealed a mean serum 25(OH)D level of 19.20 ng/ml. Notably, 18% of patients had vitamin D insufficiency, while 60.7% exhibited vitamin D deficiency. In patients with low vitamin D, the average serum calcium was 121.8 mg/l, and the mean parathyroid hormone (PTH) level was 261.7 ng/ml. Patients with insufficient vitamin D displayed higher PTH and blood calcium levels compared to those with normal vitamin D levels.
Discussion/Conclusion
Primary hyperparathyroidism is commonly associated with vitamin D deficiency, resulting in more pronounced bone damage and a significant elevation in blood calcium and parathyroid hormone levels. This study emphasizes the importance of vitamin D supplementation in individuals with primary hyperparathyroidism who have deficient or insufficient 25(OH)D levels.

Hungry bone syndrome following parathyroidectomy for primary hyperparathyroidism treatment: a report on three cases

Gorgi Khaoula, Cheibetta Zakaria, Lamya Echchad, Rifai Kaoutar, Iraqi Hinde & Gharbi Mohamed El Hassan
Ibn Sina University Hospital, Endocrinology, Rabat, Morocco

Introduction
Hungry Bone Syndrome (HBS) is characterized by a profound and persistent state of hypocalcemia, typically observed following parathyroidectomy or thyroidectomy. This syndrome manifests in the postoperative period, and its occurrence is associated with extended exposure to elevated levels of parathyroid hormone (PTH) or thyrotoxicosis. This prolonged exposure results in heightened bone turnover rates, marked by a net loss of bone minerals through resorption. We report three cases of Hungry bone syndrome after parathyroidectomy for primary hyperparathyroidism.
Cases
Three patients, aged 46, 78, and 58, presented with altered general conditions, prompting a work-up revealing hypercalcemia (185 mg/l, 141 mg/l, and 140 mg/ml, respectively), hypophosphatemia (19 mg/l in all cases), and elevated parathyroid hormone levels indicative of hyperparathyroidism (4936 pg/ml, 392 pg/ml, and 420 pg/ml, respectively). Initial medical management included rehydration and intravenous bisphosphonates administration. Following localization workup confirming a parathyroid origin, parathyroidectomy was performed in each case, revealing parathyroid adenomas on anatomopathological examination. Post-operatively, all patients experienced prolonged hypocalcemia and hypophosphatemia with normal PTH levels, consistent with the diagnosis of Hungry Bone Syndrome (HBS). These cases underline the clinical challenges and postoperative complications associated with hyperparathyroidism and emphasize the importance of vigilant management in mitigating adverse outcomes.
Dicussion & Conclusion
Hungry Bone Syndrome (HBS), though infrequent, manifests as a severe and enduring condition characterized by profound hypocalcemia. The severity of hypocalcemia stems from a substantial escalation in calcium utilization by the skeletal system. This heightened demand is a consequence of the abrupt cessation of bone resorption, despite persistently elevated circulating parathyroid hormone (PTH) levels, leading to a rapid and pronounced shift towards increased bone formation. The therapeutic approach to HBS is focused on rectifying the substantial calcium deficit and reinstating normal bone turnover. This is achieved through the administration of high doses of calcium and active metabolites or analogues of vitamin D, aiming to restore the delicate balance of bone metabolism and alleviate the severe hypocalcemic state associated with this syndrome.

Hypercalcemic crisis in pregnancy, a case report

Nour El Houda Bedrane & Khiter Chafika
Centre Hospitalier Intercommunal de Villeneuve-Saint-Georges, Lucie & Raymond Aubrac, Val de marne, Villeneuve-Saint-Georges, France

Introduction
Hypercalcemic crisis is a rare therapeutic emergency, but one that should not be overlooked, particularly during pregnancy, when it is associated with significant maternal-fetal morbidity. The most frequent etiology is PHPT, including during pregnancy.
Observation
We report the case of a 34-year-old patient with no particular pathological history, pregnant at 34 weeks of amenorrhea, who presented with acute cholecystitis. The blood test showed malignant hypercalcemia at 3.56 mmol/l, hypophosphatemia and elevated PTH at 30.7 pg/l (1.9-8.5). Good fetal vitality but IUGR. We started with hydration, and after discussion with the gynecologists, we decided not to start FUROSEMIDE because of the risk of placental hypo-perfusion and worsening of the IUGR. Cervical ultrasound revealed a 7 mm parathyroid adenoma. Given the relative contraindication to bisphosphonates and calcinomimetics, and after a collegial decision, we requested a F-choline PET scan, which was concordant with the ultrasound. We had a choice between either minimally invasive surgery under local anaesthetic and parahyroidectomy with acouhement at term, or Caesarean section, extraction of the baby and subsequent conventional parathyroid surgery. In the end, we opted for the first solution, given the baby's IUGR. methoxylated

derivatives of catecholamines are negative in the NEM2 hypothesis. Following the operation, blood calcium and PTH levels returned to normal.
Conclusion
Hypercalcemic crisis is rare, particularly during pregnancy, and is responsible for high maternal-fetal morbidity: miscarriage, IUGR. The etiological and therapeutic management during pregnancy is complex, and there are few recommendations. A multidisciplinary approach is required.

Calcium- alkali syndrome: an endocrine complication in the management of hypoparathyroidism

Eleni Kouroglou[1], Efthymia Kallistrou[1], Stella Proikaki[1], Anastasia Dede[2], Sofia Dionysopoulou[1], Georgios Gavriiloglou[1], Dimitra Ragia[1], Vasiliki Tsiama[1], Konstantinos Belis[1], Ioannis Ilias[1] & Christos Savvidis[1]
[1]Hippocration General Hospital of Athens, Department of Endocrinology, Athens, Greece; [2]Chelsea and Westminster Hospital, London, United Kingdom

Background
Milk- alkali syndrome (MAS), characterized by the triad of hypercalcemia, metabolic alkalosis, and renal dysfunction, is increasingly recognized as a complication of calcium supplementation, particularly in the management of hypoparathyroidism. Some have proposed should be called calcium- alkali syndrome (CAS). We delineate two cases of CAS and provide a review of relevant literature, emphasizing the endocrine aspects of CAS.
Case Presentations
The first case details a 52-year-old male with iatrogenic hypoparathyroidism post-thyroidectomy, who developed marked hypercalcemia (corrected serum calcium: 13.1 mg/dl) and acute kidney injury (serum creatinine: 2.8 mg/dl) and alkalosis (pH: 7.52, $HCO3^-$: 33.5 mmol/l, PCO_2: 41mmHg). This was attributed to olmesartan/hydrochlorothiazide, alphacalcidol, calcium carbonate and cholecalciferol. Treatment included intravenous hydration and medication titration, leading to calcium level normalization. The second case involved an 83-year-old woman with a background of hypoparathyroidism, presenting with cognitive impairment and hypercalcemia (corrected serum calcium: 15.36 mg/dl) and acute kidney injury (serum creatinine: 2.6 mg/dl) and alkalosis (pH: 7.51, HCO3: 33.5 mmol/l, PCO_2: 42mmHg) secondary to alfacalcidol, irbesartan and calcium carbonate ingestion; renal function was also compromised. Intravenous fluid administration and medication dose adjustment led to clinical improvement; renal impairment remained.
Discussion
The pathophysiology of CAS is anchored in hypercalcemia-induced nephropathy, precipitated by excessive exogenous calcium intake. This initiates a cascade involving decreased glomerular filtration, enhanced renal calcium reabsorption. Volume depletion promotes tubular reabsorption of bicarbonate creating metabolic alkalosis which in turn decreases renal calcium excretion enhancing metabolic alkalosis. Clinical manifestations are varied, ranging from subacute neuromuscular symptoms to chronic renal insufficiency. Historically associated with antacid overuse, the contemporary landscape of CAS has shifted towards excessive calcium supplementation in the context of osteoporosis, post-surgical hypoparathyroidism, and specific demographics like postmenopausal women or those with renal insufficiency.
Conclusion
These cases highlight the importance of cautious calcium supplementation in hypoparathyroidism management. Endocrinologists and healthcare providers should maintain a high index of suspicion for CAS, especially in predisposed subjects, and advocate for regular serum calcium monitoring. Adjustments in calcium and vitamin D supplementation must be made judiciously to prevent the potentially serious complications of CAS, including irreversible renal damage.

Diagnostic value of daily calciuria on a strict diet in patients with primary hyperparathyroidism

Michal Popow & Sebastian Szewczyk
Warsaw Medical University, Endocrinology, Warsaw

Diagnostic value of daily calciuria on a strict diet in patients with primary hyperparathyroidism. The most common cause of primary hyperparathyroidism is monoclonal hyperplasia of a single mutant cell. Most somatic mutations found in adenomas regulate the cell cycle by increasing the speed of cell division. This means that stimulating stimuli, such as negative calcium balance, increased phosphorus retention, disturbances of the calcitriol/VDR/FGF23/KLOTHO axis, or lack of inhibitory stimuli, such as estrogen deficiency, will favor the development of adenomas. One of the causes of stimulation of parathyroid cell division is chronic renal calcium loss. The aim of the study was to assess daily calciuria in a population of patients with hyperparathyroidism hospitalized at the Department of Endocrinology of the Medical University of Warsaw. Due to the predominant hyperabsorptive nature of hypercalciuria, two daily urine collections were performed in the studied patients on a standard diet and on a strict diet. The results were correlated with the assessment of the urinary system for nephrolithiasis and the level of vitamin D. The results showed significant differences in calcium excretion on a regular and strict diet in some patients, which was interpreted as the possibility of co-occurring mild tubulopathies. A negative calcium balance would promote increased proliferation of a clone of parathyroid cells whose cell cycle is disrupted by the presence of the somatic mutation.
Conclusion
Assessment of fasting 24-hour calciuria as an adjunct to routine 24-hour calciuria testing may help determine the cause of stimulation of a clone of cells with a somatic mutation predisposing to hyperparathyroidism

Exacerbation of hypercalcaemia in primary hyperparathyroidism following immobilisation in the elderly

Timothy Green, Rhiannon Berkeley, Genevieve Tellier & Anthony Wilton
Bangor Hospital, Endocrinology, Bangor, United Kingdom

Primary hyperparathyroidism is a common cause of hypercalcaemia increasing in prevalence with age peaking in females at 70-90 years of age (492 cases/100,000 population) and in males above 80 years of age (264 cases/100,000 population). Immobilisation hypercalcaemia is regarded as an uncommon non-parathyroid hormone dependent cause of hypercalcaemia typically occurring in young patients with spinal cord injuries and neuromuscular disorders. It is of complex physical and molecular aetiology with increased osteoclast activity predominating over osteoblast activity resulting in bone loss and hypercalcaemia. When superimposed on primary hyperparathyroidism confusion as to the aetiology of the hypercalcaemia can occur.
Case studies
We describe the cases of two elderly females (92 years of age case 1 and 77 years of age case 2) with known 'asymptomatic' primary hyperparathyroidism. Both were independently living prior to hospitalisation with recent falls. Both had acute kidney injury and biochemical evidence of mild primary hyperparathyroidism. Following admission they were immobile due to the sustained soft tissue injuries and calcium levels significantly increased despite a fall in parathyroid hormone levels. Beta-cross laps were raised in both and case 1 had vitamin D deficiency. Both developed delirium prolonging their immobilisation. Case 1 was initially treated with cinacalcet which was ineffective. Treatment with intravenous pamidronate lowered calcium levels with a rise in PTH levels and resolution of delirium and acute kidney injury. Mobilisation maintained calcium at 'asymptomatic' pre-admission levels.
Discussion
Despite the high prevalence of the falls, immobilisation and hyperparathyroidism triad in the elderly there is a paucity of cases reporting hypercalcaemia. The commonest reported causes of hypercalcemia in the elderly being primary hyperparathyroidism and malignancy. Hypercalcaemia causes neurological, muscular and psychiatric symptoms in the elderly at a lower level than in younger patients which may contribute to falls. In the patients we describe it is possible that the hypercalcaemia contributed to the falls with consequent immobilisation and rapid rise in calcium resulting in delirium which delayed their rehabilitation.
Conclusion
1) Immobilisation should be considered in the differential diagnosis of hypercalcaemia in elderly patients particularly those with primary hyperparathyroidism. 2) 'Asymptomatic' primary hyperparathyroidism may have subtle neuromuscular and psychiatric effects contributing to falls risk. 3) The threshold for treatment of hypercalcaemia in the elderly should possibly be lower than in younger patients.

Evaluation of bone status in obese women: about 48 cases

Salsabil Haouach[1], Mennani Fatima Ezzahra[2], Sana Rafi[3], Ghizlane El Mghari[3] & Nawal El Ansari[3]

[1]Rue Ibn Qodama, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakech, Morocco; [2]Amerchich, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakesh, Morocco; [3]Marrakesh, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakesh, Morocco

Introduction
Obesity has become a major health problem and a global epidemic, with a worldwide prevalence that has doubled over the last three decades. According to the WHO, obesity is defined as a body mass index of 30 kg/m2 or more The relationship between obesity and bone capital has been proven. A few years ago, it was thought that obesity had a protective effect on bone, a belief that influenced clinical practice. However, various pathogenic mechanisms, notably vitaminD deficiency through sequestration, may be responsible for bone loss in obese populations, increasing the risk of osteopenia, osteoporosis and fractures. The aim of our study is to determine bone status in obese population.
Materials and methods
Retrospective descriptive study conducted at the Department of Endocrinology, Diabetology and Metabolic Diseases, CHU MohamedVI, on 48 obese patients with BMI $\geq$ 30 kg/m^2
Results
We identified 48 patients with a BMI $\geq$ 30 kg/m^2. The mean age was: 46.18 years, with extremes ranging from 22 to 71 years. The main comorbidities found were: cardiovascular in 31.25% of cases, diabetes in 27.08% of cases, dyslipidemia in 14.58% of cases and osteoarthritis in 10.41% of cases. Blood calcium and phosphorus levels were normal in all patients Vitamin D deficiency in 72.91%of cases, secondary osteoporosis in 4.17%, osteopenia in 25% and normal bone mineral density in 70.83%. Fractures occurred in 4% of cases, and vitamin D supplementation was performed in patients with vitamin D deficiency. All patients with osteoporosis or fracture received anti-osteoporotic treatment
Discussion
The association between bone and adipose tissue is complex both tissues are metabolically very active, interacting via adipokines, estrogens and metabolic factors of bone origin. The data currently available, provided by numerous studies in obese subjects, seem to show that obesity can affect bone metabolism via several mechanisms. It can increase adipocyte differentiation and fat accumulation, while decreasing osteoblast differentiation and bone formation. It is associated with chronic inflammation through increased pro-inflammatory cytokines, which can promote osteoclast activity and bone resorption by modifying the receptor activator of NF-κB (RANK)/RANK ligand/osteoprotegerin pathway In addition, excessive leptin secretion and/or reduced adiponectin production by adipocytes can affect bone formation, while high fat consumption can interfere with intestinal calcium absorption and reduce calcium availability for bone formation
Conclusions
In fact the prevalence of bone loss and vitamin Ddeficiency are quite frequent in obese people as our study shows, with a non-negligible risk of fractures

Management of acute hypocalcemia in a tertiary referral center in morocco

Nabil Skouta, Nassim Essabah Haraj, Siham El aziz & Asma Chadli
UHC Ibn Rochd, Casablanca, Morocco, Department of Endocrinology, Diabetology and Metabolic Diseases, Casablanca

Introduction
Hypocalcemia is one of the most common electrolyte disorders. It is defined by a total calcium level $<$2.12 mmol/l (85 mg/l). Acute hypocalcemia is considered as a medical emergency.
Objectives
To describe the epidemiological, clinical, and etiological profile of patients undergoing treatment for acute hypocalcemia, as well as the management.
Patients Et Methods
This is a retrospective study including 60 patients hospitalized in the Endocrinology and Diabetology Department of Ibn Rochd University Hospital in Casablanca for acute hypocalcemia from January 2020 to December 2023. Patients with renal insufficiency were excluded. Data were analyzed using IBM SPSS Statistics 27.0.
Results
The mean age was 40 years with a female predominance of 78%. The average duration of symptoms was 16 days. Patients experienced tetany episodes, with 33% showing QT interval prolongation on ECG. The mean corrected calcium level at admission was 59 mg/l. Etiologies included 72% post-surgical hypoparathyroidism, 22% autoimmune hypoparathyroidism, 5% pseudohypoparathyroidism, and 1% infiltrative hypoparathyroidism (hemochromatosis). Before hospitalization, 80% of patients were already on replacement therapy with poor therapeutic compliance. Patients received intravenous calcium infusion with a good clinical and biological response.
Conclusion
Acute hypocalcemia is a life-threatening emergency, requiring careful evaluation by clinicians for diagnosis and management. Patients with hypoparathyroidism should be educated about the vital necessity of replacement therapy.

Vitamin d and reproduction in hereditary vitamin d resistant rickets. what we can learn from an *in vivo* model

Francesca Allosso, Lucia Digitale Selvaggio, Graziella Grande, Martina Errico, Claudia Di Ludovico, Raffaele Navarra & Daniela Pasquali
University of Campania L. Vanvitelli, Department of Advanced Medical and Surgical Sciences, Naples, Italy

Several studies suggest that vitamin D (VitD) has beneficial effects on male reproduction. Analysis of the correlation between VitD and sperm quality parameters demonstrated that it has a significant impact on sperm motility, partially suggesting a relationship between higher serum testosterone levels and VitD levels. In females, vitD deficiency is associated with adverse pregnancy outcomes and metabolic complications in PCOS. However, there is still no concrete evidence to support the use of VitD supplementation to improve the outcomes of patients with altered sperm parameters and hormonal disorders. Here we analyze reproductive hormonal function, fertility outcome, and sexual dysfunction in a rare disease, X-linked hypophosphatemic rickets (XLH), as an *in vivo* model for VitD resistance, in patients not on conventional therapy with calcitriol or phosphate salts. Nine patients with XLH were studied, 3 men and 6 women (mean age 36.89 $\pm$ 12.10). We evaluated: BMI, HOMA index, 25OHVitD, 17-β-estradiol, testosterone, FSH, LH, number of pregnancies with live births. All patients responded to questionnaires to identify sexual dysfunctions: FDSF (Female Sexual Distress Scale) and FSFI (Female Sexual Function Index) for female sexual dysfunctions and IIEF-5 (International Index of Erectile Function-5), SIEDY (Structured Interview on Erectile Dysfunction) and PEDT (Premature Ejaculation Diagnostic Tool) for erectile dysfunction and premature ejaculation. We found that the male population was obese (I degree) and with an increased HOMA index. All patients had low VitD levels, normal gonadotropin levels and only one patient had low testosterone levels but was father of two daughters. In the female population, only 1 patient was obese (II degree) and with an increased HOMA index. All had low levels of VitD, normal levels of estrogens and gonadotropins. The questionnaires used showed no sexual dysfunction, except for premature ejaculation in one patient. Three females had one or more spontaneous pregnancies; two males were fathers of their children. No patient had to undertake assisted reproductive techniques. Studies claim that VitD can positively affect fertility by influencing hormone levels and metabolic markers. Here we show an apparently normal hormonal profile, fertility and sexual health in our patients with XLH. The limited number of our sample does not allow us to reach solid conclusions. Further data are needed to evaluate the real role of VitD in the reproductive process.

Long-term complications of chronic hypoparathyroidism

Malak Iggar, Haraj Nassim Essabah, El Aziz Siham & Chadli Asma
CHU Ibn Rochd, Endocrinology, Diabetology, Nutrition and Metabolic Diseases, Casablanca, Morocco

Introduction
Chronic hypoparathyroidism and its treatment are associated with an increased risk of complications that can impact the patient's quality of life.
Objectives
To describe the epidemiological, clinical, etiological profile, and long-term complications of patients with chronic hypoparathyroidism.
Patients and methods
A retrospective descriptive study over a 4-year period involving 66 patients with chronic hypoparathyroidism at the Department of Endocrinology and Metabolic Diseases of Ibn Rochd University Hospital.
Results
Of the 66 included patients, 48 had post-surgical hypoparathyroidism, 15 non-surgical, and 3 had pseudohypoparathyroidism. The average age was 41.2 years with a female predominance in 80.3% of cases. The average disease duration was

5.8 years. Regarding complications of chronic hypoparathyroidism, 24.2% of patients had nail and hair disorders, 15% had bilateral cataracts, and 13.6% experienced generalized seizure episodes. Brain imaging was performed in 42% of patients, with Fahr's syndrome observed in 21.2% of cases, with no observed link between seizures and Fahr's syndrome. Kidney stones were observed in 22.7% of patients. 93.9% of patients presented signs of hypocalcemia requiring hospitalization, and 6% manifested a hypercalcemia crisis requiring intensive care and dialysis in one patient.
Conclusion
Patients with chronic hypoparathyroidism frequently develop complications, including ectopic calcifications. Therefore, there is a need to increase screening for long-term complications in accordance with guidelines.

Cardiovascular risk in primary hyperparathyroidism

Ikram Karabila[1], Khawla Rhouzali[1], Soumiya Berrabeh[1], Rania El Amel[1], Yousra Laalaoua[1], lamiae zarraa[1], Siham Rouf[2] & Hanane Latrech[2]
[1]Endocrinology-Diabetology and Nutrition Department CHU Mohamed VI Oujda, Faculty of Medicine and Pharmacy, Mohammed First University Oujda, Morocco; [2]Endocrinology-Diabetology and Nutrition Department CHU Mohamed VI Oujda, Faculty of Medicine and Pharmacy, Mohammed First University Oujda, Morocco, Laboratory of Epidemiology, Clinical Research and Public Health, Faculty of Medicine and Pharmacy, Mohammed First University Oujda, Morocco

Introduction
Primary hyperparathyroidism (PHPT) is characterized by parathyroid hormone (PTH)-dependent hypercalcemia. It is associated with numerous complications, including an increased risk of cardiovascular disease. The aim of our study is to assess the cardiovascular risk of patients with PHPT.
Methods
We conducted a retrospective descriptive study, including 51 patients hospitalized in the department of endocrinology-diabetology and nutrition for the management of PHPT. Clinical and paraclinical data were collected from medical records and analyzed using the SPSS-V21 software. The Framigham Risk Score (FRS) was used to assess the cardiovascular risk of our patients. It estimates the risk of the occurrence of cardiovascular disease in 10 years. Patients are considered at high risk if the FRS is equal to or higher than 20%, at moderate risk if it ranges from 10 to 19%, and at low risk if the FRS is less than 10%.
Results
Our population consisted of 40 women and 11 men, with a mean age of 55.5 ± 13 years. Type 2 diabetes, hypertension, and dyslipidemia were found in 20.8%, 33.3%, and 41.3%, respectively. Only 2.2% were smokers, and there was no history of cardiopathy among our patients. The majority of cases had moderate cardiovascular risk (44.4%), followed by low risk (33.1%) and high risk (24.4%). The mean FRS in our patients was 14.4 ± 8, and it was significantly correlated to calcemia and PTH1-84 levels ($P = 0.028$, $P = 0.029$).
Conclusion
Cardiovascular risk appears to be correlated with calcemia and PTH1-84 levels in PHPT. Consequently, an assessment of the effect of PHPT treatment on the improvement of cardiovascular risk is necessary in order to improve the quality of life and life expectancy.

Primary hyperparathyroidism revealed by hypercalcemia crisis

Malak Iggar, Haraj Nassim Essabah, El Aziz Siham & Chadli Asma
CHU Ibn Rochd, Endocrinology, Diabetology, Nutrition and Metabolic Diseases, Casablanca, Morocco

Introduction
Hypercalcemia crisis constitutes a metabolic emergency associated with high mortality. Occasionally, it can be the mode of revelation of primary hyperparathyroidism.
Objectives
To analyze the clinical characteristics of patients presenting with hypercalcemia crisis revealing primary hyperparathyroidism. And to describe the complications and evolution of the disease.
Patients and methods
Retrospective descriptive study of 32 cases of primary hyperparathyroidism collected at the Department of Endocrinology and Metabolic Diseases of Ibn Rochd University Hospital over a 4-year period from January 2020 to December 2023. We included 9 cases of hypercalcemia crisis revealing primary hyperparathyroidism.
Results
In our series, there was a female predominance (5 women/4 men) with an average age of 40.7 years (10–78). The mean value of serum calcium was 154.7 mg/l (140-184), and PTH was 1270 pg/ml (117–2500). The discovery of hypercalcemia crisis was either incidental in 3 patients or associated with symptoms such as bone pain in 3 patients, renal colic in one patient, and vomiting in a patient who was 24 weeks pregnant. The topographic diagnosis was established by MIBI scintigraphy in 6 patients, cervical MRI in 2 patients, and ultrasound in one patient. The average size of the nodules was 23 mm. Among the bone complications, 4 patients experienced fractures (patella, tibia, and humerus), bone densitometry revealed osteoporosis in 7 patients, renal ultrasound identified kidney stones in 4 patients, one patient developed a cardiac arrhythmia, and one patient presented with pancreatitis. The treatment included reanimation measures for all patients with dialysis for some, followed by parathyroid surgery in 8 patients, with one patient refusing surgery. The histological examination revealed 7 parathyroid adenomas and 1 carcinoma. In the postoperative period, 3 patients experienced hypocalcemia.
Conclusion
Hypercalcemia crisis is an unusual mode of primary hyperparathyroidism revelation, indicative of a longstanding form with delayed diagnosis. Its management must be rapid and effective as the prognosis is at stake.

The effects of obesity on bone mineral density in women with Ehlers–Danlos syndrome

Podstawka Jakub[1], Emilia Babula[1], Poprawa Iga[1], Żuk-Łapan Aleksandra[1], Julia Latocha[1], Zuzanna Szymańska[1], Domański Jan[1], Bernadetta Kaluza[1] & Edward Franek[1,2]
[1]National Medical Institute of the Ministry of the Interior and Administration in Warsaw, Warszawa, Poland; [2]Mossakowski Medical Research Centre Polish Academy of Sciences, Department of Human Epigenetics, Warszawa, Poland

Background
Ehlers–Danlos syndrome is a group of genetic diseases characterized by alterations in connective tissue structure, which may lead to increased bone mass loss and predispose to osteopenia and osteoporosis. The effect of obesity on bone mass loss is inconclusive. The purpose of this study was to assess the relationship between obesity and bone mineral density (BMD) in women with Ehlers–Danlos syndrome.
Material and methods
The study involved a prospective assessment of 30 female patients, aged 20–53 years, with hypermobile or classical Ehlers–Danlos syndrome. All patients underwent calcium and phosphorus metabolism testing, BMD scans of the femoral neck and lumbar spine, and had their body mass index (BMI) calculated as the body weight [kg]/(height [m])^2. The patients were divided into two subgroups: those without obesity (BMI <30 kg/m^2) (group 1, $n = 21$) and those with obesity (BMI >30 kg/m^2) (group 2, $n = 9$).
Results
Groups 1 and 2 showed no significant differences in terms of bone turnover markers, such as bone-specific alkaline phosphatase (9.37 ± 2.76 µg/l vs 9.9 ± 2.6 µg/l, $P = 0.54$), beta-crossLaps (CTX 0.421 ± 0.19 ng/ml vs 0.31 ± 0.13 ng/ml, $P = 0.1$), and osteocalcin (22.3 ± 7.57 ng/ml vs 16.5 ± 5.3 ng/ml, $P = 0.06$), as well as femoral neck BMD (0.92 ± 0.11 vs 0.97 ± 0.16, $P = 0.49$); however, differed significantly in terms of lumbar spine BMD (0.91 ± 0.11 vs 1.06 ± 0.11, $P = 0.007$). The study showed no significant correlation between the BMI and femoral neck BMD (r_s 0.15, $P = 0.44$), bone-specific alkaline phosphatase (r_s 0.27, $P = 0.15$), CTX (r_s -0.12, $P = 0.54$), and osteocalcin (r_s -0.18, $P = 0.34$); however, there was a significant correlation between BMI and lumbar spine BMD (r_s 0.48, $P = 0.007$).
Conclusions
The study showed a statistically significant, positive correlation between BMI and lumbar spine BMD; however, no such correlation was observed between BMI and either bone turnover markers or femoral neck BMD, which indicates a complex nature of the effects of obesity on BMD, also in patients with Ehlers–Danlos syndrome.

Vitamin D deficiency in patients with Ehlers–Danlos syndrome

Poprawa Iga[1,2], Babula Emilia[1,2], Żuk-Łapan Aleksandra[1,2], Podstawka Jakub[1,2], Julia Latocha[1,2], Zuzanna Szymańska[1,2], Domański Jan[1,2], Bernadetta Kaluza[1,2] & Franek Edward[1,2,3]
[1]National Medical Institute of the Ministry of the Interior and Administration, Department of Internal Medicine, Endocrinology and Diabetology, Warsaw, Poland; [2]National Medical Institute of the Ministry of the Interior and Administration, Students Scientific Group of the Medical University of Warsaw at the Department of Internal Medicine, Endocrinology and Diabetology, Warsaw, Poland; [3]Mossakowski Medical Research Centre Polish Academy of Sciences, Warsaw, Poland, Department of Human Epigenetics, Warsaw, Poland

Background
Ehlers–Danlos syndrome encompasses a group of genetic conditions characterized by alterations in connective tissue structure, with the consequent increased risk of developing osteopenia, osteoporosis, and incurring fractures. Maintaining vitamin D levels within normal limits is known to play an important role in preventing these complications, which seems to be particularly important in patients with Ehlers–Danlos syndrome. The purpose of this study was to assess serum 25-hydroxyvitamin D, or 25(OH)D, levels in women with Ehlers–Danlos syndrome.
Material and methods
The study involved a prospective assessment of 30 female patients, aged 20–53 years, with hypermobile or classical Ehlers–Danlos syndrome. All patients underwent calcium and phosphorus metabolism testing and bone mineral density (BMD) scans of the femoral neck and lumbar spine. The patients were divided into two groups: those with vitamin D deficiency, defined as serum 25(OH)D levels of $<$ 30 ng/ml (group 1, $n=18$) and those with normal ($>$ 30 ng/ml) 25(OH)D levels (group 2, $n=12$).
Results
Eighteen patients (60%) showed vitamin 25(OH)D deficiency, with three of those (16.7%) showing secondary hyperparathyroidism. Study groups 1 and 2 showed no significant differences in terms of serum levels of calcium (2.4 ± 0.09 mmol/l vs 2.39 ± 0.07 mmol/l, $P=0.88$), phosphorus (3.51 ± 0.7 mg/dl vs 3.42 ± 0.51 mg/dl, $P=0.86$), bone-specific alkaline phosphatase (10.36 ± 3.06 µg/l vs 8.28 ± 1.31 µg/l, $P=0.007$), beta-CrossLaps (0.39 ± 0.19 ng/ml vs 0.39 ± 0.17 ng/ml, $P=0.69$), or osteocalcin (20.14 ± 8 ng/ml vs 21.23 ± 6.67 ng/ml, $P=0.46$), femoral neck BMD (0.95 ± 0.12 g/cm^2 vs 0.92 ± 0.13 g/cm^2, $P=0.57$), or lumbar spine BMD (0.12 ± 0.16 g/cm^2 vs 0.13 ± 0.11 g/cm^2, $P=0.14$).
Conclusions
Sixty percent of patients with Ehlers–Danlos syndrome showed vitamin 25(OH)D deficiency. Parameters of calcium–phosphorus metabolism in these patients were not significantly different from those in patients with normal serum vitamin 25(OH)D levels.

Primary hyperparathyroidism imaging

Sameh Mezri[1], Chaima Zitouni[1], Wadii Thabet[2] & Khemaies Akkari[1]
[1]Principal Military Hospital, ENT, Tunis, Tunisia; [2]Taher Sfar Hospital, Mahdia, Tunisia

Introduction
Hyperparathyroidism is the third most common endocrinopathy. Minimally invasive surgery using a unilateral approach is now increasingly common. In such cases, preoperative localization of the lesion by imaging is essential. Among the techniques available, ultrasound and scintigraphy play a predominant role.
Objective
our aim is to evaluate the diagnostic contribution of ultrasound and parathyroid scintigraphy in localizing the pathological gland(s) in primary hyperparathyroidism.
Methods
This is a retrospective study including 84 patients treated for primary hyperthyroidism in our department over a period from 2015 to 2023.
Results
Ultrasound and parathyroid scintigraphy were performed in all cases. CT or MRI scans were performed in 5 cases. The sensitivity of ultrasound, scintigraphy and combined ultrasound-scintigraphy was 51%, 68% and 80% respectively. The specificity of ultrasound, scintigraphy and combined ultrasound-scintigraphy was 96%, 97% and 98% respectively. The sensitivity of these examinations was lower in the case of multi-glandular or ectopic involvement, or in the case of lesions $<$ 2 cm.
Conclusion
Coupled use of cervical ultrasound and scintigraphy enables reliable preoperative location of pathological glands.

Severe biphasic disorder of calcium homeostasis in a patient with rhabdomyolysis: Case report

entela Puca[1,2], Edmond Puca[3] & Dorina Ylli[4]
[1]Western Balkan University, Internal Medicine, tirana, Albania; [2]Western Balkans University, Tirana, Albania; [3]Mother Teresa Hospital, infectious Disease, Tiranë, Albania; [4]Mother Teresa Hospital, endocrinology, Tiranë, Albania

Management of calcium disorders can be a real challenge during the different stages of acute kidney injury complicating rhabdomyolysis.
Aim
The aim of this presentation is to present a clinical case diagnosed with rhabdomyolysis, which was complicated by severe hypocalcemia during the acute phase and later on during the recovery phase with hypercalcemia.
Case presentation
We present a female patient, 57 years old, who presented to the hospital with profound weakness and difficulty in breathing. Physical examination upon admission showed normal consciousness, body temperature of 37 °C, blood pressure of 110/70 mmHg, heart rate of 98/min, and oxygen saturation 90-92%. Her initial Creatine kinase (CK) was 5852 U/l (26-192). Creatinine was 0.9 mg/dl and ionized calcium was 0.71 nmol/l (1.13-1.32) total calcium was 8.59 mg/dl (8.8-10.2), PTH 204 pg/ml (15-65), 25OHD3 24.4 ng/ml (25-80) and phosphor 7.9 mg/dl (2.5-4.5) and myoglobinuria $>$500 ug/ml $<$30. She was hospitalized because she told us that some years before she suffered a similar situation. During the clinical course in hospital, the patient was transferred to intensive care unit because she was complicated with multiple organ failure: acute kidney injury with a rapid increase in serum creatinine 8.06 mg/dl). During the oliguric phase the calcium reached the lowest level: total calcium 5.04 mg/dl and ionized calcium 0.65 mmol/l, CK was $>$ 174608. She had some hemodialysis sessions and was discharged from hospital on day 13. During her recovery as her renal function was improving she developed progressive severe hypercalcemia with a peak calcium level 17.5 mg/dl and ionized calcium 2,15 mmol/l. Renal replacement therapy was restarted to correct hypercalcaemia. On day 30 her calcium level was normal 9.24. The patient had an excellent outcome 1 week following her discharge, calcium levels remained within normal range.
Conclusions
This case report showed us that rhabdomyolysis may present initially with severe hypocalcemia and followed by hypercalcemia. In most of the cases, these situations are self-limited and do not require specific measures other than monitoring and rehydration, but may require more intensive treatment when it becomes severe and symptomatic. Clinicians must take into account this kinetic of calcium in order to prevent the complications of hypo and or hypercalcemia.

Study of vitamin D status with SARS-CoV-2 infection

Jihene Ben Abdallah[1], Chaima Boughzala[1], Sawssen Mrad[1], Yosra Hasni[2], Hamza Elfekih[2], Oumayma Zarrouk[2], Mohamed Ilehi Aiachi[3], Naoufel Chbili[3], Bassem Charfeddine[1] & Selima Ferchichi[1]
[1]University Hospital of Farhat Hached, Biochemistry laboratory, sousse; [2]University Hospital of Farhat Hached, Endocrinology departement, sousse; [3]university hospital of sahloul, Emergency Medical Assistance Service 03, sousse

Introduction
COVID-19 is a potentially serious disease with a high case fatality. At present no specific drug has been shown to be effective and safe in treating it. Recently, evidence suggests that higher levels of vitamin D protect against this infection. However, published studies on this subject are limited. The aim of this work was to investigate an association between hypovitaminosis D and SARS-CoV-2 infection.
Methods
This was an analytical cross-sectional study over a period from 1 December 2020 to 07 January 2021 including patients suspected of COVID-19. They had undergone a PCR test and a vitamin D assay. The "Wondfo" SARS-CoV-2 real-time RT-PCR assay was used to detect coronavirus nucleic acid.

Vitamin D status was assessed by measuring 25(OH)D using the direct competitive immunoassay technique with chemiluminescence revelation on Cobas e601. 25(OH)D deficiency was defined as a level below 10 ng/ml, insufficiency was defined as values between 10-30 ng/ml and a result above 30 ng/ml was considered optimal.
Results
Two hundred and thirty-five patients suspected of having COVID-19 were included, with a median age of 35 years and a sex ratio of 0.71. The RT-PCR test was positive in 49.4%. The prevalence of vitamin D deficiency was 79.9% in non-diseased subjects and 81.9% in diseased subjects, with mean vitamin D concentrations of 21.5 ng/ml and 21.8 ng/ml, respectively. There was no significant difference in vitamin D levels between coronavirus-affected and nonaffected subjects ($P = 0.857$).
Discussion
Our preliminary results, which do not support a potential link between vitamin D levels and infectious risk, are in line with the literature. However, contrasting results were reported in two Israeli and US studies, providing strong evidence of an association between lower 25(OH)D levels and an increased risk of COVID-19.
Conclusion
The design of large-scale studies will be required to assess the relationship between vitamin D and COVID-19 and generate more robust conclusions.

Primary hyperparathyroidism and acute pancreatitis: about three cases

Gorgi Khaoula, Lamya Echchad, Rifai Kaoutar, Iraqi Hinde & Gharbi Mohamed El Hassan
Ibn Sina University Hospital, Endocrinology, Rabat, Morocco

Introduction
Primary hyperparathyroidism (PPH) may be complicated by pancreatitis. The association of primary hyperparathyroidism with pancreatitis is rare, We report the case of three patients presenting with hyperparathyroidism revealed by acute pancreatitis.
Observation
A 78-year-old female patient with no previous history of pancreatitis presented to the emergency department with abdominal pain and bilious vomiting. An abdominal CT scan was ordered, revealing pancreatitis stage C. A etiological investigation revealed a profile of primary hyperparathyroidism with PTH at 397 pg/ml, hypercalcemia at 147 mg/l and hypophosphatemia at 19 mg/l. Patient aged 60, with no particular history, admitted for management of primary hyperparathyroidism, during his hospitalization he presented with epigastric pain associated with vomiting, a workup was ordered in favor of very high lipasemia and an abdominal CT scan was also ordered in favor of stage A pancreatitis. A 56-year-old patient with chronic kidney disease presented with an acute digestive complaint of abdominal pain and vomiting, associated with diffuse bone pain. A workup was ordered, and found to be consistent with primary hyperparathyroidism. Localization workup confirmed parathyroid localization in our 3 patients, and parathyroidectomy was performed with good evolution.
Discussion/conclusion
The association between HPTP and pancreatitis is rare, however, the pathophysiology of this association is still poorly understood. The relationship between HPTP1 and pancreatitis is controversial to date, although most publications and experimental data in favor of a direct or indirect causal role for hypercalcemia via activation of pancreatic proteases. The degree of hypercalcemia may play an important role in this association. Calcium levels should be measured in all patients with acute pancreatitis.

Hypercalcemia in locally advanced laryngeal cancer: an etiology to consider and a case report

Houas Jihene[1], Heyfa Belhadj-Miled[1], Monia Ghammam[1], Ben arfi Tayssir[1], Malika El Omri[1], Abir Meherzi[1], Mouna Bellakhdhar[1], El Ghali Wassim[2], Yosra Hasni El Abed[3], Wassim Kermani[1] & Mohamed Abdelkafi[1]
[1]Farhat Hached Hospital, ENT department, Sousse, Tunisia; [2], Department of Anaesthesia, Sousse, Tunisia; [3], departement of endocrinology, Sousse, Tunisia

Introduction
Although Primary hyperparathyroidism is the most common cause of hypercalcemia in the general population, it is a less frequent cause of hypercalcemia among patients with cancer. It is estimated that approximately 80% of the hypercalcemia in cancer is mediated by humoral hypercalcemia of malignancy resulting from elevated parathyroid hormone-related peptide (PTHrp), while almost 20% is the result of local osteolytic hypercalcemia. The aim of this work is to present a clinical case of head and neck cancer associated with hypercalcemia and the etiological and therapeutic management.
Observation
This concerns a 75-year-old man, known to have diabetes and a history of alcohol and tobacco use, who was admitted to our ENT department for the management of laryngeal dyspnea overlaid on chronic hoarseness that the patient had neglected. Upon examination: A poorly defined, hard, midline cervical mass was observed, adjacent to the thyroid cartilage, with skin infiltration. Clinically suspicious cervical lymph nodes were present. CT scan revealed an extensive tumoral process of the larynx invading the three levels, classified as T4aN2. Direct laryngoscopy with biopsy confirmed the diagnosis of laryngeal squamous cell carcinoma. Additionally, asymptomatic hypercalcemia of 2.8 mmol/l was incidentally discovered during the pre-surgical biological assessment. Parathyroid hormone (PTH) was measured at 123 ng/l, and parathyroid scintigraphy returned negative. The patient underwent an extended total laryngectomy with total thyroidectomy and central and bilateral lateral neck dissection. Postoperatively, calcium and PTH levels normalized. The final histopathological examination confirmed the cancer diagnosis and identified a 2 cm parathyroid adenoma.
Conclusion
Although primary hyperparathyroidism is a less common cause of hypercalcemia in malignancy, it nonetheless should not be overlooked and an elevated calcium concentration cannot always be attributed to a known malignancy.

Acute pancreatitis revealing hyperparathyroidism: an unusual presentation: three case reports and literature review

Hind Ouakrim, Eleazar Nyogushima, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Chu Mohamed Vi Marrakesh - Drh, Marrakech, Morocco

Introduction
Primary hyperparathyroidism(PHPT) is a prevalent endocrine disorder characterized by hypercalcemia due to the overproduction of parathyroid hormone(PTH) from one or more parathyroid glands. While PHPT is typically diagnosed incidentally through routine laboratory testing due to asymptomatic hypercalcemia, acute pancreatitis as the initial symptom is a rare occurrence. This article presents three cases where acute pancreatitis served as the first manifestation ofPHPT.
Case reports
A 69-year-old patient was with an acute digestive presentation of transfixing epigastric pain and bilious vomiting, revealing pancreatitis classified as Balthazar stage D. The etiological assessment revealed primary hyperparathyroidism. Scintigraphy with SestamibiTc99m identified 2 focal retention areas in the MIBI-Tc99m. The patient received rehydration followed by bisphosphonate infusion and underwent successful surgical intervention. A 35-year-old patient was admitted for an acute digestive presentation, revealing pancreatitis classified as stage B. The etiological assessment showed hypercalcemia at 132 mg/l with hypophosphatemia at 19 mg/l. PTH was elevated at 985 pg/ml. Cervical ultrasound revealed a hyper-vascularized right retro-thyroid formation. SestamibiTc99m scintigraphy revealed a focus below the lower right thyroid pole. The patient underwent an adrenalectomy, with pathological examination confirming a parathyroid adenoma. A 28-year-old patient was admitted for epigastric pain, nausea. Lipase levels were elevated, and a CT scan revealed pancreatitis stage C. Primary hyperparathyroidism was diagnosed in the etiological assessment, with a PTH level of 3111 pg/ml, hypercalcemia of 136 mg/l, and hypophosphatemia of 22 mg/l. Sestamibi scintigraphy revealed three focal retention areas in the MIBI-Tc99m. The patient underwent a 7/8 parathyroidectomy with total thyroidectomy. Histological examination indicated parathyroid carcinoma, and unfortunately, the patient's condition became fatal after the development of multiple metastases.
Discussion
Hypercalcemia is a rare cause of acute pancreatitis, even more so if secondary to primaryhyperparathyroidism, with a prevalence varying from 1.5% to 5%. The association between hyperparathyroidism and acute pancreatitis has been debated, with three proposed mechanisms supporting this connection. These mechanisms involve hypercalcemia triggering trypsinogen conversion, calcium accumulation obstructing pancreatic ducts, and elevated calcium levels combined with genetic mutations increasing pancreatitis risk in PHPT patients. Patients with PHPT exhibit

a higher pancreatitis rate than those without, and given the high morbidity and mortality associated with acute pancreatitis, immediate treatment is crucial. The primary focus should be on managing pancreatitis initially. Once pancreatitis subsides, parathyroidectomy becomes imperative as it is the sole treatment for symptomatic PHPT. This comprehensive approach aims to address both acute pancreatitis and the underlying primary hyperparathyroidism to optimize patient outcomes.

Primary hyperparathyroidism caused by an ectopic thymic parathyroid adenoma: A Case Report

Amal Ourdi[1], Houda Ennaifer[1], Françoise Latil Plat[1], Amina Bounaga[1], Arnaud Pforr[2] & Guillaume Granier[3]
[1]Avignon, endocrinology, Avignon, France; [2]Avignon, thoracic surgery, Avignon, France; [3]Avignon, anathomopathology, Avignon, France

Introduction
Primary hyperparathyroidism, is a common endocrine disorder, but rarely related to ectopic parathyroid. Often asymptomatic, it presents a problem of localization and hence therapeutic management. We report a rare case of an ectopic thymic parathyroid adenoma.
Description
We report a case of 62-year-old women, with a history of recurrent urinary infection due to pyelocalcic lithiasis, whose etiological investigation revealed the presence of hypercalcemia. Clinically, she had polydipsia, muscle cramps and tingling of the extremities. The diagnosis was primary hyperparathyroidism (hypercalcemia 3.51 mmol/l, hypophosphatemia 0.45 mmol/l and elevated PTH 1041 ng/ml). Cervical ultrasound was normal. Parathyroid scintigraphy showed the presence of an anterior mediastinal hypermetabolic mass in the thymic lodge with a heterogeneous cystic component. CT scan showed a solid cystic mass of the anterosuperior mediastinum region, measuring 46×37×55 mm. Genetic testing was performed, and excluded genetic forms of hyperparathyroidism. Correction of hypercalcemia was based on rehydration and cincalcet hydrochloride. Thymectomy was performed by video-thoracoscopy. Anatomopathological examination concluded to an intra-thymic parathyroid adenoma. Post-operatory calcemia was normal, and PTH decreased to 84.9 ng/ml. The 3 months CT scan was normal.
Discussion
Parathyroid glands and the thymus had a common embryological origin, which explains the thymic ectopy of the parathyroid. It's a rare entity, whose prevalence is about 16% in patients with primary hyperaldosteronism[1]. The diagnosis can be evoked by persistent disorders of phosphocalcic metabolism. Cervical ultrasound and scintigraphy are first line imaging. Imaging remains an essential step in management, providing accurate cervical and mediastinal mapping enabling the surgeon to perform a targeted surgical excision, avoiding white surgical explorations. Minimally invasive radio-guided surgery, assisted with PTH measurement, improves surgical outcomes.

Acute necrotising pancreatitis in Primary Hyperparathyroidism

Keerthi Madhurya Kethireddi[1] & Maria Luiza Silveira[2]
[1]Worthing Hospital, Endocrinology and Diabetes, Worthing, United Kingdom; [2]Worthing Hopsital, Endocrinology and Diabetes, Worthing, United Kingdom

Introduction
Acute Necrotising Pancreatitis caused by Hypercalcemia secondary to Primary hyperparathyroidism is a rare condition[1]. The prevalence of acute pancreatitis in patients with PHPT is estimated between 1.5% and 7%[2]. We report a case of male patient with severe necrotising pancreatitis associated with hypercalcemia secondary to primary hyperparathyroidism.
Case Report
A 55-year-old man presented with sudden episode of severe abdominal pain to emergency department. He had a CT abdomen that showed the extensive necrotising pancreatitis. He was diagnosed with primary hyperparathyroidism 6 months ago, when he initially presented with polyuria, polydipsia, painful joints, back ache. He has no significant past medical history and not on any regular medications. He is a non-smoker and drinks alcohol socially. His blood analysis showed adjusted calcium 3.16 mmol/l, phosphate 0.79 mmol/parathormone –17.9 pmol/l, egfr-49 ml/min. He was managed conservatively with free fluids and analgesia. His stay was complicated by worsening abdominal pain and required critical care admission. His management included sliding scale insulin, patient-controlled analgesia and Naso jejunostomy feeding. His repeat imaging showed pancreatic pseudocyst for which surgical intervention was performed. Cinacalcet was commenced. Sestamibi imaging of parathyroid showed mild tracer uptake in all four parathyroid glands suggesting multi gland hyperplasia.4D CT imaging showed a nodule below the inferior pole of left lobe of thyroid gland could potentially a parathyroid adenoma. His case was discussed in Parathyroid multidisciplinary team meeting, and plan is for surgery. Interim, he had a cardiac arrest due to massive Myocardial infarction and was revived. Currently he is managing well on cinacalcet 90 mg twice daily which was gently up titrated, waiting for surgery.
Conclusion
This case illustrates primary hyperparathyroidism as one of the causes for acute necrotising pancreatitis, which can be fatal.

Crosstalk between neurovegetative control, bone status and physical exercise: clinical use of a unitary autonomic nervous system index in postmenopausal women with osteoporosis

Luca Giovanelli[1], Vittoria Favero[1], Mara Malacarne[1], Sabrina Corbetta[2,3] & Daniela Lucini[1,4]
[1]University of Milan, Department of Medical Biotechnology and Translational Medicine, Milan, Italy; [2]University of Milan, Department of Biomedical, Surgical and Dental Sciences, Milan, Italy; [3]Istituto Auxologico Italiano, IRCCS, Unit for Bone Metabolism Diseases and Diabetes, Department of Endocrine and Metabolic Diseases, Milan, Italy; [4]Istituto Auxologico Italiano, IRCCS, Exercise Medicine Unit, Milan, Italy

Background
In the multifarious etiopathogenesis of skeletal fragility, an intriguing novel element is the possible existence of a crosstalk between autonomic nervous system (ANS) function and bone health. Indeed, sympathetic overactivity might stimulate osteoclastogenesis and inhibit osteoblastic proliferation, whereas opposite effects would be exerted by a prevalent parasympathetic activation. Autonomic Nervous System Index (ANSI) is a percent ranked (0–100) unitary proxy of cardiac autonomic regulation (CAR), derived from the autoregressive spectral analysis of heart rate variability by combining the three most informative indexes. It is a simple and non-invasive method for evaluating ANS function, being by design free of age and gender bias. Notably, this index has also proved to highlight neurovegetative improvements induced by therapeutic strategies such as aerobic endurance exercise. In this respect, physical activity itself is well-known to play a key part in reducing (re)fracture risk.
Aim
To investigate CAR as well as the effects of a structured and personalized exercise program on CAR, skeletal turnover, bone mass and body composition, in postmenopausal women affected with osteopenia/osteoporosis.
Methods
17 osteopenic/osteoporotic women aged between 50 and 70, referred to the Exercise Medicine Clinic of Istituto Auxologico IRCCS, were enrolled. Several evaluations, including bone turnover markers, CAR (by means of ANSI), body composition, and lifestyle (with ad hoc questionnaires) were performed, and a structured and personalized exercise program was prescribed.
Preliminary results and future perspectives
At the baseline assessment, bone turnover biomarkers were significantly impaired in comparison with reference populations from other studies. High variability in the ANSI score (32.5-79.5%) was observed. It will be interesting to explore CAR in a wider sample, as well as the effects of a customized exercise program both on bone metabolism and ANS function (as evaluated by non-invasive techniques), and their potential mutual correlation/interaction.

[1]Biochemistry Unit, Department of Surgical, Medical and Molecular Pathology and Critical Care, Pisa, Italy; [2]Stella Maris IRCCS, Calambrone, Italy; [3]University of Bari, Department of Translational Biomedicine and Neuroscience, Bari, Italy; [4]University of Bari, Department of Precision and Regenerative Medicine and Ionian Area, Bari, Italy; [5]University of Pisa

Introduction
Cerebral palsy (CP) is the most common chronic disability in childhood, burden by motor, sensation, cognition, feeding and communication impairment. A serious concern in children with CP is bone/muscle health deterioration, which negatively impacts the already reduced quality of life (QoL). Irisin is a myokine secreted by contracting muscle, which mediates beneficial effects on several targets, including brain. The aim of this pilot study was to evaluate serum levels of irisin in children with PC compared to healthy matched controls, to understand if irisin could be considered a biomarker of disability.
Methods
$n=39$ consecutive young patients (aged 3-18) with CP were enrolled at Fondazione IRCCS Stella Maris (Pisa) between 2021 and 2023 and $n=40$ healthy children matched for age and gender, were enrolled in the same period at Paediatric Unit, University of Pisa. Serum samples were collected in all of them, stocked at -80°C at Biochemistry Laboratory, University of Pisa and sent to University of Bari for Irisin serum levels measurement.
Results
Serum levels of Irisin were statistically significantly lower in the CP group compared with healthy matched controls or Crl (10.8 ± 2.4 vs 12.5 ± 3.2 ng/ml, $P=0.01$) and this difference was even greater when considering subjects with irisin levels under the median value (CP 8.7 ± 0.9 vs Crl 9.9 ± 1.3 ng/ml, $P=0.001$). In the CP group there was not difference in irisin levels between females ($n=12$) and males ($n=27$) (11.1 ± 3.1 vs 10.6 ± 3.2 ng/ml, $P=0.9$). Younger patients (aged <11 years) showed the higher difference in irisin levels between CP and Crl subjects ($P=0.004$).
Conclusions
Irisin is a myokine, with potential protective effects on CNS. We observed for the first time that irisin is markedly decreased in young patients with CP compared with controls, suggesting a potential role as biomarker of disability. Moreover, further analysis will correlate irisin levels with clinical, biochemical, and morphological markers of muscle-bone health in these patients, to understand the role of irisin as marker or as therapeutical target.

Influence of muscle function on bone status in patients with hypophosphatasia

Victoria Contreras Bolivar[1,2,3], María Del Carmen Andreo-Lopez[1], Enrique Moratalla-Aranda[2,4], Trinidad González-Cejudo[2,5], Luis Martínez-Heredia[2], Francisco Andújar-Vera[2,3,6], Cristina García-Fontana[1,2,3], Beatriz García-Fontana[1,2,3] & Manuel Muñoz-Torres[1,2,3,7]
[1]Endocrinology and Nutrition Unit, Hospital Universitario Clínico San Cecilio, Granada, Spain; [2]Institute of Biosanitary Research of Granada (ibs.GRANADA); [3]CIBER on Frailty and Healthy Ageing (CIBERFES), Instituto de Salud Carlos III, Granada, Spain; [4]Nuclear Medicine Unit, Hospital Universitario Clínico San Cecilio, Granada; [5]Clinical Analysis Unit, Hospital Universitario Clínico San Cecilio, Granada, Spain; [6]Andalusian Institute for Research in Data Science and Computational Intelligence, Granada, Granada, Spain; [7]Department of Medicine, University of Granada, Granada, Spain

Introduction
Hypophosphatasia (HPP) is characterised by a deficiency of non-tissue-specific alkaline phosphatase. This results in abnormal mineralisation of bone tissue which predisposes to fragility fractures. Moreover, an affected muscle compartment could favour the risk of fracture. The aim was to evaluate the relationship between the bone and muscle compartment.
Material and Methods
Cross-sectional study in adults with PPH. Demographic (age, sex), analytical (alkaline phosphatase-FA-) and clinical variables were collected (fractures, muscle strength measured with Jamar dynamometer in kilograms (kg) -cut-off point: <p10 of Spanish population-, muscle mass of the rectus femoris of the quadriceps with ultrasound -Sonosite S-Nerve®- and bone mineral density with dual energy X-ray absorptiometry expressed according to T and Z-score. Statistical analysis was performed with IBM SPSS v.25.
Results
Thirty-three subjects were studied, 55% women, mean age: 49 ± 18 years and mean AF: 29 ± 11. Fifty-one per cent had affected family members. 52% had at least one bone fracture and 67% had dental pathology. Low muscle strength was detected in 24%. The mean rectus femoris quadriceps muscle thickness was 1.4 ± 0.7 and its mean area, 4.4 ± 2. 22.2% (4) of the women suffered from osteopenia and 27.8% (5) from osteoporosis (OP). Of the males, 26.7% (4) had osteopenia and none had OP. Muscle strength was positively correlated with Y-axis or thickness ($r=0.42$, $P=0.02$), with muscle area ($r=0.4$, $P=0.02$), with T-score in femoral neck ($r=0.48$, $P=0.01$) and in lumbar spine ($r=0.66$, $P=0.00$). A positive correlation was even found with FA values ($r=0.48$, $P=0.008$).
Conclusions
Hand dynamometry is associated with body composition and bone parameters, and is a useful parameter for assessing muscle status in PPH patients. Therefore, given the high prevalence of fractures in PPH patients, it could be useful to enhance the muscle compartment.

Management of maxillary osteitis fibrosa cystica in a patient with secondary hyperparathyroidism: a report of a case

Amel Elkorbi, Nawres Bouaziz, Mahdi Ferjaoui, Rachida Bouatay, Naourez Kolsi, Harrathi Khaled & Jamel Koubaa
مستشفى فطومة بورقيبة بالمنستير, Monastir, Tunisia

Introduction
Brown tumor of bone, also called osteitis fibrosa cystica is a rare non-neoplastic lesion resulting from abnormal bone metabolism in hyperparathyroidism (HPT). Facial involvement is exceptional and, when present, usually involves the mandible, but is rare in the maxilla. These lesions can simulate a malignancy on clinical examination and routine radiographs. We aim through this case to present clinical and therapeutic particularities of a maxillary located brown tumor secondary to a HPT in a young woman.
Case report
A 36-year-old female presented to our department complaining about a 6 months history of an asymptomatic, expansive mass in the right side of the face causing facial disfigurement. She had a 6-year history of hemodialysis dependent anuric renal failure of undetermined cause. The physical examination showed a bilaterally enlarged jaw, more to the right associated with facial asymmetry and deletion of the right nasolabial fold. The oral examination revealed a hardened, expansive exuberant lesion in the right palate, causing multiple diastemas in maxillary teeth and transverse and anterior expansion of the maxilla, extending from anterior region to posterior right side. This expansive lesion measured 5 cm* 3 cm. The overlying mucosa was intact. Laboratory work up showed elevated creatinine, urea and parathormone (PTH) level of 1237 pg/dl, total serum calcium level was normal. Scintigraphy showed hyperfixation in the four parathyroid gland. Facial computer tomography found an expansive well limited lesion on the left maxilla associated with a thinning of the bony cortex sized 44x54x34 millimeters. A generalized demineralization of the facial bones was noted. Fine needle aspiration cytology of the maxillary mass showed a giant cell lesion. The patient underwent subtotal parathyroidectomy associated to a partial hemi-maxillectomy using the Caldwell-Luc approach. The post-operative course was unremarkable. The oral diet was restored on the second postoperative day. Histological sections confirmed the diagnosis of a brown cell tumor associated with parathyroid hyperplasia. Post-operative PTH levels decreased towards normal values and the patient benefited from an obturator prothesis. Four years after the surgery, no noticeable bone changes were observed in the patient.
Discussion/Conclusion
The bony complications of HPT have declined over a period of time, due to early diagnosis and multidisciplinary follow-up. Appropriate management of hyperparathyroidism is the the primary treatment of brown tumors; however, in the case of larger growing lesions or those causing incapacity, surgical management should be considered.

Hyperparathyroidism and the kidney: the culprit or the victim

Hind Ouakrim, Mennani Fatimaeezzahra, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Chu Mohamed Vi Marrakesh - Drh, Marrakech, Morocco

Introduction
Hyperparathyroidism is a condition marked by an overproduction of parathyroid hormone (PTH) due to excessive activity in one or more parathyroid glands. It is a prevalent disorder that may manifest as primary, secondary, or tertiary. In this report, we present three clinical cases highlighting intricate scenarios where determining the primary or tertiary origin of hyperparathyroidism proves challenging.
Case reports
A 33-year-old female with end-stage renal failure was diagnosed with hyperparathyroidism during her medical follow-up. Symptoms were associated with severe headaches and bilateral vision loss. An MRI revealed a pathological mass compressing the optic chiasm. Laboratory evaluation showed an elevated prolactin level, leading to the diagnosis of both hyperparathyroidism and prolactinoma. A 60-year-old female, under treatment for renal insufficiency due to multiple kidney stones, developed hypercalcemia with hyperparathyroidism. A MIBI scintigraphy revealed hyperactive uptake in a parathyroid gland in the left basal lower region. Parathyroidectomy was performed, revealing hyperplasia of the parathyroid gland. However, despite the intervention, persistent hyperparathyroidism was observed. A subsequent MIBIscintigraphy revealed an enlarged parathyroid gland on the right side. Parathyroidectomy was performed Patient, 63, with a 20-year history of nephropathy and end-stage renal failure, presented with progressive BAV, diplopia, hypoacusis, bone pain, and renal colic. Brain MRI showed a locally infiltrating lesion in the sphenoethmoidal complex. Nasal biopsy suggested a reparative granuloma. Cervical ultrasound revealed a multinodular goiter and a left parathyroid nodule. Hyperparathyroidism was confirmed. The patient underwent a left parathyroidectomy.
Discussion and conclusion
These three clinical cases present diagnostic and therapeutic challenges due to uncertainty regarding the primary or tertiary origin of hyperparathyroidism. In first case, the concurrent presence of a prolactinoma complicates the situation, making it difficult to determine whether the association between the prolactinoma and hyperparathyroidism is coincidental or part of multiple endocrine neoplasia type 1(MEN1). This uncertainty is further heightened by the inability to confirm the primary origin of hyperparathyroidism. Insecond case, despite the identification and surgical removal of a hyperplastic parathyroid gland, persistent hyperparathyroidism is observed, raising questions about possible primary or tertiary hyperparathyroidism related to parathyroid hyperplasia. In the third case, the diagnosis of hyperparathyroidism was established after the appearance of brown tumors in the context of chronic nephropathy with multi-lithiasic kidneys, complicating the clinical situation and highlighting the difficulty in distinguishing between primary and tertiary hyperparathyroidism. A multidisciplinary approach involving endocrinologists, nephrologists, and surgeons is essential for a comprehensive evaluation and optimal management of these patients.

Is autoimmune thyroiditis in females with Ehlers–Danlos syndrome associated with lower bone density?

Emilia Babula, Poprawa Iga, Żuk-Łapan Aleksandra, Podstawka Jakub, Julia Latocha, Zuzanna Szymańska, Domański Jan, Bernadetta Kaluza & Edward Franek
National Medical Institute of the Ministry of the Interior and Administration in Warsaw, Department of Internal Medicine, Endocrinology and Diabetology, Warszawa, Poland

Background
Collagen, whose biosynthesis is regulated by thyroid hormones, is the most abundant connective tissue protein. Ehlers–Danlos syndrome alters collagen structure, which may affect bone mineral density (BMD). The purpose of this study was to assess the effect of autoimmune thyroiditis on BMD in females with Ehlers–Danlos syndrome.
Material and methods
The study involved a prospective assessment of 30 female patients, aged 20–53 years, with either hypermobile or classical Ehlers–Danlos syndrome. All patients underwent thyroid function tests, calcium and phosphorus metabolism tests, and BMD scans of the femoral neck and lumbar spine. Patients were divided into two groups: those with no autoimmune thyroiditis (group 1, $n=24$) and those with autoimmune thyroiditis (group 2, $n=6$).
Results
Study groups 1 and 2 showed no significant differences in terms of hypothyroidism ($n=4$ (16.7%) vs $n=2$ (33.3%), $P=0.39$), thyroid-stimulating hormone (TSH) levels (2.06 $\pm$1.16 µIU/ml vs 2.35$\pm$2.16 µIU/ml, $P=0.59$), free triiodothyronine levels (3.43$\pm$0.64 pg/ml vs 3.19$\pm$0.72 pg/ml, $P=0.42$), or free thyroxine levels (1.35$\pm$0.25 ng/dl vs 1.34$\pm$0.12 ng/dl, $P=0.44$), respectively. Moreover, no significant differences were noted in bone turnover markers, such as bone-specific alkaline phosphatase (9.89$\pm$2.88 µg/l vs 8.1$\pm$0.81 µg/l, $P=0.19$), beta-crossLaps (0.411$\pm$0.19 ng/ml vs 0.3$\pm$0.15 ng/ml, $P=0.2$), and osteocalcin (21.32$\pm$7.82 ng/ml vs 17.62$\pm$4.76 ng/ml, $P=0.34$), or in the BMD of the femoral neck (0.93$\pm$0.12 vs 0.96$\pm$0.15, $P=0.59$) or lumbar spine (0.95$\pm$0.12 vs 0.94$\pm$0.17, $P=0.98$). Furthermore, no significant correlation was observed between the levels of TSH, anti-thyroperoxidase autoantibodies, or anti-thyroglobulin antibodies on one hand and femoral neck BMD on the other (r_s 0.09, $P=0.61$; r_s 0.1, $P=0.59$; and r_s -0.03, $P=0.89$, respectively) or between any of those three markers and lumbar BMD (r_s 0.11, $P=0.56$; r_s 0.02, $P=0.93$; and r_s -0.03, $P=0.84$).
Conclusions
This study showed no relationship between autoimmune thyroiditis, bone turnover markers, and the BMD of either the femoral neck or the lumbar spine in women with Ehlers–Danlos syndrome.

Can tenascin - X be a marker of bone turnover in patients with Ehlers-Danlos syndrome?

Aleksandra Żuk - Łapan, Babula Emilia, Poprawa Iga, Podstawka Jakub, Julia Latocha, Zuzanna Szymańska, Domański Jan, Zagozda Małgorzata, Wilk Juliusz, Korcz Tomasz, Cicha-Brzezińska Małgorzata, Bernadetta Kaluza & Edward Franek
National Medical Institute of the Ministry of the Interior and Administration in Warsaw, Warszawa, Poland

Background
The alterations in collagen synthesis and connective tissue structure that occur in Ehlers–Danlos syndrome translate to an increased risk of bone mass loss and development of osteopenia and osteoporosis, which may be evaluated with bone turnover biomarkers. Some subtypes of Ehlers–Danlos syndrome are associated with structural alterations in the extracellular matrix glycoprotein tenascin-X. The purpose of this study was to assess the relationship between tenascin-X and both bone turnover markers and bone mineral density (BMD) in patients with Ehlers–Danlos syndrome.
Material and methods
This study involved a prospective evaluation of 30 female patients, aged 20–53 years, with hypermobile or classical Ehlers–Danlos syndrome. All patients underwent tests of their tenascin-X levels, calcium and phosphorus metabolism parameters, and BMD scans of the femoral neck and lumbar spine.
Results
The study showed no significant correlation between tenascin-X levels on one hand and femoral neck BMD (r_s 0.13, $P=0.49$), lumbar spine BMD (r_s 0.17, $P=0.36$), alkaline phosphatase levels (r_s 0.18, $P=0.33$), beta-crossLaps levels (r_s 0.11, $P=0.56$), or osteocalcin levels (r_s -0.08, $P=0.66$). Univariate logistic regression showed no statistically significant effect of tenascin-X levels on the development of osteoporosis (OR 0.48, 95% CI 0–1.32, $P=0.99$).
Conclusions
Tenascin-X does not show significant correlation with either bone turnover markers or BMD in females with Ehlers–Danlos syndrome.

A Case of Seizure Revealing Fahr's Syndrome with Primary Hypoparathyroidism

Hemmat El Haddad, Heba Murad, Nehal Hamdy, Rokaya Abdel Aziz, Heba Moustafa, Randa Salam, Mohamed magdy, Fady Nagi & Ahmed Atef
Cairo University, Internal medicine, endocrinology, Cairo, Egypt

Introduction
Fahr's disease, is a rare neurological disorder characterized by abnormal calcified deposits in the basal ganglia with a prevalence of $<1/1\ 000\ 000$
Case report
A 15-year-old male presented with focal seizures in right upper and lower limbs that progressed to generalized tonic clonic seizure and status epilepticus. No

history of head trauma, central nervous system infection, stroke, hypertension, diabetes, or autoimmune disease No family history of epilepsy He had recurrent episodes of focal seizures since the age of 10. EEG showed epileptiform waves, antiepileptic drug were started The patient was admitted to ICU with status epilepticus sedated on midazolam infusion, intubated and mechanically ventilated Pulse: 90/min, Bp: 100/70, RR: 18/min, Temperature: 37c (Hb) 13.4 g/dl, white blood cell count (WBC) 17.4 u/l; platelet 300 u/l, glucose 111 mg/dl (AST) 108 U/l; (ALT) 38 U/l U/l, creatinine 1.3 mg/dl; potassium 3.5 mmol/l; calcium 3.3 mg/dl; phosphorus 6.3 mg/dl; magnesium, 2.2 mg/dl (1.9–3.1 mg/dl); parathormone (PTH) 2.1 pg/dl (15–65 pg/dl); 25-OH vitamin D3 14.4 ng/ml (8.0–51.9 ng/ml); ANCA negative CT brain showed extensive bilateral cerebral calcification The patient received, calcium IV infusion (rate 0.5 mg/kg/h) for 24 h, antiepileptics (Levetiracetam 500 mg twice daily. Discharged on, oral medication started. Calcium Carbonate 600 mg 3 times daily oral Cholecalciferol) one bottle weekly Upon discharge calcium: 6.2 mg/dl, with no recurrent convulsions
Conclusion
We report a case of Fahr's syndrome with hypoparathyroidism in a patient with seizures as the main symptom. suspected by symmetrical and abnormal cerebral calcification

DOI: 10.1530/endoabs.99.EP773

Brown Tumor in a Normocalcemic Patient with Primary Hyperparathyroidism - A Case Report

Rokaya Abdel Aziz, Randa Salam & Walid Hassan
Cairo University, Internal medicine, endocrinology, Cairo, Egypt

Introduction
Brown tumor is a rare expansile osteolytic lesions benign bone lesion that arises as a direct result of parathyroid hormone on bony tissue in some patients with hyperparathyroidism. The reported prevalence of the brown tumour is 0.1% Brown tumor as the only and initial symptom of normocalcemic primary hyperparathyroidism is a rare clinical entity. Here, we present a case with multiple brown tumors in a young normocalcemic woman as a sequele of primary hyperparathyroidism mimicking bone metastases
Case report
44 year old female diabetic, hypertensive and hypothyroid presented by painless swelling over the lumbo-sacral region gradually increased in size not related to trauma. PAN-CT: large infiltrative heterogenous soft tissue mass at the sacrum (19.8×19.5×12.3 cm) serum calcium, phosphate and alkaline phosphatase, PTH were normal. Biopsy taken showed: numerous osteoclast-like multinucleated giant cells follow up of the mass size was advised every 3 – 6 months The patient developed anemic manifestation (Hb= 5 g/dl), for which She received blood transfusion 3 times and referred to our hospital for further assessment
Examination
She was depressed, BP:170/80, pulse:103 /mint, Temp: 37 C, pallor, Bilateral lower limb edema A mass felt occupying right iliac, suprapubic, left iliac fossae, large oval Lumbo-sacral swelling 19×10 cm, normal neurological examination HB 7.6 g/dl, MCV 90 fl, Platelet 351 U/l, TLC 6.4 U/l, creatinine 1.39 mg/dl, calcium 9 mg/dl, phosphrous 4.3 mg/dl, PTH 199.7 pg/ml (10-55) Abdominal and pelivc sonar showed, pelvi- abdominal mass with multiple cystic areas (23.3×15 cm) Kidneys: Bilateral Moderate Back pressure with bilateral Hydroureter 19×11 cm. 99 mTc Sestamibi parathyroid scan showed intense radiotracer uptake in the left upper neck (parathyroid adenoma), uptake in the sacrum (?brown tumor) Surgical removal of sacral mass was not applicable Left parathyroidectomy was done biopsy reported parathyroid adenoma Follow up after 3 years: normal serum PTH level, marked decrease in mass size (6.2×5.2×3.3 cm)
Conclusions
Brown tumors are extremely rare in normocalcemic primary hyperparathyroidism, accurate diagnosis enables the proper treatment

DOI: 10.1530/endoabs.99.EP775

EP776

Hypophosphatemic Rickets a clinical case report

Miriam Cozar, Rossana Manzanares Cordova & Manuel Martín López
Hospital Juan Ramón Jiménez, Endocrinology, Huelva, Spain

Background
Hypophosphatemic rickets, mostly of the X-linked dominant form caused by pathogenic variants of the PHEX gene, poses therapeutic challenges with consequences for growth and bone development and portends a high risk of fractions and poor bone healing, dental problems and nephrolithiasis/nephrocalcinosis (1). Children with hypophosphatemic rickets present poor growth, deformities of weight-bearing limbs such as genu varum or valgus, a 'rachitic rosary' involving the costochondral junctions, or enlargement of wrist, knees, or ankles among other symptoms. Family history may lead to detection of genetic forms prior to demonstration of rickets. (2)
Case report
14-year-old woman, referred from pediatrics due to growth retardation since early childhood. Family history of mother with pathological short stature of unstudied origin. Analyzes show persistently low phosphorus with low 25 OH vitamin D and elevated alkaline phosphatase, normal IGF1 and IGFP3. Karyotype 46XX. Bone age delayed 2 and a half years for chronological age. On physical examination, discrete genu varus, with short stature of 143 cms (-2.87 SD). Given the suspicion of hypophosphatemic rickets, a genetic study is requested: The patient is a heterozygous carrier of the variant c.1843A>C (p.Thr615Pro) in the PHEX gene, which is later confirmed in her mother. Currently undergoing treatment with oral phosphorus and cholecalciferol, she remains asymptomatic, with normalization of analytical parameters and with good clinical evolution.
Conclusions
Hypophosphatemic rickets/osteomalacia represent a set of rare disorders with many genetic and acquired causes and potential in long-term complications for children and adults, and diminishing physical function and quality of life. Conventional treatment with phosphate supplements and pharmacologic doses of active vitamin D may require the addition of growth hormone and calcimimetics. New biological therapeutics, including FGF23 targeting monoclonal antibodies or recombinant receptor blockers, are being developed and becoming available. Lastly, identification of genetic mutations associated with hypophosphatemia syndromes has contributed to our understanding of the pathogenesis and potential treatment of hypercalciuria, nephrocalcinosis, and renal stones disease.

Exploring the Uncharted Territory: Abacavir in HIV Treatment Unveils Rare Side Effect - A Focus on Hypophosphatemia

Abhishek Vyas & Asad Ali
King's Mill Hospital, United Kingdom

This case report highlights an unusual side effect of hypophosphatemia linked to Abacavir; a medication commonly used in the treatment of HIV. A 36-year-old male patient was referred to the endocrine team due to persistent hypophosphatemia while receiving Abacavir for his HIV management. Extensive investigations, including assessments of calcium levels Urea and Electrolytes, parathyroid hormone (PTH), Vitamin D, serum magnesium, and serum cortisol and fibroblast growth factor 23 (FGF23), yielded normal results. Following these findings, the case was discussed in an endocrine multidisciplinary team (MDT) meeting, leading to a consensus that the hypophosphatemia was likely associated with Abacavir use. This report aims to contribute to the existing body of evidence regarding this uncommon side effect. By presenting this case, we seek to raise awareness among healthcare professionals about the potential for hypophosphatemia in individuals undergoing Abacavir treatment for HIV. The involvement of various experts in the MDT discussion adds weight to the conclusion that the observed hypophosphatemia is likely attributed to Abacavir. This case report underscores the importance of considering medication-induced complications in patients with persistent hypophosphatemia, even when routine investigations produce normal results. By sharing this clinical observation, we hope to contribute valuable information to the medical community, fostering a better understanding of potential side effects associated with Abacavir and aiding in the optimization of patient care.

DOI: 10.1530/endoabs.99.EP780

EP782

Klinefelter Syndrome and Primary hyperparathyroidism—just a coincidence?

Cristina Ene
"Doctor Victor Babes" Foundation, Bucharest, Romania

Background
Two prevalent and underdiagnosed endocrine disorders are primary hyperparathyroidism and Klinefelter syndrome. The main cause of primary hyperparathyroidism is parathyroid adenoma. Less commonly multiple parathyroid hyperplasia have been described with or without genetic mutations. Klinefelter

syndrome could also be seen as a genetic disorder, being a chromosomal condition.
Methods
We report an uncommon association, without any family history, between Klinefelter syndrome and primary hyperaparathyroidism caused by the affection of two parathyroid glands.
Case report
The patient is a 50 year-old man, previosly diagnsticated with Klinefelter syndrome. He was referred by the urologist because of the suggestive clinical profile. The hypergonadotropic hypogonadism was confirmed as a Klinefelter syndrome by the cartiotip analysis. At the time of diagnosis, he also had a normocalcemic hyperparathyroidism in the presence of a vitamin D deficiency. Dual-energy X-ray absorptiometry (DXA) was normal. The patient receveid testosteron replacement. There was no need for fertility assessment. 1000 IU per day were used to treat the vitamin D3 deficit. After the diagnosis, the calcium levels started to rise above normal two years later. By now, the neck ultrasound had revealed a small right hyperechoic thyroid nodule and hypoechoic images with a polar doppler signal in the lower half, posterior to the left and right thyroid lobes, indicating parathyroid adenomas or hyperplasia. Technetium 99m-MBI-SPECT confirmed bilateral enhanced radionuclide accumulation at inferior parathyroid glands. DXA reveals a small decrease in bone mineral density only in the 1/3 distal part of the radius (osteopenia). The level of metanephrines/normetanephrines and calcitonin were normal. The patient was proposed to surgery, but due to the epidemiological context of COVID-19, survaillance was the choice. For now, the level of calcium is still above the normal level, with a normal level of phosphorous and vitamin D and normal renal function. No renal stones or progressive demineralization in the DXA study were observed. Ultrasound showed a growing left parathyroid nodule and a stationary right one. The thyroid nodule is also stationary. Surgery is scheduled to be done. Genetic testing is to be performed.
Conclusion
There hasn't been any evidence of a pathological or genetic connection between the two endocrine disorders. Our patient is scheduled for genetic testing – MEN syndrome and familial hyperparathyroidism must be ruled out in this instance, due to the enlargement of two parathyroid glands. Monitoring these rare occurrences is nevertheless essential to identify more abnormalities in the future.

EP786

Milk alkali syndrome secondary to over counter Antacids
Kalyani Nagarajah[1] & Marc Lyndon Evans[2]
[1]Swansea, Department of Endocrinology and diabetes, Swansea, United Kingdom; [2]University Hospital Llandough, Department of Endocrinology and diabetes, Cardiff, United Kingdom

Introduction
Milk – alkali syndrome is a rare and distinctive disorder caused by ingestion of large amounts of calcium and absorbable alkali resulting in hypercalcemia. It is characterized by a triad of hypercalcemia, metabolic alkalosis and renal failure. It was first described in 1920s, as it was mainly caused by administration of milk and bicarbonate for treatment of peptic ulcers. Since the usage of new treatment modalities for peptic ulcer disease, the incidences of milk alkali syndrome have decreased.
Case report
Here we present a 59 years old female patient, who presented to Emergency department for a fall and Syncopal episode. Our patient had few days history of increasing thirst, polyuria and diffuse abdominal discomfort. This prior to her syncopal episode, which lasted for few minutes with quick recovery. She had a past medical history of Endometriosis, Type 2 diabetes mellitus, epilepsy and ex-IVDU user with hep B in remission. She was suffering with frequent episodes of heart burns and self-treated this with over counter Rennie tablets. She had been taking almost 100 Rennie tablets per day and this over few weeks. On admission our patient was found to be confused and dehydrated. she had an adjusted calcium level of 4.55, Phosphate levels of 0.85, Suppressed PTH levels and acute kidney injury. Her Vitamin D levels on admission was 34 with urea of 16.9 and creatinine of 334. She had ECG changes related to the severe hypercalcemia. CT head performed for her syncopal episode did not report any abnormalities. Bence jones proteins, electrophoresis and ACE levels were within normal range. A CT Thorax, Abdomen and Pelvis was reported a 25 mm exophytic low density lesion over the upper pole of the right kidney. Following this an ultrasound was performed and this resulted in simple cyst as the lesion found on the upper pole of the kidney. Her Calcium levels responded well to aggressive Intravenous fluid resuscitations. Her latest calcium levels and renal function are within normal range and she was also imitated on vitamin D therapy.
Conclusion
We would like to emphasise the importance of considering over counter antacids treatment as iatrogenic cause of hypercalcemia, especially severe hypercalcemia like our patients. As mentioned above milk Alkali syndrome is rare nowadays, given new treatment modalities for indigestion and peptic ulcers.

Severe Hypercalcemia After Parathyroidectomy: When the Unexpected Happens
Tânia Carvalho, Gustavo Rodrigues, Bárbara Filipa Araújo, Joana Saraiva, Mara Ventura, Sofia Gouveia, Dírcea Rodrigues & Isabel Paiva
Centro Hospitalar e Universitário de Coimbra, Serviço de Endocrinologia, Diabetes e Metabolismo, Coimbra, Portugal

Introduction
Severe hypercalcemia is defined as a total serum calcium level >14 mg/dl or ionized calcium >10 mg/dl . The most common causes are primary hyperparathyroidism (PHPT) and neoplasms (90% of cases). Vitamin D intoxication is an extremely rare cause.
Case Report
A 56-year-old man presented to the emergency department with vomiting, generalized weakness and complaints of imbalance over one week. Upon physical examination, he displayed confusion, trunk and limb ataxia and abolished osteotendinous reflexes. He had history of multiple endocrine neoplasia (MEN) 1 and PHPT with a hypercaptant left inferior parathyroid on scintigraphy. Six weeks before admission, he underwent parathyroidectomy of the inferior glands (histology: hyperplasia). Postoperatively, calcium and parathyroid hormone (PTH) declined, reaching levels of 6.0 mg/dl for calcium and 0.3 pg/ml for PTH. His 25(OH)vitamin D level was 22 ng/ml. Supplementation was adjusted, and he was discharged with a regimen of Calcium Carbonate + Colecalciferol 1500 mg + 400IU, 2 tablets every 8 hours, and Calcitriol 0.25µg, 1 tablet every 6 hours. Upon admission, the patient's total serum calcium was exceptionally elevated at 23.8 mg/dl, with albumin measuring 4.4 g/dl, creatinine at 4.35 mg/dl (baseline 1.62), PTH <0.5 pg/ml, and 25(OH)vitamin D at 42 ng/ml. Phosphate and magnesium levels were within normal ranges. The therapeutic approach encompassed intensive fluid therapy, furosemide administration, calcitonin and zoledronic acid. Subsequently, the patient's serum calcium exhibited a gradual reduction, reaching 7.9 mg/dl by the 10th day of hospitalization. At this time, the patient reported that he had been taking not one but four calcitriol tablets every 6 hours due to a misunderstanding of the prescription, supporting the hypothesis of 1,25(OH)vitamin D intoxication. Oral supplementation was re-initiated. Serum calcium continued to decrease, reaching 6.6 mg/dl on the 13th day of hospitalization, which required intravenous calcium and adjustments to oral supplementation. Upon discharge, there was an improvement in renal function (creatinine 2.06 mg/dl), and serum calcium was stabilized at 8.4 mg/dl with a regimen of Calcium Carbonate + Colecalciferol 1500 mg + 400IU $2+2+1+2$ tablets and Alfacalcidol 1 mg $1+1$ tablet.
Conclusion
The possibility of vitamin D intoxication should be considered in the presence of hypercalcemia, decreased PTH, and no suspicion of malignancy. The patient was taking 4 mg of calcitriol daily, a dose much higher than recommended for hypoparathyroidism treatment (0.5–1.0 µg/day). This case reminds us of the need to regularly monitor calcium levels in patients with post-surgical hypoparathyroidism and ensure that patients understand the proposed therapeutic regimen.

Burnett's Syndrome – A Modern Presentation
Mohammad Jeeyavudeen & Ganesh Arunagirinathan
Metabolic Unit, Western General Hospital, Edinburgh, United Kingdom

Introduction
Milk-Alkali Syndrome (MAS), also known as Burnett's syndrome, is a triad of hypercalcemia, acute kidney injury and metabolic alkalosis, traditionally associated with excessive intake of milk and absorbable alkali. With changes in dietary supplements and medical prescriptions, its re-presentation in modern clinical practice has evolved making it the third common cause for hypercalcemia. This abstract presents a unique case of MAS resulting from relatively supraphysiological doses of calcium supplements in a patient with a low body mass index (BMI).
Case presentation
A woman in her early 60s presented with symptoms including confusion, constipation, excessive thirst, and tiredness. She has chronic excessive alcohol

intake, self-neglect, and poor oral nutritional intake. Three years prior to this admission, following low-velocity falls resulting in fractures, she was started on calcium and vitamin D supplementation containing 500 mg of calcium carbonate and 400 IU of cholecalciferol. Given her extremely low BMI of 10.59 kg/m^2, she was supplemented with Fortisip which contains additional calcium. On examination, she appeared severely emaciated with dry mucous membranes and signs of dehydration. Laboratory findings indicated a significantly low parathyroid hormone (PTH) level, elevated albumin corrected calcium, low magnesium and phosphate levels, and normal 25-hydroxy vitamin D. Her serum bicarbonate was extremely elevated. A full-body CT scan showed multiple bladder calculi with no evidence of underlying malignancy.

Discussion

The patient's medical history and acute presentation led to the diagnosis of MAS, primarily due to her high intake of calcium carbonate relative to her body weight, as evidenced by her metabolic alkalosis despite acute kidney injury. Upon discontinuation of calcium supplements, her PTH rose to 33.1 pmol/l, while calcium levels dropped to 2.16 mmol/l. MAS is classified into three types based on symptom duration and organ dysfunction: acute MAS or toxemic form, subacute form or Cope's syndrome, and chronic form or Burnett's syndrome. This case emphasizes the importance of individualized patient care, especially in managing dietary supplements, and highlights the potential risks of excessive calcium intake in patients with low BMI. It also stresses the need for vigilant monitoring of calcium and PTH levels to prevent recurrent hypercalciuria and kidney stone formation.

	Patient's value	Normal range
Adjusted calcium	4.38	2.2- 2.6 mmol/l
Phosphate	0.61	0.8-1.4 mmol/l
Magnesium	0.45	0.7-1.0 mmo/l
Bicarbonate	34	22-30 mmol/l
PTH	1.6	1.6-6.9 pmol/l
25-Hydroxy Vitamin D3	86	50-170 nmol/l
Estimated Glomerular Filtration Rate	59	
Myeloma and coeliac screen	Negative

Severe bone disease: Unusual mode of revelation of primary hyperparathyroidism in young A case Report

Meryam Alahyane, Sana Rafi, Salma El Hilali, Ghizlane El Mghari & Nawal El Ansari
Mohammed VI university hospital of Marrakesh, Department of Endocrinology, Diabetes, Metabolic diseases and Nutrition, MARRAKESH, Morocco

Background

Primary hyperparathyroidism (PHPT) is a systemic disease caused by lesions of the parathyroid gland, such as parathyroid adenoma, parathyroid hyperplasia, and parathyroid carcinoma. Bone disease is an important complication of hyperparathyroidism. We herein report a rare case of severe bone disease caused by primary hyperparathyroidism.

Case report

A 33-year-old female patient presented with a history of right lower limb pathological fracture, that restricted her mobility. The fracture was first treated surgically, without any medical follow-up. 5 years later, she presented in Emergency department with a severe anemia requiring a blood transfusion. Meanwhile laboratory data showed a hypercalcemia of 129 mg/l with an elevated serum Parathormone (PTH)of 744.3 pg/ml and vitamin D deficiency. Thyroid and multiple endocrine neoplasia (MEN) assessment were normal. X-ray examination showed Multiple osteolytic brown bone tumors disseminated throughout the skeleton. The CT scan demonstrated heterogeneous nodular formation located in the postero-inferior pole of the left thyroid lobe with a mediastinal extension measuring 26×25×47 mm. The patient was finally diagnosed with PHPT. She was prepared pre operatively with isotonic salin hydratation to manage hypercalcemia and vitamin D supplementation to avoid hungry bone syndrom. The patient underwent a surgical excision of the left inferior parathyroid. The surgical exploration of the remaining parathyroid glands was normal. The patient was discharged in good clinical condition. Total serum calcium and parathormone were within the reference range on the second day after surgery. Anatomopathological study in still in progress.

Discussion

PHPT leads to an excessive synthesis and secretion of PTH which causes an enhancement of osteoclasts' effects and causes Therefore calcium and phosphore in bones to be dissolved into the blood, resulting in hypercalcemia and hyperphosphatemia. Most patients with PHPT are asymptomatic. Very few may present with skeletal system manifestations such as bone pain, osteoporosis and pathological fracture; they may also develop brown tumors and osteitis fibrosa cystica. Most patients are first diagnosed in the department of orthopedics, resulting in a high rate of delayed treatment or misdiagnosis which can lead to further aggravation of pathological bone damage. Once confirmed, timely resection of the diseased parathyroid glands is considered to be the preferred method for the treatment of PHPT with severe bone disease, rather than treatment of the skeletal system disease only. After surgery PTH and other relevant indicators gradually return to normal levels, and new bone tissue gradually grows within and resolves the skeletal lesions.

Predictive factors of postoperative hypocalcemia in primary hyperparathyroidism

Sameh Mezri[1], Chaima Zitouni[1], Wadii Thabet[2] & Khemaies Akkari[1]
[1]Principal Military Hospital, Tunis, Tunisia; [2]Taher Sfar Hospital, Mahdia, Tunisia

Introduction

hyperparathyroidism is an endocrinopathy affecting calcium metabolism. Its curative treatment is surgical. Postoperative hypocalcemia is one of the main risks of this surgery.

Objective

The aim of this study is to identify predictive factors of postoperative hypocalcemia after surgery for primary hyperparathyroidism.

Method

This is a retrospective study including 84 patients operated on for pimary hyperparathyroidism in our department over a period from 2015 to 2023. We performed a statistical study in order to identify predictive factors of postoperative hypocalcemia.

Results

Early hypocalcemia (<4 days from surgery) was noted in 18 cases. It was related to hypoparathyroidism in 2 cases and to Hungry bone syndrome in 3 cases. Hypocalcemia was severe, leading to tetany in 3 cases. Predictive factors of early postoperative hypocalcemia were: the nature of the approach (unilateral or bilateral), association with a thyroid surgery, preoperative vitamin D deficiency and postoperative hypoparathyroidism (after 24 hours). Predictors of prolonged hypocalcemia (> 2 months) were: preoperative vitamin D deficiency, removal of a healthy gland in addition to the adenoma, preoperative malignant hypercalcemia, advanced bone disease, postoperative hypoparathyroidism and bulky adenomas.

Conclusion

Postoperative hypocalcemia is conditioned by certain clinical and biological factors. Demonstrating the involvement of these factors allows selecting at-risk patients in order to act on these parameters preoperatively, and to ensure stricter monitoring of the at-risk population postoperatively.

Surgery of primary hyperparathyroidism

Sameh Mezri[1], Chaima Zitouni[1], Wadii Thabet[2] & Khemaies Akkari[1]
[1]Principal Military Hospital, ENT, Tunis, Tunisia; [2]Taher Sfar Hospital, Mahdia, Tunisia

Introduction

Primary hyperthyroidism relates to the thyroid gland producing large amounts of hormone due to either uncontrolled growth of hormone-producing functional tissue. This condition needs to be treated surgically in order to prevent complications.

Objective

The aim of this study is to describe the surgical treatment of primary hyperparathyroidism.

Method

This is a retrospective study of 84 patients operated on for pimary hyperparathyroidism in our department over a period from 2015 to 2023.

Results

The mean age of our patients was 49 years, with a clear female predominance. Cervical ultrasound and parathyroid scintigraphy were performed in all cases. CT or MRI scans were performed in 5 cases. The approach was bilateral in 29% of cases, and unilateral in 71%. Among the patients operated on, a single gland was removed in 78 cases: an adenoma in 77 patients, and a hyperplasia in 1 case. Two glands were removed in 6 patients: a healthy gland with an adenoma in 2 cases, a

hyperplasia of both glands in 2 patients, and a double adenoma in 2 patients. Thyroid surgery was performed in 42.8% of cases. Postoperatively, dysphonia associated with unilateral recurrent paralysis was noted in 2 cases. Early hypocalcemia was noted in 18 cases. It was related to hypoparathyroidism in 2 cases and to Hungry bone syndrome in 3. Hypocalcemia was severe, leading to generalized tetany in 3 cases. We noted normalization of PTH levels within 72 hours of surgery in 90.5% of cases. Failure was noted in 6 cases, related to incomplete surgery for triple adenoma in 1 case, hyperplasia in 3 cases, glandular ectopy in 1 case and multiple endocrine neoplasia in 1 case.
Conclusion
Surgery of primary hyperparathyroidism leads to good therapeutic results. However, there is a risk of failure. It may be related to multiple adenoma, glandular ectopy or hyperplasia of several glands.

Case Report- An Atypical Case of Familial Hypocalciuric Hypercalcemia: A Novel missense mutation in the CASR Gene?

Taqiyeddine Louifi[1], Jana Perpetue[2] & Hajer Zayet[2]
[1]Nord Franche-Comte Hospital (HNFC), Department of Endocrinology and Diabetes, Trevenans, France; [2]Nord Franche-Comte Hospital (HNFC), Trevenans, France

Back Ground
Familial hypocalciuric hypercalcemia (FHH) is a benin cause of hypercalcemia that is characterized by autosomal dominant inheritence with high penetrance. In most cases, FHH results from inactivating mutations in the CaSR, the phenotypic aspect is a mild to moderate hypercalcemia, inappropriately normal or high PTH levels and relative hypocalciuria.
Case report
We describe an atypical case of a 46 years old man who had clinical finding compatible with FHH but with unusual description: asymptomatic severe hypercalcemia up to 3.02 mmol/l, high PTH level up to 166 ng/l and a very low 24 hours calciuria: calcium-to-creatinine-clearance ratio 0.0013. First Genetic analysis revealed an unknown missense variant CASR gene sequence: c.1682G>A (p.Cys561Tyr).
Discussion
Severe hypercalcemia is unusual with FHH type 1, we describe an atypical presentation of FHH. To our knowledge, this CASR sequence variation has not previously reported in the literature. Nevertheless, this is still a provisional result, it will be completed and confirmed by a second genetic analysis on a PAXgene blood DNA Tube.
Conclusion
This CASR mutation will probably represent a novel pathogenic sequence variation causing a type 1 FHH with severe hypercalcemia.

Assesement of the quality of life among patients followed for chronic hypoparathyroidism

Nabil Skouta, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
UHC Ibn Rochd, Casablanca, Morocco, Department of Endocrinology, Diabetology and Metabolic Diseases, Casablanca

Introduction
Hypoparathyroidism refers to a set of clinical and biological manifestations that occur when parathormone secretion is insufficient. Individuals enduring persistent hypoparathyroidism encounter various symptoms and face enduring complications that may jeopardize their overall well-being."
Objectives
The objective of our study is to assess the quality of life (QOL) of patients followed for hypoparathyroidism receiving conventional treatment.
Patients Et Methods
This is a descriptive cross-sectional study involving 39 patients followed in the endocrinology outpatient clinic at Ibn Rochd University Hospital in Casablanca from January 2023 to November 2023. The impact on QOL was assessed using the SF-36 score. Data were analyzed using IBM SPSS Statistics 27.0.
Results
Our study included 39 patients with an average age of 41 years, with a female predominance of 80%. The etiologies of hypoparathyroidism were as follows: 74% post-surgical hypoparathyroidism, 20% autoimmune hypoparathyroidism, and 5% pseudo-hypoparathyroidism. The scores were on average 47% for physical limitation, 33% for psychological limitation, 43% for energy, 60% for mental health, 75% for social activity, 45% for pain, and 54% for general health.
Conclusion
This study suggests an impairment of the quality of life in multiple domains in patients with chronic hypoparathyroidism. It is necessary to improve medical treatment and management for these patients.

Milk-alkali syndrome in primary hypoparathyroidism: a case report

José Vicente Rocha[1], Mariana Silva de Sousa[2], Mariana de Griné Severino[1], Yolanda de Sá Pereira[2], Tiago Santos[2] & Ana Gomes[2]
[1]ULS Santa Maria, Endocrinology, Diabetes and Metabolism, Lisbon, Portugal; [2]ULS Santa Maria, Internal Medicine, Lisbon, Portugal

Introduction
Hypoparathyroidism treatment is aimed to achieve a serum calcium at the lower limit of normal providing symptom resolution and preventing complications such as urolithiasis and renal impairment. Milk-alkali syndrome (MAS) incidence has been gradually rising associated with the increase of calcium carbonate and vitamin D supplementation. The classic triad is characterized by metabolic alkalosis, hypercalcemia and renal failure.
Case report
A 34-year-old male with DiGeorge syndrome was referred to the Endocrinology clinic due to primary hypoparathyroidism. Previous personal history was relevant for Evans syndrome under Eltrombopag treatment, epilepsy and schizophrenia. He was treated with a calcium carbonate/cholecalciferol association (1500 mg + 400 UI) and calcitriol 0.25 mg with daily doses being titrated to 9000 mg of calcium carbonate and 1.25 mg of calcitriol daily in order to achieve a serum calcium of 8-8.4 mg/dl and a normal serum phosphorus. At a scheduled revaluation, the patient presented with hypercalcemia (serum calcium of 13.9 mg/dl), acute renal failure (serum creatinine of 2.72 mg/dl), and metabolic alkalosis (pH of 7.52, pCO2 46.3 mmHg and HCO3 29.2 mmol/l). The patient denied anti-inflammatory medication, nausea and vomiting, fever, respiratory or gastrointestinal symptoms. Hypoparathyroidism treatment was stopped and the patient was admitted to the hospital. Intravenous fluid replacement was started with a slow gradual renal function recovery and calcium normalization. Malignant hypercalcemia was excluded with whole body CT scan, PTHrP measurement and serum PSA. Angiotensin converting enzyme and serum immunofixation were normal. Patient denied frequent consumption of antacids or canned or preserved foods but admitted to daily consumption of calcium enriched milk. MAS diagnosis was assumed. Calcium carbonate and calcitriol were restarted at lower dosages, and dietary counselling was made. Patient maintained desired calcium levels with 4500 mg of calcium carbonate 1 mg of calcitriol.
Conclusion
This case highlights that MAS is a possible complication of hypoparathyroidism treatment. Calcium and vitamin D supplementation should be tailored to individual patients and a closer monitoring may be needed in patients under higher daily doses.

Lameness revealing primary hyperparathyroidism jaw-tumor syndrome (HPT-JT)!

Marwa El Arem[1], Taieb Ach[2], Asma Ben Abdelkarim[2], Amel Maaroufi[2], Molka Chadli Chaieb[2] & Koussay Ach[2]
[1]Hospital Fatouma Bourguiba, Endocrinology; [2]Farhat Hached University Hospital Sousse, Endocrinology

Introduction
Primary hyperparathyroidism JawTumor Syndrome is a rare genetic disorder characterized by the synchronous or metachronous occurrence of primary hyperparathyroidism and an ossifying fibroma of the maxilla and/or mandible, associated with an increased risk of parathyroid carcinoma.
Observation
We report the case of a 30-year-old young woman who consulted for a limp in walking,6 months after having been operated for a juvenile ossifying fibroma of the mandible. Standard X-ray showed multiple giant lacunar images at the level of the two iliac bones and the right femur, evoking brown tumours. A phosphocalcic assessment was requested showing a malignant hypercalcemia at 4.3 mmol/l,

hypophosphatemia at 0.4 mmol/l, PTH = 1360 pg/ml, PAL = 900 IU/l, creatinine = 85 µmol/l. Dual energy X-ray (DXA) showed osteoporosis at the neck of hip and 1/3 proximal of the radius. Cervical ultrasound and the SPECT-CT scintigraphy with 99m Tc-MIBI showed a 2.5×15 mm hypoechoic left subthyroidal formation with regular contours and hypervascularisation, no thyroid nodule, and no cervical adenopathies. The clinical picture was strongly suggestive of primary hyperparathyroidism in the context of jaw tumour syndrome. The abdomino- pelvic ultrasound was also performed, which showed no associated uterine polyps or tumours, nor renal tumors. The patient underwent a left inferior parathyroidectomy which was atypical in appearance. The histological examination revealed a parathyroid adenoma with no evidence of malignancy.

Conclusion

Primary hyperparathyroidism jaw -tumor syndrome is an entity that should be known given the association with malignant and atypical forms of parathyroid tumors of non-endocrine tumors that should be sought.

DOI: 10.1530/endoabs.99.EP863

Non-traumatic fractures in the elderly do not omit primary hyperparathyroidism

Abdelkader Yahi, Longo Redoune, Benabdellatif Katia, Lachekham Aicha, Haffaf Lounes, Amokrane Affaf, Boumesbah A, Addab Fahd, Rannai A, Ould-Kablia Samia & Bensalah Meriem
Algeria, Endocrinology, Bir Mourad Rais

Background

The presentation of primary hyperparathyroidism has changed radically over 30 years. Indeed, currently, asymptomatic forms which represented around a quarter are now estimated at 80% of cases.

Case description

We report the case of a 57-year-old women, postmenopausal for 10 years, who presented following a fall from height with a triple pathological fracture (the left humeral head and the two upper ends of the femurs). Surgical treatment was indicated but rejected in the face of severe osteoporosis (Tscore a -6.3 at the cortical bone level). The pre-therapeutic assessment of bisphosphonates revealed severe hypercalcemia (> 3 mmol/l). The diagnosis of primary hyperparathyroidism was confirmed with a PTH level > 5000 pg/ml on a left parathyroid macroadenoma, mixed solido-cystic with a long axis of 44 mm. Morphological exploration revealed multiple brown tumors, and multiple bilateral renal micro- and macro-lithiasis with right hydronephrosis. The patient underwent a successful parathyroid adenectomy (post-operative PTH had PTH at 11 pg/ml). The histological study is in favor of benignity.

Discussion

The revelation of primary hyperparathyroidism by a fracture is rare. Brown tumors can be completely asymptomatic, manifest as bone pain or even pathological fractures. Histologically they correspond to an area of osteoclastic hyper-resorption containing hypervascular inflammatory connective tissue, giant cells, and hemosiderin deposits. The classic sites of involvement are the facial bones, ribs, pelvis, femur, other long bones and rarely the vertebrae. Primary hyperparathyroidism is most often related to a benign parathyroid adenoma. However, the existence of a polymorphic and more pronounced symptomatology due to severe hypercalcemia, with bone and renal manifestations; as well as other digestive, cardiovascular and psychological signs, should point towards parathyroid carcinoma

Conclusion

Serious skeletal manifestations of primary hyperparathyroidism (fibrocystic osteitis, brown tumors, pathological fractures) are rare. Any medical practitioner must consider the diagnosis of primary hyperparathyroidism at the stage of bone pain before complications set in.

Simpson Golabi Behmel Syndrome: a new case and review of the literature

El Jadi Hamza[1], Moumen Amal[2] & Gaouzi Ahmed[3]
[1]Oued Eddahab Military Hospital, Endocrinology, Agadir, Morocco; [2]Moulay Ismail Military Hospital, Endocrinology, Meknes, Morocco; [3]Rabat Children's Hospital, Faculty of Medicine and pharmacy- Rabat, Mohamed 5 University, Pediatric Endocrinology Department, Rabat, Morocco

Summary

Simpson Golabi Behmel Syndrome (SGBS) is a rare syndrome characterized clinically by multiple congenital anomalies, pre and postnatal overgrowth, characteristic craniofacial anomalies, macrocephaly, and organomegaly associated with abnormalities of the skeletal system. The spectrum of signs and symptoms associated with SGBS is wide, ranging from very mild to fatal forms, especially in affected men. We report a rare case of a child affected by SGBS type 1, emphasizing the clinical, paraclinical, therapeutic and monitoring modalities of this possibly serious syndrome. A 12-year-old child from a non-consanguineous marriage consulted for tallness, mental retardation and school difficulties. The clinical examination finds a stature advance: his weight is 43 kg (+1 Standard Deviation (SD)) and his height is 168 cm (between +2 and +3 SD) with macrocephaly, facial dysmorphism made up of hypertelorism, an erased nasal root with a nasal saddle, a macrostomy with a thin upper lip, an everted lower lip with the presence of dental caries (figure 1). Furthermore, the patient presents with supernumerary breasts (figure 2), left post-axial polydactyly (image 3) and cryptorchidism. The skeletal assessment reveals rib synostosis. Ophthalmological, cardiovascular and abdominal examinations were normal. The biological and hormonal dosages are unremarkable. The genetic study suggested the diagnosis of SGBS type 1. The molecular study of the GPC3 gene showed that he carries a de novo nonsense mutation (c.271C>T: p.Gln91X), because his mother does not carry this mutation. SGBS is a rare syndrome. The spectrum of signs and symptoms associated with SGBS is broad, varying from very mild forms in carrier females to infantile lethal forms in affected males. A percentage of affected males die in the newborn period, some of them probably due to heart defects. Carrier females and people with milder cases often live into adulthood. Because of the varying degrees of manifestations and severity associated with the condition, prediction of prognosis and life expectancy most likely varies on an individual basis. Intellectual disability must be carefully evaluated due to the majority of patients have normal intelligence, and do not have the coarse facial and difficulties in speech as we expected for classical SGBS. Our observation reports a new case of SGBS type 1. Despite its rarity, this syndrome requires early and, above all, multidisciplinary management in order to take care of all potential complications in time.

Morphofunctional assessment in patients with hypophosphatasia: usefulness of muscle ultrasound in the diagnosis of sarcopenia

María Del Carmen Andreo-Lopez[1], Victoria Contreras Bolivar[1,2,3], Enrique Moratalla-Aranda[2,4], Trinidad González-Cejudo[2,5], Luis Martínez-Heredia[2], Francisco Andújar-Vera[2,6,7], Cristina García-Fontana[1,2,3], Beatriz García-Fontana[1,2,3] & Manuel Muñoz-Torres[1,2,3,8]
[1]Endocrinology and Nutrition Unit, Hospital Universitario Clínico San Cecilio, Granada, Spain; [2]Institute of Biosanitary Research of Granada (ibs.GRANADA), Granada, Granada, Spain; [3]CIBER on Frailty and Healthy Ageing (CIBERFES), Instituto de Salud Carlos III, Spain; [4]Nuclear Medicine Unit, Hospital Universitario Clínico San Cecilio, Granada, Spain; [5]Clinical Analysis Unit, Hospital Universitario Clínico San Cecilio, Granada, Spain; [6]Andalusian Institute for Research in Data Science and Computational Intelligence, Granada, Spain; [7]Department of Computer Science and Artificial Intelligence, Granada, Spain; [8]Department of Medicine, University of Granada, Granada, Spain

Introduction

Hypophosphatasia (HPP) presents with defective bone mineralisation secondary to a deficit of non-tissue-specific alkaline phosphatase, increasing the risk of bone fracture. Sarcopenia may increase this risk. Therefore, rapid diagnosis with accessible and cost-effective tools such as ultrasound could be useful in clinical practice. The aim was to assess the correlation of ultrasound with another validated muscle mass assessment technique.

Material and Methods

Cross-sectional study in adults with PPH. Demographic (age, sex), analytical (alkaline phosphatase-AP) and clinical variables were collected (fractures, muscle strength measured with Jamar dynamometer in kilograms (kg) -cut-off point: <p10 of Spanish population-, rectus femoris quadriceps muscle mass with ultrasound -Sonosite S-Nerve®-, fat-free mass (FFM) in kg, fat mass and bone mineral density (according to T and Z-score) by dual-energy X-ray absorptiometry (DXA). Statistical analysis was performed with IBM SPSS v.25.

Results

Thirty-three subjects were studied, 55% women aged 49 ± 18 years and mean FA: 29 ± 11. 52% had at least one bone fracture and 67% had dental pathology. Low muscle strength was detected in 24% (62.5% men). Mean Y-axis was 1.4 ± 0.7, mean circumference 9 ± 2 and mean area 4.4 ± 2. Mean FFM was 46.5 ± 13.5. Muscle strength was positively correlated with Y-axis ($r = 0.42$, $P = 0.02$), with

muscle area ($r=0.4$, $P=0.02$), with T-score in femoral neck ($r=0.48$, $P=0.01$) and in lumbar spine ($r=0.66$, $P<0.001$). Pressor strength in women was associated with BMI and FFM ($P=0.004$). It also showed a tendency to be associated with ultrasound muscle circumference ($P=0.09$). Muscle area correlated positively with FFM ($r=0.52$, $P=0.01$) and negatively with fat ($r=-0.37$ $P=0.03$).

Conclusions

Ultrasound assessment was associated with body composition and muscle function parameters. Given its accessibility, ultrasound is a useful tool to assess muscle in PPH patients, allowing an early approach to reduce the risk of osteosarcopenia.

Corticosteroid-associated osteonecrosis of the femoral head in young adolescents post-COVID 19 era - Two case reports

Andreea Anne-Marie Stefan[1,2], Burcea Iulia-Florentina[1,2], Dobre Ramona[1,2] & Catalina Poiana[1,2]

[1]C.I Parhon National Institute of Endocrinology, Pituitary and Neuroendocrinology Department, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucureşti, Romania

Background

Avascular necrosis of the femoral head (AVNFH) is a disorder caused mainly by chronic glucocorticoid use. Systemic corticosteroid (CS) therapy was widely used in patients with mild or moderate SARS-CoV 2 infection despite lack of clinical benefits. However, emerging evidence suggests that COVID-19 infection can cause long-term effects, affecting different body systems, known as 'long COVID-19'[1]. One such sequela is AVNFH, although the link between AVNFH and SARS-CoV 2 infection has not been fully documented. We describe two cases of AVNFH following COVID-19 infection who received high-doses of CS.

Case study

The first case is that of a 17-year-old female patient, with history of non-Hodgkin lymphoma (NHL) stage III, treated with intensive chemotherapy, according to a specific protocol, which included dexamethasone (an approximate dose of 120 mg prednisone equivalent per day). Six months later, she received Prednisone, 50 mg/day for fourteen days for moderate COVID-19 infection. After three months, she was referred to our hospital with severe bilateral hip joint pain. Magnetic resonance imaging (MRI) of the hip showed AVNFH: on the right, stage IV and on the left, stage III according to FICAT and ARLET classification. The patient received one intravenous (iv) ibandronate injection, but the treatment was discontinued at the indication of her paediatric oncologist. Bilateral total hip arthroplasty was planned. The second case is that of a 16-year-old female patient with history of myasthenia gravis for which she received Prednisone, 45 mg/day, initiated in January 2022. Three months later, she developed severe SARS-CoV 2 infection, so the dose of Prednisone was increased at 50 mg/day. She was referred to our clinic after three months, presenting cushingoid phenotype and severe thoracic back pain caused by vertebral compression fracture at T4 and T8 level. She underwent progressive dose reduction of CS until cessation and was treated with iv ibandronate. One year later, after a mild COVID-19 infection, she experienced severe bilateral hip joint pain. MRI of the hip revealed bilateral AVNFH (right> left), stage II-III according (FICAT and ARLET classification). Treatment with iv bisphosphonate was continued and hyperbaric oxygen therapy was performed.

Conclusions

AVNFH in patients surviving COVID-19 could be considered a multifactorial problem and additional research is needed to establish a risk stratification and long-term follow-up protocol for these patients in order to properly diagnose and treat them.

Garofalidis', School of Medicine, Athens, Greece; [4]National and Kapodistrian University of Athens, School of Medicine, Post Graduate Course on Bone Metabolic Diseases, Athens, Greece

Objective

Menopausal hormone therapy (MHT) is efficacious in reducing the risk of vertebral, non-vertebral and hip fractures, irrespective of age, falls risk or baseline FRAX probability. However, the optimal sequential anti-osteoporotic treatment after MHT discontinuation has not yet been designated. This systematic review aimed to obtain the best evidence regarding the effect of antiresorptive or osteoanabolic treatment on bone mineral density (BMD) and/or fracture risk following MHT.

Methods

A comprehensive search was conducted in PubMed, Scopus and Cochrane databases up to October 31, 2023. Randomized-controlled trials (RCTs) and observational studies conducted in postmenopausal women were included.

Results

After the exclusion of duplicates, 717 studies were identified. Two were eligible for qualitative analysis, one RCT and one retrospective cohort study. The RCT showed that alendronate 10 mg/day for 12 months further increased lumbar spine (LS) BMD by 2.3% following MHT, whereas a mean loss of 3.2% was observed in the placebo group (mean difference: +5.5% between groups). Regarding femoral neck (FN), alendronate maintained BMD, whereas it decreased by 1.4% in the placebo group ($n=144$). Alendronate also decreased bone anabolic and resorption markers by 47% and 36%, respectively. In the retrospective study ($n=34$), raloxifene 60 mg/day increased both LS and FN BMD at 12 months by 3% and 2.9%, respectively. A limitation of this study was the lack of a placebo group. No fractures were reported.

Conclusions

Anti-resorptive therapy with either a bisphosphonate (i.e., alendronate) or raloxifene could be considered a sequential anti-osteoporosis therapy after MHT withdrawal, since they have shown in studies to further increase BMD. However, no safe conclusions can be drawn from the existing literature.

Superficial phlebitis: mode of revelation or complication of primary hyperparathyroidism: about 2 cases

Malak Riznat

Mohamed V Military training hospital, Rabat

Introduction

Superficial phlebitis is a clinical manifestation found in many pathologies, often unexplored or mistaken for simple venitis. It should be noted that it may be part of the thromboembolic complications of primary hyperparathyroidism, or an unusual mode of revelation. We describe 2 clinical situations which illustrate this symptom discovered in two different contexts

Observation 1

60-year-old patient admitted for investigation of symptomatic primary hyperparathyroidism revealed in a context of microlithiasis complicated by acute pyelonephritis with associated osteoarticular repercussions. During her hospitalization, the patient presented with painful edema of the limb, and ultrasound revealed venitis with thrombosis of the cephalic vein of the forearm. She was put on anticoagulant therapy for one month.

Observation 2

26-year-old patient admitted to the endocrinology department for management of hyperparathyroidism with the following biological criteria: PTH: 5 times normal Hypercalcemia 120 mg/ and hypophosphatemia and hypercalciuria 430 mg/24 h. This is an asymptomatic hyperparathyroidism with no complications, for which the phosphocalcic work-up was performed mainly when superficial venous thrombophlebitis of the ESV occurred.

Discussion and conclusion

Primary hyperparathyroidism is an increasingly frequent pathology, the diagnosis of which may be delayed by a clinical picture that may be suggestive of non-specific clinical signs. Thromboembolic manifestations have been reported as part of the complications of primary hyperparathyroidism, and can also constitute an unexpected mode of revelation, ranging from simple superficial phlebitis to deep vein thrombosis, with the risk of progression to pulmonary embolism, which can be life-threatening. A phosphocalcic assessment should be carried out in any patient presenting a clinical thromboembolic picture.

Recurrent hyperparathyroidism after total parathyroidectomy with autotransplantation in a patient with long-term hemodialysis

Cristina Serban, Nicoleta Baculescu & Catalina Poiana
C.I. Parhon National Institute of Endocrinology

Background
Recurrenthyperparathyroidism following total parathyroidectomy with auto-transplantation in patients with end-stage renal disease who are on hemodialysis is not an uncommon condition and can be due to hyperplastic autografted tissue, remnant parathyroid tissues in the neck or in the presence of ectopic and/or supernumerary parathyroid glands.
Case report
We report the case of a 66-year-old patient with a history of chronic kidney disease on hemodialysis since 2012, surgical hypothyroidism (she underwent total thyroidectomy in 2017 for non-toxic multinodular goiter) and tertiary hyperparathyroidism for which she underwent total parathyroidectomy with autograft transplantation into the left sternocleidomastoid muscle in 2017, who referred to our clinic with a progressive swelling on the left side of the neck over the last few months. The clinical examination was unremarkable except for a soft, non-tender, mobile left-sided cervical mass of approximately 3×1.5 cm. Biochemical evaluation revealed normal corrected serum calcium (9.3 mg/dl, $n=8.5$-10.2) and serum phosphorus (3.6 mg/dl, $n=2.5$-4.5) levels and the intact PTH level was significantly increased (915.3 pg/ml, $n=15$-65) demonstrating secondary hyperparathyroidism. The bone turnover markers were elevated: crosslaps = 2.8 ng/ml ($n=0.33$-0.78), osteocalci$n$ = 463.6 ng/ml ($n=15$-46); alkaline phosphatase was 119 IU/l ($n=38$-105) and serum 25 OHD was 17.9 ng/ml ($n=20$-100). Her thyroid function revealed subclinical hypothyroidism; ATPO, ATG and calcitonin were within normal ranges. Neck ultrasound showed a hypoechoic nodular mass of 2.85/1.48 cm in the left thyroidectomy bed. Fine needle aspiration of the neck mass was performed; the level of PTH in the aspiration needle wash-out fluid was over 5000 pg/ml. We recommended treatment with Paricalcitol at a dose of 5 mg three times a week during hemodialysis sessions. Cinacalcet was not available as a therapeutic option. A three months follow-up revealed an iPTH level of 1515 pg/ml.
Conclusions
We presented a patient with end-stage renal disease and secondary hyperparathyroidism at 6 years after the total parathyroidectomy with autograft transplantation for tertiary hyperparathyroidism. Considering the refractory hyperparathyroidism on the pharmacological treatment available in this case, surgical reintervention to remove the hyperfunctioning parathyroid tissue is necessary.

Case report - congenital ichthyosis and hypoparathyroidism with hypocalcemic seizures in a teenager

Alexandra Mirica[1], Maria Lavinia Popa[1], Adriana Diaconeasa[1], Diana Monica Preda[1] & Diana Loreta Paun[2]
[1]Grigore Alexandrescu Emergency Clinical Hospital for Children, Bucharest, Romania; [2]Carol Davila University of Medicine and Pharmacy, Bucureşti, Romania

Introduction
Congenital ichthyoses are a group of inherited keratinization disorders that pose a challenge in terms of diagnosis, treatment, and clinical associations with other pathologies. The association with vitamin D deficiency and possible bone changes is cited, but the exact mechanism of occurrence of endocrine pathologies is not described.
Case report
We report the case of a 16-year-old teenage boy known to have congenital ichthyosis, having been under the care of a dermatologist since birth. He was recently admitted to our clinic for hypocalcemic seizures, without a detectable etiology, with good response to calcium supplementation. On clinical examination, the adolescent had a normal waist and weight, being in Tanner stage 4 development. At the first endocrine evaluation we detected a total calcemia of 6 mg/dl, with low PTH values, slightly increased phosphorus, mild vitamin D deficiency, and normal albuminemia, glucose, renal and liver function values. In addition, evaluation of thyroid, adrenal, testicular and pituitary hormone axes showed normal values. Neurological and ophthalmological evaluation did not identify pathological changes, but cerebral CT showed the presence of intracerebral calcifications. In the face of a diagnosis of hypoparathyroidism the evolution was favourable on optimal treatment with oral calcium together with active vitamin D.
Conclusion
Hypoparathyroidism may be associated with congenital ichthyosis but further studies are needed to establish the exact etiopathogenic mechanisms.

EP1008

Primary hyperparathyroidism in familial multiple endocrine neoplasia type 1- Case Report

Ana Tofan[1], Letitia Leustean[2,3], Cristina Preda[2,3], Gina Neculaes[3], Nada Akad[3] & Maria- Christina Ungureanu[2,3]
[1]Arcadia Hospital, Medical Departament, Iasi, Romania; [2]University of Medicine and Pharmacy –Gr.T. Popa, Endocrinology, Iasi, Romania; [3]St. Spiridon Hospital, Endocrinology, Iasi, Romania

Recurrent hypercalcemia after successful parathyroidectomy has been reported to be higher than previously thought. Most cases are transient and often associated with other factors, with only a minority requiring treatment. Multidisciplinary diagnosis is necessary to prevent persistence and recurrence. A 55-year-old female patient with a history of surgical removal of a right parathyroid adenoma four years prior, lost from follow-up, was referred to our clinic for persistent asthenia, weight loss and stool modification. Recent familial history with two sons operated for primary hyperparathyroidism. The biological assessment revealed a recurrence of primary hyperparathyroidism, renal failure (creatinine clearance 27 mg/dl), persistent anemia with high levels of Ca19-9 and Chromogranine A, and normal adrenal and pituitary hormonal profile. Abdominal CT scan pointed out bilateral adrenal adenoma, left renal lithiasis, obstructive pelvic calculus and grade IV left hydronephrosis. An exploration of the upper and lower digestive tubes was performed by endo and colonoscopy, revealing an active ulcer and chronic gastroduodenitis. In addition, a Scintigraphy with Tektrotyde (573.7 MBq) highlighted a small nodular hepatic lesion with a Krenning 2 score. The Tc99 Sestamibi imaging confirmed hot uptake lesions in the superior and inferior left parathyroid regions and a slight uptake in the right parathyroid region. With confirmatory imaging findings and presenting symptoms, our patient was clinically diagnosed with MEN 1 syndrome and underwent surgical and medical management in the urology and surgical department. Genetic findings and confirmation of MEN 1 syndrome in her eldest son reinforced our clinical suspicion.
Conclusion
Multiple endocrine neoplasia (MEN1) is a rare, inherited multi-tumor syndrome, often underdiagnosed, affecting neuroendocrine and non-endocrine tissues. Its aspects are highly variable, with no genotype-phenotype correlation. In our patient, MEN1 syndrome was revealed at an advanced age by recurrent primary hyperparathyroidism (parathyroid hyperplasia), non-functional adrenal bilateral lesions and neuroendocrine hepatic tumour. Long-term follow-up of serum calcium should be considered in patients after successful parathyroidectomy.

A bibliometric approach to scientific production on familialhypophosphatemic rickets in scopus (2000-2022)

Frank Hernández García[1,2], Helena Gil Peña[3], Julían Rodríguez Suárez[4], José López García[5], Patricia Oro Carbajosa[5], Rocío Fuente Pérez[6] & Ibraín Corrales Reyes[7]
[1]University of Oviedo - El Cristo Campus, Medicine, Oviedo, Spain; [2]Instituto de Investigación Sanitaria del Principado de Asturias (ISPA), Paediatrics Research Group, Oviedo, Spain; [3]Instituto de Investigación Sanitaria del Principado de Asturias (ISPA), Oviedo, Spain; [4]Central University Hospital of Asturias, Oviedo, Spain; [5]University of Oviedo - El Cristo Campus, Oviedo, Spain; [6]Fundación Jiménez Diaz, Madrid, Spain; [7], Florida, United States

Background
Hypophosphatemic rickets are disabling conditions that negatively impact physical functioning, activities of daily living, mental health, social life, and leisure activities. The most common cause of Hypophosphatemic rickets is genetic factors, such as X-linked hypophosphatemia. The evaluation of the scientific application of familial hypophosphatemic rickets aids in understanding the research landscape, identifying opportunities for improvement, and promoting significant advancements in the understanding and treatment of this medical condition.
Methods
An observational, descriptive, and cross-sectional study was conducted through a bibliometric analysis of the scientific output of the Familial Hypophosphatemic

Rickets published in journals indexed in Scopus during 2020-2022. To retrieve the publications, Scopus was accessed on April 4, 2023, and an advanced search was performed using a filter by title, abstract and key words, source (journals), publication year, and type of article (article and review). The search terms used were extracted from the PubMed Medical Subject Headings (MeSH) related to the disease included in the MeSH catalog. Additionally, an analysis of co-occurrence between countries and keywords was carried out with VOSviewer software.
Results
This study identified 1,269 articles on hypophosphatemic rickets (938 articles and 331 reviews). In total, 39,548 citations were received, with an H index of 95. The majority of the articles (76.9%) were published in high-impact journals (Q1 and Q2 journals). Scientific production has shown a growing trend in recent years. The countries with the highest scientific production are the U.S, Japan, and the United Kingdom, considering that middle- and low-income countries contribute less to international scientific production.
Conclusions
Scientific production has shown sustained growth in recent years. The U.S solidifies itself as the country leading scientific production on hypophosphatemic rickets.
Keywords: bibliometrics, familial hypophosphatemic rickets**,** rickets, FGF23 protein, PHEX protein, X-linked hypophosphatemic rickets, burosumab.

Severe osteoporosis in a patient with primary adrenal insufficiency and hypothyroidism: is there an association?
Davis Ogeto, Muhammad Tahir Chohan & Kamal Abouglila
University Hospital of North Durham, United Kingdom

Introduction
Osteoporosis can be associated with Cushing syndrome or hyperthyroidism but is an unusual finding in a patient with primary adrenal insufficiency (with physiological dose of steroid replacement) and concurrent autoimmune hypothyroidism without any other secondary causes of osteoporosis. We present a case of severe osteoporosis in a postmenopausal female in whom we could not establish a verifiable cause.
Case
A 60-year-old postmenopausal woman, previously fit and well and no past medical history of significance, not on any regular medications, initially diagnosed with autoimmune hypothyroidism but levothyroxine replacement resulted in further worsening of her symptoms mainly tiredness, lightheadedness and dizziness which prompted further screening of autoimmune adrenal insufficiency and physiological doses of hydrocortisone and fludrocortisone were initiated resulting in complete resolution of her symptoms remaining clinically well for the following 6-7 months. Beacuse of ongoing back pain and normal MRI lumbosacral spine, we did bone densitometry scan revealing severe osteoporosis with total hip T score of -3.5, lumbar spine -4.5 and femoral neck -2.9. There was no history of eating disorder, malabsorption or premature ovarian failure. She was not on any medications to cause severe osteoporosis except physiological doses of steroids (hydrocortisone 10 mg a.m., 5 mg lunchtime and 5 mg teatime). She was a non-smoker, no alcohol excess and no family history of osteoporosis or fragile fractures. All her secondary workup for osteoporosis were normal including renal functions, liver functions, bone profile, vitamin D, pituitary profile and coeliac screen. Osteoporosis was treated with weekly bisphosphonate resulting in improvement in her bone densitometry scan.
Conclusion
- Autoimmune adrenal insufficiency and autoimmune hypothyroidism can coexist as part of autoimmune polyendocrinopathy but it is extremely important to replace steroids first as patient can clinically deteriorate and levothyroxine replacement before steroids can lead to Addisonian crisis.
- It is well established that Cushing syndrome or hyperthyroidism can lead to osteoporosis but it remains unclear if there is any association of adrenal insufficiency and hypothyroidism with osteoporosis.

EP1061

Intoxication with vitamin D as the cause of severe hypercalcaemia
Martina Jambrović & Marina Gradišer
County Hospital Čakovec, Department of Internal medicine, Čakovec

A 71-year-old man presented to the emergency department with dyspnoea and general weakness. He had a history of stable COPD, coronary artery disease, abdominal aneurysm surgery, and prostate cancer. One month ago, he had survived a SARS-CoV-2 infection. His somatic status was normal, blood pressure was 115/65 mmHg, heart rate was 63/min, he was afebrile 36.6 °C with the exception of SpO2 which was 83%. His initial laboratory results showed severe hypercalcaemia (Ca 3.52 mmol/l), other electrolytes were normal. Due to partial respiratory failure and severe hypercalcaemia, he was admitted to the Department of Internal Medicine. Further laboratory results showed a low PTH level (0.5 pmol/l, reference range 1.3 - 9.3 pmol/l) and a high vitamin D level (> 375 nmol/l). The patient and his family denied misuse of vitamin D supplements. Paraneoplastic hypercalcaemia was suspected, but imaging (US of the neck, CT of the thorax, abdomen and pelvis X-rays revealed no possible substrate). Tumour markers were normal and electrophoresis and immunoelectrophoresis of serum proteins were not suggestive of multiple myeloma. There was also no lymphadenopathy suggestive of lymphoma. At this point in the investigation, we suspected a granulomatous disease and additional sensitive immunological tests were carried out. Hypercalcemia was treated with crystalloid solutions and intravenous zoledronic acid, which led to an improvement in the hypercalcaemia (Ca 3.43 mmol/l – 3.18 mmol/l). At the next outpatient follow-up after discharge from hospital, the serum calcium level decreased accordingly (Ca 2.72- 2.66 mmol/l, iCa++ 1.31- 1.22 mmol/l). The patient admitted that he had been taking vitamin D supplements since overcoming SARS-CoV-2, two capsules of 20000 IJ twice a day.
Conclusion
The hypercalcaemia in this patient is a consequence of continued vitamin D therapy after treatment of the SARS-CoV-2 infection. More frequent monitoring and patient education on the use of supplements is required.

Autoimmune diseases and DiGeorge Syndrom: a case report
Samir Mkaouer, Nadia Khessairi, Elyes Kamoun, Meriem Yazidi, Oueslati ibtissem, Fatma Chaker & chihaoui melika
La Rabta university hospital, Endocrinology department, tunis, Tunisia

Introduction
DiGeorge syndrome (DGS) is mainly characterized by congenital heart defects, dysmorphic features, hopolasia of the thymus and parathyroid glands and immunodeficiency. Approximately 10% of patients with DGS have autoimmune disease[1].
Observation
This is a 21-year-old patient, diagnosed with DGS at the age of 14 year old. The diagnosis was suspected on the association of characteristic facial, hypoparathyroidism and a congenital heart defect (a right aortic arch with an aberrant retro-esophageal left subclavian artery). It was confirmed by a genetic study detecting a microdeletion of the T-box transcription factor TBX1. The patient was well balanced on low-dose Alphacalcidol. During follow-up, the patient developed an inaugural diabetic ketosis with Hb1Ac at 12%. The autoimmune type 1 diabetes was confirmed by positive GAD antibodies (>2000 IU/ml). We noted also autoimmune thyroiditis with high anti thyroperoxydase levels (>1000 IU/ml) with normal TSH Level. Antibodies caeliac disease were negative.
Discussion
DGS increases the risk of autoimmunity 10-fold compared with the general population. This may be explained by thymic hypoplasia and the inability of T lymphocytes to recognize peripheral antigens. Thyroid autoimmunity was associated with DGS in 22% of cases[2]. Anti-pancreatic autoimmunity appears to be less frequent and only 3 cases of type 1 diabetes have been published.
Conclusion
The association of autoimmune diseases with DGS remains underestimated and poorly studied. This prompts us to look for them in cases of clinical suspicion and to establish screening recommendations.

Unusual hypocalcemia in the context of neoplastic disease
Hind Ouakrim, Zineb Ait si ali, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Chu Mohamed Vi Marrakesh - Drh, Marrakech, Morocco

Introduction
While hypercalcemia is extensively studied in cancer patients, the occurrence of hypocalcemia is not as commonly reported. The unique aspect of this case lies in severe hypocalcemia against the background of a malignant tumor of the cervix, a condition often associated with hypercalcemia.
Case report
A 66-year-old patient, diabetic for 13 years with insulin therapy, is being treated for poorly differentiated squamous cell carcinoma of the cervix for the past 4 years. She underwent an extensive hysterectomy, lymph node dissection, followed by radiotherapy with chemotherapy. Five days after the last chemotherapy session, the patient experienced paresthesias and tingling in the face and upper and lower limbs, along with muscle cramps and a tetanic episodes. Faced with this clinical presentation, she was referred to our department. Upon clinical examination, the patient was stable, and Chvostek's sign was positive. The investigation revealed corrected hypocalcemia at 68 mg/l with a phosphorus level of 40 mg/l and a Vitamin D deficiency of 11.6 ng/ml. The PTH level was normal at 39.2 pg/ml. Renal and hepatic function tests were normal. The patient was placed on calcium and vitamin D supplementation, leading to significant improvement.
Discussion
While hypercalcemia is a well-recognized paraneoplastic syndrome, hypocalcemia remains a rare event in neoplastic diseases. Several factors may contribute to the development of hypocalcemia in cancer patients, including Chemotherapeutic agents, commonly used in cancer treatment, may contribute to hypocalcemia, as well as bisphosphonates frequently employed for bone metastases. Proton pump inhibitors, widely used in cancer patients, may decrease calcium absorption directly or through hypomagnesemia. Tumor lysis syndrome, common in hematological malignancies, can also occur in solid tumors, leading to acute renal failure and metabolic alterations, including hypocalcemia. Osteoblastic bone metastases can cause hypocalcemia through the avid capture of calcium, known as "hungry bone syndrome." Other causes include radiotherapy, infections, renal failure, and malnutrition.
Conclusion
Understanding the multifactorial nature of hypocalcemia development is crucial for appropriate diagnosis and management in cancer patients.

EP1087

Primary hyperparathyroidism and autoimmune disorder: coealiac disease

Ghita Khamel, Lamyae Echchad, Ikram Amira, Hind Iraqi, Kaoutar Rifai & Mohamed Hassan Gharbi
chu ibn sina, chu ibn sina, rabat

Theassociation of primary hyperparathyroidism with autoimmune diseases is described very rarely in the literature so far. There are only few cases of immune-mediated hyperparathyroidism, associated with anti-calcium- sensing receptor autoantibodies, Recent epidemiological studies have shown that coeliac disease is more common than previously thought, with prevalence approaching 1%.
Observation
A 47-year-old woman was diagnosed as having coeliac disease revealed by weight loss and asthenia Laboratory showed a hypovitaminosis D with elevated PTH level, suggestive at first of secondary hyperparathyroidism. transglutaminase antibodies, Antinuclear antibodies were positive with elevated liver enzymes in favor of autoimmune hepatitis In addition, the patient presented with intermittent low-back pain; a phosphocalcic test was again ordered, showing hypercalcemia at 122 mg/ and osteoporosis on bone densitometry. Cervical ultrasound and mibi scintigraphy revealed a left retro-thyroidal formation in favour of a parathyroid adenoma; the patient was referred for surgery.
Discussion
In patients with primary hyperparathyroidism, there is a higher prevalence of autoimmune disease than in the general population. Primary hyperparathyroidism may present with nonspecific features, many of which are shared with coeliac disease, including fatigue, poor appetite and depression. that may compound the clinical diagnosis. There is a time lag of 1–5 years between diagnoses, because the low-normal vitamin D level was taken to be compensatory secondary hyperparathyroidism. The authors emphasised the need to look for intestinal malabsorption in the case of normocalcaemic hyperparathyroidism. The association of primary hyperparathyroidism with coeliac disease has both diagnostic and therapeutic implications. Hyperplasia of the parathyroid glands is the predominant morphological feature in tertiary hyperparathyroidism which implies that the adenoma in our case arose sporadically rather than as a result of chronic stimulation However, detecting a reduced expression of calcium-sensing receptor protein could also help to confirm the sporadic occurrence of adenoma in association with coeliac disease
Conclusion
Carrying out a screen for coeliac disease in patients with confirmed primary hyperparathyroidism and a control group may strengthen the evidence for an association. Further studies will be required to establish the link.

EP1129

Lithium Induced Endocrinopathy; A reversible Entity

Asad Ali
King's Mill Hospital, Mansfield, United Kingdom

In the presented case, an 85-year-old female patient with bipolar disorder exhibited significant endocrine complications, including hyperparathyroidism and diabetes insipidus, which were strongly associated with long-term lithium therapy. The resolution of these complications following the discontinuation of lithium and the transition to an alternative mood stabilizer underscores several important clinical implications. Firstly, this case highlights the need for vigilant monitoring of elderly patients undergoing lithium therapy. Lithium-induced endocrine disturbances, although relatively uncommon, can manifest insidiously and have the potential to substantially impact the patient's quality of life and overall health. Secondly, the observed reversibility of hyperparathyroidism and diabetes insipidus upon discontinuation of lithium underscores the importance of early intervention. Furthermore, the case highlights the significance of individualizing treatment plans for elderly patients with bipolar disorder. In this population, where comorbidities are prevalent and overall health is a paramount concern, clinicians should carefully weigh the benefits of lithium therapy against the potential risks, particularly those related to endocrine function. In conclusion, this case report sheds light on the reversible nature of lithium-induced hyperparathyroidism and diabetes insipidus in an elderly patient with bipolar disorder. It underscores the importance of vigilant monitoring, early recognition, and individualized treatment strategies to optimize the care of bipolar disorder patients, especially in older individuals, where preserving overall health becomes increasingly crucial. While lithium remains a valuable tool in the management of bipolar disorder, its potential adverse effects should be carefully considered, and alternative mood stabilizers explored when deemed appropriate for the patient's well-being.

Primary hyperparathyroidism caused by an ectopic thymic parathyroid adenoma: A Case Report

Amal ourdi[1], Houda Ennaifer[1], Françoise Plat Latil[1], Amina Bounaga[1], Arnaud Pforr[2] & Guillaume Granier[3]
[1]Avignon, endocrinology, Avignon, France; [2]Avignon, thoracic surgery, Avignon, France; [3]Avignon, anathomopathology, Avignon, France

Introduction
Primary hyperparathyroidism, is a common endocrine disorder, but rarely related to ectopic parathyroid. Often asymptomatic, it presents a problem of localization and hence therapeutic management. We report a rare case of an ectopic thymic parathyroid adenoma.
Description
We report a case of 62-year-old women, with a history of recurrent urinary infection due to pyelocalcic lithiasis, whose etiological investigation revealed the presence of hypercalcemia. Clinically, she had polydipsia, muscle cramps and tingling of the extremities. The diagnosis of primary hyperparathyroidism was retained: hypercalcemia at 3.51 mmol/l, hypophosphatemia (0.45 mmol/l) and elevated PTH at 1041 pg/ml. Cervical ultrasound was normal. Parathyroid scintigraphy showed the presence of an anterior mediastinal hypermetabolic mass in the thymic lodge with a heterogeneous cystic component. CT scan showed a solid cystic mass of the anterosuperior mediastinum region, measuring 46×37×55 mm. Genetic testing was performed, and excluded genetic forms of hyperparathyroidism. Correction of hypercalcemia was based on rehydration and cincalcet hydrochloride. Thymectomy was performed by video-thoracoscopy. Anatomopathological examination concluded to an intra-thymic parathyroid adenoma. Post-operatory calcemia was normal, and PTH decreased to 84.9 pg/ml. The 3 months CT scan was normal.
Discussion
Parathyroid glands and the thymus had a common embryological origin, which explains the thymic ectopy of the parathyroid. It's a rare entity, whose prevalence is about 16% in patients with primary hyperparathyroidism[1]. Imaging

investigation remains an essential step in management, providing accurate cervical and mediastinal mapping enabling the surgeon to perform a targeted surgical excision, avoiding white surgical explorations. Minimally invasive radio-guided surgery, assisted with PTH measurement, improves surgical outcomes.

Secondary hyperparathyroidism after total en bloc gastrectomy due to Non-Hodgkin's lymphoma

Bratu Gratiela[1,2], Vlad Radulescu[1], Cristina Stancu[1] & Corin Badiu[1,3]
[1]National Institute of Endocrinology, Endocrinology IV, Bucuresti; [2]Parhon Hospital Bucharest, Bucureşti; [3]Carol Davila University of Medicine and Pharmacy, Endocrinology, Bucuresti

Introduction
Primary hyperparathyroidism is a condition in which one or more parathyroid glands have a pathological secretion of parathyroid hormone due to their abnormal function. Secondary hyperparathyroidism has normal parathyroid glands, but an abnormal secretion of PTH because of an underlying condition that influence their activity. It is important to differentiate between primary and secondary hyperparathyroidism because of the different treatment.
Methods
Review of the patient's record and the relevant literature.
Case report
A 68 year old woman, with personal antecedents of non-Hodgkin's lymphoma suffered a total en bloc gastrectomy with caudal splenopancreatectomy, left adrenalectomy and cholecystectomy; was admitted to the hospital with recently diagnosed hyperparathyroidism and hypocalcemia most probably due to malabsorption. The patient also associates type II diabetes, postmenopausal osteoporosis and renal failure stage IIIa. The patient complains of paresthesia in all four limbs. Physical examination revealed height of 165 cm, weight of 83 kg (gained 10 kg in the last year), BMI of 30.40 kg/m^2, excess of fat tissue with central disposition, moist and warm skin, blood pressure was 110/70 mmHg, heart rate was 65 beats/minute, normal thyroid dimensions. No signs of hypocalcemie were noticed. Blood tests showed elevated blood glucose, normal thyroid function, slightly low serum calcium (Ca = 7.6 mg/dl, normal value 8.4-10.2 mg/dl), elevated parathyroid hormone (PTH = 1158 pg/ml, normal value $<$65 pg/ml) and a deficit of 25-OH vitamin D (25-OH vit D = 8.1 ng/ml, normal value 20-100 ng/ml). The complete blood count, hepatic and renal tests results were normal. A computer tomograph was performed and it revealed no tumoral rest or recurrence near the eso-jejunal anastomosis.
Results
Considering all of the above, we concluded that the pacient had secondary hyperparathyroidism due to malabsorption after total en bloc gastrectomy. We initiated supplementation oral treatment with vitamin D spray 4000UI/day and calcium 40 mg/day. The evolution was favorable, with a decrease of PTH value from 1158 pg/ml to 153.2 pg/ml and vitamin D from 8.1 ng/ml to 22.8 ng/ml after 1 year of treatment.
Conclusions
This case report highlights the importance of determining the etiology of the hyperparathyroidism. This is because the treatment for primary hyperparathyroidism in most cases is surgical (parathyroidectomy), while in the case of a secondary parathyroidism, the treatment consists mostly of supplementation with calcium and vitamin D.

Hungry bone syndrome following parathyroidectomy - a case report

Milena Lackovic[1], Bojan Joksimovic[1], Vladimir Samardzic[1], Marija Sinik[1], Martina Tomasovic[1], Milos Marinkovic[1], Sonja Zafirovic[2], Esma R. Isenovic[2], Milan Obradovic[2], Emina Sudar-Milovanovic[2] & Zoran Gluvic[1]
[1]Zemun Clinical Hospital, Dept. of Endocrinology, Belgrade, Serbia, [2]"VINČA" Institute of Nuclear Sciences – National Institute of the Republic of Serbia, Department of Radiobiology and Molecular Genetics, Belgrade

One of the main causes of protracted, severe hypocalcemia after parathyroidectomy is hungry bone syndrome (HBS). We report the case of a 40-year-old man who was first admitted to the Endocrinology department of Zemun Clinical Hospital (ZCH) in order to perform a workup for hypercalcemia. Further laboratory and imaging diagnostics indicated that a giant parathyroid adenoma, measuring approximately 6 cm in size, was the cause of the hypercalcaemia. An endocrine surgeon at the Clinical Centre of Serbia performed a lower left parathyroidectomy and a left thyroid lobectomy due to intraoperative detection of suspicious thyroid nodule. Patient was readmitted to ZCH shortly after surgery, exhibiting hypocalcaemia symptoms and signs. He began receiving intense parenteral and oral calcium and vitamin D substitution, which he continued after his discharge. The histology examination of the removed lower parathyroid gland and left thyroid lobe pointed to an atypical parathyroid adenoma and micropapillary cancer. His findings from tests at follow-up revealed low normal serum calcium levels, elevated PTH, and decreased vitamin D. Patient is additionally being prepared for another thyroid surgery. Despite being rare, the risk of developing HBS following a parathyroidectomy should not be ignored, especially in the presence of several preoperative predictors (e.g. giant parathyroid adenoma, higher preoperative PTH, calcium or alkaline phosphatase levels, etc.). Treatment for HBS must be individualized for each patient and could require an extended period of time.

A rare cause of type B insulin resistance presenting after delivery

Alexandra Giannou[1], Evangelia-Ntaniella Dimopoulou[1], Paraskevi-Maria Bougiouka[1], Katerina Saltiki[2], Stavroula Paschou[2] & Vasiliki Vasileiou[1]
[1]Endocrinology Department and Diabetological Centre, Alexandra General Hospital, Athens, Greece; [2]Endocrine Unit, Department of Clinical Therapeutics, National and Kapodistrian University, Athens, Greece

Introduction
Type B insulin resistance is an extremely rare disease with unknown incidence. It is caused by autoantibodies, mostly IgG, against the insulin receptor that in low titres act as partial agonists. This can cause symptoms that include both hypoglycemia and hyperglycemia. It mostly affects middle-aged African-American women and the proposed treatment approaches include plasmapheresis, cyclosporine or cyclophosphamide, steroids and rituximab.
Case Report
We present a case of a 30-year-old Caucasian woman who referred to our outpatient department due to amenorrhea, worsening of pre-existing hirsutism, polyurea and weight loss, 8 months after giving birth. Medical history included Raynaud Syndrome, Polycystic Ovary Syndrome (PCOS) and newly diagnosed Systemic Lupus Erythematosus (SLE) on treatment with prednisolone. Clinical examination revealed severe hirsutism (Ferryman-Gallway score 24) and profound acanthosis nigricans. Her BMI was 19,2 kg/m^2. The paraclinical investigation showed deranged glucose metabolism with fasting hypoglycemia (65 mg/dl) and postprandial hyperglycemia ($>$200 mg/dl) with concomitant hyperinsulinemia (insulin 1201 μIU/ml) during OGTT and increased HbA1C (9.3%). Also, hyperandrogenemia with increased testosterone 575 ng/dl (5-52), and $\Delta 4\alpha$ 12.3 ng/dl (0.3-3.3). DHEAS,17OHPRG, SHBG were within normal limits and low titres of triglycerides were recorded. Immune panel revealed high IgG [2069 mg/dl (700-1600)], ANA and anti-RNP titres, and low C3 [46 g/l (90-180)] and C4[5 g/l (10- 40)]. Imaging was uneventful except from polycystic ovaries. Due to her medical history including a recent diagnosis of SLE and the affected glycemic control (hypoglycemia and hyperglycemia), the diagnosis of insulin resistance type B was proposed. Positive antibodies against the insulin receptor confirmed it (immunoprecipitation assay). Therapeutic approach consisted of dietary modifications, dapagliflozin and the immunoregulatory agent rituximab, an anti-CD 20 antibody, combined with pulses of steroids. Patient responded well with remission of hirsutism and an excellent glycemic control. Menstruation was restored. She remains stable until now.
Conclusion
Type B insulin resistance is an extremely rare disease with non-standardized treatment. Its clinical course can be confusing and the mortality rates remain high. Our patient benefited greatly from treatment with rituximab and steroids, and her current health status suggests that this approach may benefit more patients that fit similar characteristics.

Identification of two novel LMNA variants causing familial partial lipodystrophy

Caterina Pelosini[1], Silvia Magno[2], Giovanni Ceccarini[2], Melania Paoli[1], Francesca Menconi[3], Donatella Gilio[2], Lavinia Palladino[2], Maria Rita Sessa[1] & Ferruccio Santini[2]
[1]Chemistry and Endocrinology Laboratory, University Hospital of Pisa, Italy; [2]Obesity and Lipodystrophy Center, Endocrinology Unit, University Hospital of Pisa, Italy; [3]Endocrinology Unit, University Hospital of Pisa, Italy

The predominant subtype of familial partial lipodystrophy (FPLD) is a rare autosomal dominant disease occurring in Arginine 482 codon of *LMNA* gene (FPLD subtype 2, also known as Dunnigan-type lipodystrophy). FPLD may also occur in patients harboring mutations in different exons of *LMNA*. We herein describe two unrelated patients referred to our Center for the suspicion of partial lipodystrophy and carrying two novel heterozygous *LMNA* variants. The first one is a 20-year-old woman who exhibited at physical examination an abnormal distribution of subcutaneous adipose tissue, characterized by the accumulation of fat in the neck and lipoatrophy in the lower limbs. Acanthosis nigricans was evident in the patient's groin and armpits. Her body mass index was 27.3 kg/m^2. Biochemical blood tests showed combined hyperlipidemia (triglycerides 494 mg/dl; total-cholesterol 246 mg/dl; HDL-cholesterol 45 mg/dl; LDL-cholesterol 135 mg/dl). The oral glucose tolerance test revealed severe insulin resistance (fasting 36 mUI/ml; two-hours 386 mUI/l) and the abdominal ultrasound showed hepatic steatosis. Plasma leptin and high molecular weight adiponectin levels were 23.9 mg/l and 1.9 mg/ml, respectively. She was found to carry a novel heterozygous p.Asn195Tyr *LMNA* variant in exon 3. The second case, is a 45 years old woman with a history of PCOS and insulin resistance from adolescence, at physical examination she showed an accumulation of fat in the neck and lipoatrophy in the upper and lower limbs resembling the fat distribution pattern of FPLD2. Her body mass index was 23.1 kg/m^2. Biochemical blood tests showed increased triglycerides levels (260 mg/dl). The abdominal ultrasound demonstrated hepatic steatosis. Plasma leptin and high molecular weight adiponectin levels were 4.8 mg/l and 1.5 mg/ml, respectively. Genetic testing revealed a novel heterozygous p.Ser239Arg *LMNA* variant located in exon 4. Notably, in silico analysis indicated a predicted damaging role for both aminoacid substitutions. In conclusion, we identified two novel missense variants in the *lamin* gene associated with familial partial lipodystrophy (FPLD). These previously unrecognized variants in subjects presenting with partial lipodystrophy underscore the considerable phenotypic heterogeneity in *LMNA* pathogenic mutations and emphasizes the necessity of additional research to unravel their physiopathological relevance and therapeutic implications.

Background
Atherosclerotic cardiovascular disease (ASCVD) is a major complication to type 2 diabetes (T2D), in terms of both severity and prevalence rates. The Prevalence and clinical management of the Atherosclerotic Cardiovascular Diseases in patients with Type 2 Diabetes across Middle East and Africa countries (PACT-MEA) is a multinational study that aimed to investigate the prevalence of both established ASCVD and the risk for ASCVD in people with T2D as well as its clinical management in seven countries in the Middle East and Africa. Herein, we report the results for Egypt.

Methods
This is an observational, multicenter, cross-sectional study that involved medical charts review of adults with T2D for >180 days. Data was collected from eight secondary care centers across Egypt during a single scheduled visit in the period between July and August 2022. Complete medical history, demographics, laboratory, and pharmacotherapy data were collected to determine their ASCVD risk status and report on their clinical management. ASCVD was defined as the presence of coronary, cerebrovascular, or peripheral artery disease. High risk of ASCVD was defined according to risk criteria as per the European Society of Cardiology (ESC) 2021 guidelines.[1]

Results
A total of 550 adults with T2D were enrolled by the end of the study period. The mean (standard deviation [SD]) age was 54.5 (10.5) years, with a mean T2D duration of 9.3 (7.5) years and a mean HbA1c of 8.3% (2.1). Prevalence of established ASCVD was 19.6% (95% confidence interval [CI]; 16.5, 23.2) with a prevalence of 15.1% for coronary artery disease, 3.1% for cerebrovascular disease, and 2.9% for peripheral artery disease. In people without established ASCVD, prevalence of high ASCVD risk was estimated at 85.5% (95% CI: 81.9, 88.5). The weighted distribution of cardiovascular risk categories according to the 2021 ESC guidelines revealed that 27 % were classified as very high risk, 72.1% as high risk and only 0.9% as moderate Risk. Only 20% were receiving sodium glucose cotransporter 2 inhibitors, and 3% were receiving glucagon like peptide-1 analogues.

Conclusion
Egyptian adults with T2D present high prevalence of both established ASCVD and high risk/very high risk of ASCVD; a status that is accompanied by a lack of implementation of the guideline-recommended pharmacotherapy approaches and life-style modifications. Consequently, nation-wide initiatives to address the highlighted gaps in T2D management in Egypt are highly recommended.

Background
Patients with proopiomelanocortin (POMC; including variants in *POMC* or *PCSK1*) or leptin receptor (LEPR) deficiency due to biallelic gene variants have impaired melanocortin-4 receptor signaling that leads to hyperphagia and early-onset, severe obesity. Setmelanotide treatment in this population improved weight-related measures and hunger severity and was well tolerated. Reported here are long-term extension (LTE) outcomes after 4 years of setmelanotide treatment.

Methods
Patients with POMC or LEPR deficiency who achieved clinical benefit and acceptable safety in a prior trial of setmelanotide could enroll in the LTE (NTC03651765) and continue setmelanotide for ≥5 years or transition to a commercial product or other clinical trials. This analysis reports weight outcomes and adverse events at 4 years of setmelanotide treatment for patients who achieved a clinically meaningful, age-appropriate, 1-year index trial weight response defined as either ≥10% weight reduction (age ≥18 years at baseline) or reduction of ≥5 percentage points in percent of the 95th percentile for BMI (%BMI$_{95}$; age <18 years at baseline).

Results
A total of 24 patients entered the LTE with clinically meaningful weight response; 12 patients had 4 years of measurements and were included in this analysis. Of the 12 patients excluded, 3 pediatric patients transitioned to adulthood between the index trial and this analysis, 5 transitioned to commercial therapy, and 4 discontinued treatment. Compared with index trial baseline, the mean (SD) change in body weight was −32.6 kg (36.7) for patients aged ≥18 years ($n=8$) and −42.7 (22.44) percentage points in $\%BMI_{95}$ for patients aged <18 years ($n=4$). No new safety signals were observed between the index trial and the LTE.
Conclusions
Continuous setmelanotide treatment in patients with POMC or LEPR deficiency is supported by sustained meaningful benefit in weight-related measures with no new safety signals at 4 years of treatment in this population.

Outcomes of gestational diabetes in native and non-native women – a three-year national study

Ana Quítalo[1], Francisca Leitão[1], Ricardo Capitão[1], Maria Manuel Costa[1], Sara Franco[1], Maria Carlos Cordeiro[1], Luísa Raimundo[1] & Grupo de Estudo Diabetes e Gravidez[2]
[1]Hospital Garcia de Orta, Almada, Portugal; [2]Sociedade Portuguesa De Diabetologia, Lisboa, Portugal

Introduction
In the last years, we have seen a high migration rate of people to Portugal. Not much is known about diet and lifestyle habits in some of these migrant women with gestational diabetes mellitus (GDM). On the other hand, communication can be a barrier and health care access may be more limited. For this reason, it is important to investigate whether there are differences in outcomes between these two populations, in order to question the need to change our clinical approach at national level.
Aims
To compare maternal and neonatal adverse outcomes of GDM between pregnant women born in a foreign country and those born in Portugal.
Methods
The prevalence of GDM complications was evaluated in a cohort of 5874 native women compared with 1414 non-native women, resident in Portugal along years 2020–2022 (total $n=7288$), delivering 7349 live births. For this purpose, the database of the SPD diabetes and pregnancy group was used. The variables were analysed using T test and Chi square test in SPSS®.
Results
Non-native women had higher glycated haemoglobin values in the third trimester (5.5% vs 5.2%; $P<0.001$) and needed more insulin therapy (17% vs 14.5; $P=0.028$), with no significant differences in age (15–52 years) and pre pregnancy weight. Migrants with GDM were diagnosed later (19 vs 18 weeks, $P=0.01$) and burdened by a higher rate of abortion (0.9% vs 0.4%; $P=0.018$), non-spontaneous labour (61% vs 58%; $P=0.023$) and caesarean sections (40.7% vs 36.5%; $P=0.012$). Their new-borns were significantly larger for gestational age (GA) (16.4% vs 12.6%; $P<0.001$) and they had less small for GA babies (8.7% vs 10.4%; $P<0.001$). However, these differences did not impact neonatal morbidity.
Conclusion
GDM in non-native women seem to be worse managed, with this population showing higher abortion and caesarean delivery rates, and heavier babies. These results bring us to question the reasons for these differences and highlights the eventual need to adjust our approach with these women, given their heterogeneity.

The diagnosis and treatment of lipodystrophy: the experience of a portuguese tertiary centre

Renata Barbosa, Guilherme Assunção, Miguel Saraiva, Lia Ferreira, Rui Carvalho & Liliana Fonseca
Centro Hospitalar Universitário de Santo António, Endocrinology, Porto, Portugal

Introduction
This study presents four clinical cases of lipodystrophies, which are a group of rare and heterogeneous diseases characterized by the decrease or lack of adipose tissue (AT) accompanied by metabolic complications.
Clinical cases
1) 59-year-old woman with partial familial lipodystrophy, type 7 (OMIM #606721): Diagnosis of suspected type 1 diabetes (DM) at 28 (treated with insulin with poor control), class 1 obesity and hypertriglyceridemia. Objectively, absence of AT in the lower limbs, central obesity and accumulation of AT in the face and neck. Currently medicated with pioglitazone 15 mg, metformin/dapagliflozin 1000/5 mg twice daily, semaglutide 1 mg/weekly, atorvastatin 40 mg and ezetimibe 10 mg. HbA1c=7.2% and triglycerides(Tg)=134 mg/dl. 2) 27-year-old man with congenital generalized lipodystrophy - Berardinelli-Seip Syndrome: Generalized loss of AT in the 1st year of life. Comorbidities include DM diagnosis at 10, hypertriglyceridemia, hypoleptinemia (leptin<0.7 ng/ml), cirrhosis with portal hypertension, hypertrophic cardiomyopathy and hidradenitis suppurativa. Genetic study (GS) revealed a homozygous mutation in BSCL2. The patient is currently on metformin/empagliflozin 1000/5 mg twice daily, pioglitazone 30 mg and semaglutide 1 mg/weekly. HbA1c=6.0% and Tg=150 mg/dl. Metreleptin treatment was initiated in January 2024. 3) 19-year-old woman with acquired generalized lipodystrophy - Lawrence Syndrome: Clinical onset at 3 years. Comorbidities include Hashimoto's thyroiditis, autoimmune hepatitis (AIH) with advanced fibrosis, autoimmune gastritis, hypertriglyceridemia, hypoleptinemia (leptin<0.05 ng/ml) and DM (diagnosed at 13 – treated with metformin, prandial and basal insulin). GS negative for AGPAT2, BSCL2, LMNA and PPARG. Positive anti-perilipin 1 antibodies. Metreleptin started in 2019, with improvements in hypertriglyceridemia and hepatosplenomegaly as well as remission of DM (HbA1c=5.1%). 4) 22-year-old woman with partial lipodystrophy: Central adiposity and absence of AT in the limbs identified at age 3. Comorbidities include AIH, neurodegenerative brain iron accumulation with congenital ataxia, insulin resistance (insulin=58 μU/ml; RR 2.6-24.9) and hypertriglyceridemia controlled with lifestyle measures (Tg=175 mg/dl). GS negative for AGPAT2 and LMNA - currently under evaluation in a medical genetic consultation.
Conclusion
Lipodystrophies exhibit diverse phenotypes, emphasizing the crucial role of physical examination in evaluating AT distribution. Early diagnosis allows a more appropriate treatment of both lipodystrophies and their metabolic complications.

Diabetes mellitus due to reduced insulin secretion and exocrine pancreatic dysfunction in a patient with a mutation in the carboxyl-ester lipase gene outside the VNTR region

Vasiliki Venetsanaki[1], Vasiliki Daraki[1], Amalia Sertedaki[2], Anny Mertzanian[2], Evangelia Pissadaki[1], Rodanthi Vamvoukaki[1], Grigoria Betsi[1], Maria Sfakiotaki[1], Christina Kanaka-Gantenbein[2] & Paraskevi Xekouki[1]
[1]University General Hospital of Heraklion, Department of Endocrinology Diabetes and Metabolic Diseases, Crete, Greece; [2]Children's Hospital Agia Sophia, Division of Endocrinology, Diabetes and Metabolism, Center for Rare Pediatric Endocrine Diseases, First Department of Pediatrics, Medical School, National and Kapodistrian University of Athens, Athens, Greece

Introduction
Mutations in the variable number of tandem repeats (VNTR) region of the carboxyl-ester lipase (CEL) gene can cause a very rare type of maturity-onset diabetes of the young (MODY 8) characterized by insulinopenic diabetes mellitus (DM) in early adulthood and slowly progressive exocrine pancreatic dysfunction. We present the unusual case of a patient with heterozygosity in a variant of *CEL* outside the VNTR region suffering from DM, dyslipidemia and exocrine pancreatic dysfunction.
Case-report
A 68-year-old patient was referred to the endocrinology outpatient clinic for evaluation of paroxysmal hypertension. She reported gait and balance disorders, abdominal discomfort and steatorrhea following fatty meals since early adulthood that had significantly deteriorated in the past year. She had a history of gestational diabetes and was eventually diagnosed with DM at the age of 53, treated with metformin. She also had dyslipidemia, Hashimoto's thyroiditis, osteoporosis, localized scleroderma and a frontotemporal cavernous hemangioma. Clinical evaluation revealed impaired sense of balance and low-normal BMI. Computed Tomography of the abdomen revealed mesenteric lipodystrophy and bilateral adrenal hyperplasia. Biochemical investigation excluded hypersecretion of adrenal hormones. She also had elevated lipid levels and fasting blood glucose (104 mg/dl) with low insulin(1.6 μUI/ml) and low-normal c-peptide levels (1.22 ng/ml). Her HbA1c was 5.7%. Clinical and biochemical findings were suggestive of MODY, therefore genetic testing was performed, which revealed

heterozygosity in the *CEL*gene variant c.1341C>A, p.Tyr447Ter. The patient was treated with pancreatic enzymes (pancreatin) with significant improvement of her gastrointestinal and neurological symptoms.
Discussion
CEL is mainly expressed in pancreatic acinar cells and lactating mammary glands. Mutations in the VNTR region of the *CEL* gene, have been associated with early pancreatic atrophy due to pancreatic fibrosis, lipomatosis or pancreatic cyst formation and progressive exocrine insufficiency as well as adulthood-onset DM. Mutations outside VNTR regions of *CEL* gene have been associated with dyslipidemias but evidence on insulinopenic DM is scarce. Our patient had a mutation outside of the VNTR region and developed both insulinopenic DM and exocrine pancreatic insufficiency. We hypothesize that our patient's symptoms were associated with fat-soluble vitamin malabsorption which is corroborated by the significant improvement of her symptoms after dietary modifications and pancretin substitution.
Conclusion
Patients with heterozygous mutations outside the VNTR region of the *CEL* gene should be investigated for DM and exocrine pancreatic dysfunction and be treated accordingly.

EP12

A complex phenotype with partial lipodystrophy due to mutations in HIST1H1E and OTOGL genes

Leonardo Bighetti[1], Martina Romanisio[1], Simona Mellone[2], Denise Vurchio[2], Edoardo Mollero[1], Tommaso Daffara[1], Giovanni Ceccarini[3], Caterina Pelosini[3], Gianluca Aimaretti[1], Mara Giordano[2] & Flavia Prodam[1]
[1]Endocrinology Unit and Department of Health Sciences, Università del Piemonte Orientale, Novara, Italy; [2]Laboratory of Genetics, SCDU Biochimica Clinica, Ospedale Maggiore della Carità, Novara, Italy; [3]Obesity and Lipodystrophy Center, Endocrinology Unit, University Hospital of Pisa, Pisa, Italy

Here we report a case of an adult patient (44y/o) followed for type-2 diabetes since he was 15 years, hypercholesterolemia treated with PCSK9 inhibitors and hypertension. At physical examination he presented: progeroid features, prominent forehead, hypertelorism, short palpebral fissures, broad nasal bridge, baldness, and hypotricosis. He was also affected by hearing loss with a jarring voice and lost teeth in early age. He showed developmental delay and ID, mild atrial septal defect, mild osteoporosis and a monolateral low testis volume, with subclinical hypergonadotroph hypogonadism. Diabetes was in control with metformin, and DPPIV-i, liver steatosis was in follow-up. The BMI was normal and subcutaneous fat was underrepresented in limbs, but increased in the abdomen. Since the abnormal distribution of fat and metabolic alterations at a young age, we suspected a progeroid lipodystrophy syndrome. Leptin (1.9 mg/l) was undetectable and the genes known to cause classical lypodistrophy syndromes were wild type as well as CGH-array. A whole genome sequencing (WES) of the proband and his parents was thus performed revealing a *de novo* pathogenic frameshift variant in *HIST1H1E* (MIM*142220), p.Ser150fs, c.447dupC, encoding the H1.4 histone protein. This protein is a member of the H1 histone family that acts as a structural component of the chromatin controlling DNA condensation, gene expression and DNA replication/repair. Mutations in these class of genes perturb cellular process resulting in cellular senescence and have been correlated to alteration of genome methylation. Truncating mutations in *HIST1H1E* are characteristic of the Rahman Syndrome (MIM#61743), a recently recognized developmental disorder characterized by mild to severe ID, a distinctive facial gestalt, variable somatic overgrowth which may manifest in early infancy, but not in adults, that often display decreasing height percentile over time, and an aging appearance. The WGS analysis also revealed a pathogenic variant in the *LDLR* gene explaining hypercholesterolemia and in *OTOGL* responsible for neurosensorial hearing loss. This case represented a complex phenotype that had remained for a long time without a clinical diagnosis and that reached it on the basis of the results obtained throught WGS with three genes explaining most of his phenotypic characteristics. It is remarkable that the patient also manifested lipodystrophy, characterized by a progressive metabolic impairment secondary to adipose tissue dysfunction, that might be explained by the pleiotropic effect of the *HIST1H1E* mutation. Trascriptomic analysis on the PBMC of proband and parents has been performed and is ongoing to detect molecular signaling specific of each mutation.

Five years post sleeve gastrectomy do patients experience olfactory changes

Faten Mahjoub, Abir El Amri, Nadia Ben Amor, Ramla Mizouri, Saida Boumefteh & Jamoussi Henda
Institut De Nutrition, Tunis, Tunisia

Introduction
Post-operative modification of the sense of smell has been suggested as contributing to the reduction in energy intake and weight loss achieved following bariatric surgery. The aim of our study was to determine the prevalence of smell changes and their impact on weight loss five years after sleeve gastrectomy.
Methods
This was a descriptive longitudinal study conducted at the obesity research unit of the National Institute of Nutrition in Tunis involving 30 obese patients who had undergone sleeve-gastrectomy with medical follow-up of at least 5 years. Changes in the sense of smell were assessed using the Tichansky "Taste and smell" questionnaire.
Results
The mean age of our patients was 43 $\pm$ 9.5 years. The average duration of obesity was 26.4 $\pm$ 7.71 years, with extremes varying from 15 to 40 years. Average weight decreased from 133.04 $\pm$18.36 kg to 94.63 $\pm$ 19.81 kg after 5 years, corresponding to an average weight reduction of 28.8% ($P<10^{-3}$). The excess weight loss was 48.48 $\pm$ 22.72%. Mean body mass index decreased from 52.61 $\pm$ 10.07 kg/m^2 to 38.04 $\pm$ 9.26 kg/m^2 after 5 years, a reduction of 27.69% ($P<10^{-3}$). The majority of our patients (63%) reported a change in appetite after sleeve gastrectomy. This change was better than expected in 53% of patients. A change in the sense of smell 5 years after sleeve-gastrectomy was noted in 53% of patients and consisted of either an improvement (62%) or a different smell (38%). No patient had a total loss of smell. The majority of our patients (80%) confirmed that the olfactory component of food is important for food intake. According to twenty patients, the smell of food has a direct impact on food intake and weight loss. Two-thirds of the patients expected a better change in smell than that obtained after sleeve gastrectomy. Patients who had a change in their sense of smell had the greatest loss of excess weight at 2 years ($P=0.04$) and 5 years ($P=0.001$).
Conclusions
Following sleeve gastrectomy, circulating gut hormone levels are markedly altered and these changes are suggested to contribute to post-operative olfactory changes. Gut hormones are present in saliva and their cognate receptors are found on taste buds and olfactory neurons Hence, it is plausible that gut hormones mediate olfactory changes following bariatric surgery through weight-independent mechanisms.

Glucose 'the cruel puppet master'. hyperglycaemia induced chorea with hypoglycaemia precipitated recurrence

Pablo Martinez Perez & Jana Bujanova
Southampton University Hospital NHS Foundation Trust, Department of Diabetes and Endocrinology, Southampton, United Kingdom

Introduction
Diabetic striatopathy is a rare neurological complication of diabetes presenting in most cases with an acute/subacute hemichorea associated with contralateral putamen T1 hyperintensity on MRI. It is associated with significant hyperglycaemia, high HbA1c and osmolality. It resolves within few days to 10 months in 74% of cases. Recurrence is seen in 13% of cases, mostly within the first two months. Hypoglycaemia induced chorea is extremely rare.
Case report
68-year-old male with a history of transient ischaemic attack and well controlled type 2 diabetes on oral therapies was admitted with fall and long lie. He was swaying when stood, had shuffling gait and his speech was difficult to understand. On admission had significant hyperglycaemia (33.6 mmol/l), raised osmolality (311 mosmol/kg) and dramatic HbA1c increase to 181 mmol/mol from 58 mmol/mol five months previously, likely precipitated by metabolic sequalae of severe Covid illness a year prior. He was described as 'restless, grabbing at things, picking at clothes' and was noted to have involuntary movements progressing to severe generalised and orofacial choreoathetosis. Interestingly, he was not distressed by these movements and appeared unaware. Brain MRI showed high T1 signal the putamina bilaterally and excluded a stroke. Thyroid, autoimmune, paraneoplastic and infection screen were negative. Diagnosis of hyperglycaemia induced chorea was made. Glucose control was achieved with a variable insulin infusion and basal insulin. His choreoathetosis worsened initially after

achievement of euglycemia preventing patient's ability to glucose monitor and insulin self-administer, but improved with stable glucose control allowing discharge 12 days after admission. He was readmitted 16 days later with chorea recurrence, this time in association with hypoglycaemia (glucose 2.7 mmol/l). He was discharged 6 days later and remained symptom free 2.5 years later.

Discussion

Diabetic striatopathy should be considered in a differential diagnosis of choreoathetosis of an acute or subacute onset together with a stroke, bleed, autoimmune disease, paraneoplastic syndrome, cocaine and HIV. Our case highlights several unique aspects including occurrence in a middle-aged Caucasian male, deterioration of symptoms after initial glucose normalisation, bilateral symptoms, bilateral putamina radiological changes and a recurrence precipitated by hypoglycaemia, which is to our knowledge very rare. Proposed mechanisms of hyperglycaemia induced choreoathetosis include an induction of mild ischaemia in the putamen via osmotic shift induced hypoperfusion leading to anaerobic metabolism and gamma-aminobutyric acid (GABA) depletion. Hypoglycaemia probably induces cell oedema and hypoperfusion and utilisation of GABA and acetylcysteine as alternative sources of energy.

Exploring the relationship between trimethylamine N-Oxide levels, kidney function, and diabetes

Karina Levina[1], Sabīne Upmale-Engela[1], Melita Ozola[2] & Ilze Konrade[1]
[1]Rīga Stradiņs University, Rīga, Latvia; [2]Latvijas Organiskās Sintēzes institūts (Latvian Institute of Organic Synthesis), Rīga, Latvia

Since 2011 trimethylamine N-oxide (TMAO) has been established as a cardiovascular risk biomarker in various patient populations. Previous studies have shown the association of TMAO levels with insulin resistance and diabetes. Additionally, a higher risk of cardiovascular events has been observed in patients with type 2 diabetes and higher levels of TMAO. However, the direct link between TMAO levels and kidney function in patients with diabetes is still unclear. Our objective was to investigate the association between the level of TMAO and the degree of renal damage in patients with diabetes mellitus. Patients with type 1 diabetes (T1D) and type 2 diabetes (T2D) were involved in the study. Since the level of TMAO depends greatly on the composition of the diet, patients were instructed to refrain from eating fish and other seafood for two days before blood draw to avoid artificially high levels of TMAO. Blood sampling was performed in a fasted state to analyze biochemical markers: glucose, C-peptide, HbA1c, ALT, CRO, Urea, cystatin-C, creatinine, GFR, NGAL. Quantification of TMAO concentrations in plasma samples was performed by UPLC/MS/MS analysis. The data are presented as mean ± SEM. A total of 66 diabetes patients were subjected for testing: patients with T1D ($n=16$, 24%) and with T2D ($n=50$, 76%). The mean BMI of the patients was 30.8 ± 0.94 kg/m^2. Of 66 patients, 29 (44%) were male and 37 (56%) were female. The mean age of the patients was 57.6 years, ranging from 19 to 84 years. The average concentration of TMAO in plasma of the patients was 8.05 ± 1.36 μmol/l (min. 0.56 μmol/l; max. 66.34 μmol/l). Interestingly, HbA1c, fasting glucose, C-peptide levels, showed no correlation with TMAO level in plasma. Additionally, TMAO concentrations did not depend on the type of diabetes mellitus or the age of the patient. Meanwhile, markers of kidney glomerular function, creatinine, cystatin-C, GFR, showed a weaker correlation with TMAO levels ($R^2=0.292$, $R^2=0.279$, $R^2=0.223$, respectively, $P<0.0001$) than Urea ($R^2=0.4155$, $P<0.0001$), however a strong correlation was found with renal tubular damage marker NGAL ($R^2=0.6228$, $P<0.0001$) and TMAO. Based on data collected in the clinical setting, we observed a noticeable relationship between kidney tubular damage and plasma TMAO in patients with diabetes. As kidney injury in diabetic patients typically occurs due to mixed pathophysiological mechanisms, additional testing in preclinical models should be employed to confirm the hypothesis that impaired kidney glomerular and tubular function are the initial driving factors of TMAO accumulation.

GLP-1 receptor agonists neuroprotective effect in type 2 diabetic patients is independent on glycemic control

Anna Simanenkova[1,2], Oksana Fuks[1], Natalya Timkina[1,2], Irina Matsueva[1], Tatiana Karonova[1,2] & Elena Grineva[1]
[1]Almazov National Medical Research Centre, Saint-Petersburg; [2]Pavlov First Saint-Petersburg State medical University, Saint-Petersburg

Background and aim

Acute and chronic brain dyscirculation comprise one of the main reasons of death and disability in type 2 diabetes. Glucose-lowering drugs of glucagon-like peptide-1 receptor agonists (GLP-1RA) group have proved to decrease myocardial infarction and stroke incidence, nevertheless their influence on chronic brain damage in not fully studied. Taking into account existing guidelines recommending treatment with GLP-1RA even for patients with satisfactory glycemic control, our aim was to study the influence of semaglutide in type 2 diabetic patients with target glycated hemoglobin (HbA1c) level on cognitive function and circulating neuronal damage markers.

Materials and methods

Type 2 diabetic patients aged 45-75 with target HbA1c (6.7[6.6;6.9]%) on metformin monotherapy were randomly divided into two groups: 'MET' ($n=28$) – those who continued metformin monotherapy, and 'SEMA' ($n=35$) – patients who were co-administered semaglutide (Rybelsus, Novo Nordisk) for 6 months. Additionally, 'Control' ($n=30$) group was formed – healthy volunteers comparable by age and gender. In all groups the levels of HbA1c, neuron-specific enolase (NSE), neurofilament light chains (NLC) were determined initially, cognitive assessment was performed by MOCA and MMSE scores. In 'SEMA' group these parameters were also evaluated 3 and 6 months after.

Results

Baseline NSE level in diabetic patients was higher than in healthy volunteers despite satisfactory glycemic control (3.60 [3.19;3.78] ng/ml in 'MET' and 3.78 [3.05;4.32] ng/ml in 'SEMA' groups and 2.76 [2.28;3.30] ng/ml in 'Control' group). Similarly baseline NLC concentration was high in both 'MET' and 'SEMA' groups than in 'Control' one (4.95 [3.30;5.56] ng/ml, 5.25 [3.75;5.56] and 4.10 [3.27;5.30]ng/ml, respectively). HbA1c decreased in 'SEMA' group, though not significantly, remaining in the target range. NSE concentration decreased in 'SEMA' group in 3 months (2.95 [2.42;3.4] ng/ml) and remained normal in 6 months (2.93 [2.58; 3.33] ng/ml). NLC also decreased in 'SEMA' group in 3 months (4.25 [3.13;8.50] ng/ml and even more prominently in 6 months (3.50 [1.69;5.88] ng/ml). Patients in 'MET' and 'SEMA' groups had cognitive impairment, resulting in the decreased points by both MOCA and MMSE scales. SEMA administration led to cognitive 4improvement – by 6th month of therapy MOCA scores in 'SEMA' group was 27.5 [25.75;29.75] (the normal value is 26 and more) and MMSE scores was 29.0 [27.5;29.5] (the normal value is 28-30). We found negative correlation between NLC level and MOCA, MMSE scores ($r=-0.512$, $p=0.005$ и $r=-0.703$, $p=0.000$, respectively).

Conclusions

DM, even with satisfactory glycemic control, has a negative impact on the brain, which is manifested by neuronal damage markers increase and cognitive dysfunction. Semaglutide can be neuroprotective in diabetic chronic brain damage independently on glycemic control.

Assessment of basal and stimulated C-peptide in patients with type 1 diabetes mellitus on the administration of tolerogenic dendritic cells

Tatsiana Mokhort[1], Volha Shyshko[2], Alena Mokhort[3], Andrei Hancharou[4], Natalia Antonevich[4], Yana Minich[4], Volha Lazovtseva[1], Alena Dashkevich[5] & Elena Shishko[3]
[1]Belarusian State Medical University, Minsk, Belarus; [2]Minsk City Clinical Endocrinological Center, Minsk, Belarus; [3]Belarusian State Medical University, Endocrinology, Minsk, Belarus; [4]The Institute of Biophysics and Cell Engineering of National Academy of Sciences of Belarus, Minsk, Belarus; [5]10th City Clinical Hospital, Minsk, Belarus

Introduction

Preserving of C-peptide secretion in type 1 diabetes mellitus (DM1) is an important goal in treatment, as it provides the possibility of optimal compensation. We initiated a study (ClinicalTrials.gov 26.01.2022, NCT05207995) to assess the potential effect of Tolerant Dendritic Cells (tolDC) on the newly diagnosed DM1.

Methods

Evaluation of stimulated C-peptide against the background of a standard breakfast (carbohydrate content of 50g) was carried out twice (before tol-DC therapy) ($n=14$) and 3 months after completion of therapy ($n=9$). The test was performed with fasting glycemia in the range of 3.8 - 9.0 mmol/l, short-acting insulin was not administered before breakfast. The test was carried out for 2 hours with the determination of the level of C-peptide at 0, 30, 60, 90 and 120 minutes. The levels of C-peptide after food stimulation were studied with the calculation of AUC (area under curve). All patients ($n=16$) had their basal C-peptide levels determined twice. Determination of the level of C-peptide is carried out by the method of chemiluminescent enzyme immunoassay on the analyzer Cobas E411 by Roche Diagnostics (Germany).

Results
The median (Me, Q1; Q3) basal C-peptide level before therapy was 0.74 (0.71; 0.77) ng/ml, which met the requirements for inclusion in the study. Data obtained 3 months after completion of the study indicate that C-peptide secretion remained at 0.87 (0.68, 1.06) ng/ml. The AUC value before administration of tolDC was 409 ± 202.5 ng/ml×2 h. After therapy, AUC was 385.6 ± 145.5 ng/ml×2 h; no significant differences with the AUC level before tolDC therapy were detected ($P = 0.18$).
Conclusion
Our results indicate the potential effectiveness of the method for correcting carbohydrate metabolism in patients with type 1 diabetes using tolDC. Short-term use of Tolerogenic Dendritic Cells is accompanied by preservation of C-peptide secretion, which is a prognostically favorable factor in the course of DM1.

Assessment of nutrition knowledge levels in tunisian children
Ben Othman Rym, Amorri Amani, Salma Abadlia, Ben Zina Baya, Ben Mansour Nadia, Kasraoui Sabeh, Gamoudi Amel & Jamoussi Henda
National Institute of Nutrition and Food Technology, Nutrition A, tunis

Introduction
The global prevalence of childhood obesity has surged to alarming levels, presenting a critical health issue. In order to promote a healthy lifestyle, evaluating the nutritional knowledge of children becomes imperative. We conducted our study aiming to assess the levels of dietary awareness in a sample of Tunisian children aged 9 to 11 years.
Methods
We conducted a multicenter cross-sectional study from December 2021 to June 2022, at the National Center for School and University Medicine in Tunis and five randomly selected nurseries in Ariana governorate. The study involved 315 children aged from 9 to 11 years. We evaluated participants' nutritional knowledge using an Arabic version of the validated French nutritional questionnaire QuesCA 9-11. The maximum score is 9/9. We developed the Arabic version following established translation and questionnaire validation guidelines.
Results
The participants' mean age was 9.9 ± 1 years. A slight male predominance was observed (55%). The majority of children (81%) had a normal weight, while 8% were classified as obese, and 6% were underweight. The average score on the questionnaire was 5.8 ± 0.6/9. Sixty percent of participants achieved a fair score (i.e. score ranging between 4 and 6/9). Approximately, one-third (31%) obtained a good score (i.e. score ≥ 7/9). Remarkably, 2.2% of the sample answered all items correctly, achieving the maximum score of 9/9, reflecting a strong nutritional knowledge. A minority (9%) received a poor score (i.e. score ≤ 3/9). Notably, one child among the 315 included had a score of 0/9. Furthermore, the items related to the theme of proteins, fruits and vegetables, and beverages were the easiest to answer. On average, 86% of responses to these items were correct. In contrast, the item related to the theme of starchy foods was the most challenging, with only 31.4% of correct responses.
Conclusion
Our results underscore the importance of targeted interventions to enhance nutritional education. This knowledge can serve as a foundation for developing strategies aimed at promoting healthier lifestyles and preventing childhood obesity in the Tunisian context.

[1]Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, United States; [2]Universidad Autónoma de Madrid, University Hospital Niño Jesús, CIBER 'Fisiopatología de la obesidad y nutrición' (CIBEROBN), Instituto de Salud Carlos III, Department of Pediatrics and Pediatric Endocrinology, Madrid, Spain; [3]Rhythm Pharmaceuticals, Inc.; Harvard Medical School; Massachussetts General Hospital, Boston, United States; [4]Rhythm Pharmaceuticals, Inc., Boston, United States; [5]Columbia University, Division of Molecular Genetics, Department of Pediatrics, New York, United States; [6]Hôpitaux Universitaires de Strasbourg, CARGO and Department of Medical Genetics, Institut de Génétique Médicale d'Alsace, Université de Strasbourg; [7]Assistance Publique Hôpitaux de Paris, Nutrition Department, Pitié-Salpêtrière Hospital; Sorbonne Université, Inserm, NutriOmics Research Unit, Paris, France

Background
Bardet-Biedl Syndrome (BBS) is a rare genetic disease in which impaired melanocortin-4 receptor (MC4R) signaling leads to hyperphagia and obesity. In an index Phase 3 trial, broad clinical benefit was observed in patients with BBS based on improvement or stabilization in ≥1 measure of weight, hunger, or quality of life with 1 year of treatment with the MC4R agonist setmelanotide. Reported here are long-term extension (LTE) weight outcomes after 3 years of setmelanotide.
Methods
Patients with BBS who achieved clinical benefit and tolerability in a prior trial of setmelanotide could enroll in the LTE (NCT03651765) and continue treatment for ≥5 years or transition to commercial product or other clinical trials. This analysis reports age-appropriate weight-related outcomes and adverse events for 3 years of setmelanotide treatment in patients who achieved clinically meaningful response at 1 year of index trial, defined as ≥10% weight reduction (age ≥18 years at baseline) or reduction of ≥5 percentage points in the percent of the BMI 95th percentile (%BMI_{95}; age <18 years at baseline).
Results
Of 32 patients who entered the LTE with clinically meaningful age-appropriate weight responses, 21 patients with 3-year measurements were included in the analysis. Eleven patients were excluded as 1 pediatric patient transitioned to adulthood before this analysis, 5 had <3 years of treatment, 2 transitioned to commercial therapy, and 3 discontinued treatment. Mean (SD) index trial baseline for body weight was 129.8 (21.3) kg in patients aged ≥18 years ($n = 10$) and 148.7 (36.1) percentage points for %BMI_{95} in patients aged <18 years ($n = 22$); change at Year 3 was −22.0 (18.1) kg ($n = 8$) and −19.4 (19.4) percentage points ($n = 13$), respectively. No new safety signals were observed in the LTE.
Conclusions
Sustained meaningful benefit in weight-related measures at 3 years of treatment with no new safety signals supports continuous treatment with setmelanotide in patients with BBS.

New therapeutic opportunities shared by obesity, type 2 diabetes and rheumatoid arthritis
Valentina Gavazova[1,1] & Sylvia Pashkunova
Military Medical Academy, Sofia, Bulgaria

Obesity and diabetes mellitus type 2 are proinflammatory states associated with increased disease severity in rheumatoid arthritis (RA). Weight loss is associated with improved disease activity in rheumatoid arthritis (RA). Furthermore science experiments demonstrated weight-independent anti-inflammatory and immunomodulatory effects of GLP-1 receptor agonists. Moreover, *in vitro* studies found anti-inflammatory effects of GLP-1 receptor agonists in fibroblast-like synoviocytes (FLS) from patients with RA. FLS are the main cell population in synovium. They can secrete pro-inflammatory cytokines like interleukin-6, interact with immune-related cells, and subsequently cause inflamed joints. These anti-inflammatory and immunomodulatory effects of GLP-1 receptor agonists in RA are associated with inhibition of the activation of proinflammatory signaling pathways like NF-kB, improvement of mitochondrial dysfunction induced by TNF- α, prevention of NOX-4 expression and oxidative stress, reduction of the expression of proinflammatory mediators like IL-6 and IL-1β, reduction of the expression of matrix metalloproteinases. The objective of this study was to determine whether treatment with GLP-1 receptor agonists is associated with improved disease activity in certain forms of inflammatory arthritis such as rheumatoid arthritis.
Methods
To estimate the role of GLP-1 receptor agonists in RA, we observed 30 patients (27 women and 3 men) with obesity, diabetes mellitus type 2 and RA treated with GLP-1 receptor agonist between 1 May 2023 and 1 January 2024. They are still receiving this medication. In this period observed patients did not take any disease-modifying anti-rheumatic drugs, steroids or biologic agents. The patients had morning stiffness in more than one joint, swelling in more than one joint and pain in fingers. In addition to symptoms we focused on measuring C-reactive protein (CRP) levels and erythrocyte sedimentation rate as inflammatory markers.

They were elevated before starting the applications of GLP-1 receptor agonists.
Results
For 6 months of treatment in the observed group we found out 10% weight reduction, improvement of patient's morning stiffnes and swelling and relieved pain in fingers. Furthermore the CRP levels and erythrocyte sedimentation rate were decreased after 6 months of treatment with GLP-1 receptor agonists.
Conclusions
These results suggest that GLP-receptor agonist could improve disease activity in RA associated with weight loss. Moreover GLP-1 receptor agonists have potential weight-independent anti-inflammatory effects. Their role as an adjunct in patients with rheumatoid arthritis, obesity and diabetes is understudied, require future research. The limitations of our study are low countability of patient group, short follow-up period, and lack of control group.

Impact of setmelanotide on metabolic syndrome risk in patients with bardet-biedl syndrome

Andrea M. Haqq[1], Christine Poitou-Bernert[2], Wendy Chung[3], Anoop Iqbal[4], Elizabeth Forsythe[5], Sonali Malhotra[6], Nicolas Touchot[7], Karine Clément[2] & Jesús Argente[8]
[1]Division of Pediatric Endocrinology, University of Alberta, Edmonton, AB, Canada, Edmonton, Canada; [2]Nutrition Department, Assistance Publique Hôpitaux de Paris, Pitié-Salpêtrière Hospital; Sorbonne University, Inserm, Nutrition and Obesity, Systemic Approaches (NutriOmique) Research Group, Paris, France; [3]Division of Molecular Genetics, Department of Pediatrics, Columbia University, New York, United States; [4]Department of Clinical Research, Marshfield Clinic Research Institute, Marshfield, United States; [5]Clinical Genetics Department, Guys and St. Thomas' Hospitals, London, and National Bardet-Biedl Syndrome Clinics, Great Ormond Street Hospital, London, United Kingdom; [6]Rhythm Pharmaceuticals, Inc.; Massachusetts General Hospital; Harvard Medical School, Boston, United States; [7]Rhythm Pharmaceuticals, Inc., Boston, United States; [8]Department of Pediatrics and Pediatric Endocrinology, Universidad Autónoma de Madrid, University Hospital Niño Jesús, CIBER 'Fisiopatología de la obesidad y nutrición' (CIBEROBN), Instituto de Salud Carlos III; IMDEA Food Institute, Madrid, Spain

Background
Patients with Bardet-Biedl syndrome (BBS), a rare syndrome associated with obesity and hyperphagia, commonly manifest traits of metabolic syndrome, including abdominal obesity, impaired fasting glucose, low high-density lipoprotein cholesterol, hypertriglyceridemia, and hypertension. Setmelanotide treatment results in significant improvement in weight, hunger, and quality of life in these patients and may improve measures associated with metabolic syndrome development. We evaluated the metabolic syndrome Z score based on body mass index (MetS-Z-BMI), a measure of long-term risk for developing cardiovascular disease (CVD) and type 2 diabetes mellitus (T2DM). Each 1.0-point increase in MetS-Z-BMI increases the odds of future CVD and T2DM by 9.8 and 2.7, respectively, when assessed in children and by 2.4 and 2.8, respectively, when assessed in adults.
Methods
Data from a Phase 3 trial of patients with BBS (NCT03746522) were used to calculate MetS-Z-BMI score after 1 year of setmelanotide. Patients who achieved a meaningful response of $\geq$10% weight loss (if $\geq$18 years old) or $\geq$0.3-point BMI Z score reduction (if $<$18 years old) were compared with patients who did not meet those thresholds.
Results
Of 32 patients with BBS enrolled, 22 were evaluable (59% female, 10-44 years old). Setmelanotide was associated with reduced mean (SD) MetS-Z-BMI score after 52 weeks in patients with a meaningful weight response ($n=16$; -0.54 [0.56]). Patients not meeting weight thresholds ($n=6$) had an increase in MetS-Z-BMI ($+0.17$ ([0.50]; between-group difference, -0.71, $P=0.129$). MetS-Z-BMI change was generally comparable between females and males.
Conclusions
In addition to reduced hyperphagia and improved quality of life with setmelanotide, meaningful reductions in weight-related outcomes are associated with decreases in MetS-Z-BMI score in patients with BBS. These data suggest that early treatment initiation may lead to reduction in future risk of T2DM and CVD development.

The relationship between continuous glucose monitoring metrics, circadian rhythms, and the presence of albuminuria in insulin-using patients with type 2 diabetes

Da Young Lee[1], Jung-Been Lee[2], Inha Jung[1], So Young Park[1], Ji Hee Yu[1], Ji A Seo[1], Heon-Jeong Lee[3] & Nan Hee Kim[1]
[1]Korea University Ansan Hospital, Ansan-si, Korea, Rep. of South; [2]Sun Moon University, Asan Campus, Asan-si, Korea, Rep. of South; [3]Korea University Anam Hospital, Seoul, Korea, Rep. of South

Background
We aimed to explore the relationship between continuous glucose monitoring (CGM)-derived indicators and the presence of albuminuria taking circadian features into consideration concurrently in Insulin-using patients with type 2 diabetes.
Methods
We analyzed data from 129 insulin-treated type 2 diabetes patients in Korea University Ansan Hospital. Over 10 days, we collected time-series data using Dexcom G6, Fitbit, and food diaries, along with cardiometabolic parameters. For CGM metrics, we computed daily time percentages within 70–180 mg/dl ($TIR^{70\text{-}180}$) and above 250 mg/dl ($TAR^{>250}$), standard deviation (SD), and coefficient of variation (CV). Cosinor analysis on Fitbit heart rate data yielded circadian rhythm indices, including amplitude and midline statistics of rhythm (MESOR). The amplitude represents the strength of the rhythm, whereas MESOR reflects mean heart rate. Logistic regression, adjusting for various factors, assessed albuminuria presence (urine albumin-creatinine ratio $\geq$30 mg/g). Factors included age, sex, BMI, eGFR, HbA1c, diabetes duration, systolic BP, daily step count, carbohydrate percentage, amplitude, and MESOR.
Results
Individuals with albuminuria were found to be older, with higher BP and HbA1c levels, a longer duration of diabetes, and lower amplitude compared to those without albuminuria. In logistic analysis, high HbA1c, systolic BP, and MESOR, and a low amplitude of among covariates were associated with a higher risk of albuminuria. Among the CGM-derived metrics, a low $TIR^{70\text{-}180}$ and a high $TAR^{>250}$ were significantly linked to the presence of albuminuria, even after adjustment for metabolic parameters and circadian features. In case of SD and CV, absence of significance was found.
Conclusions
We illustrated that a disrupted circadian feature, represented by a low amplitude or high MESOR, was associated with the presence of albuminuria. Considering this significance, $TIR^{70\text{-}180}$ and $TAR^{>250}$ are linked to the presence of microalbuminuria.

Table 1. Features associated with the presence of albuminuria

Clinical and circadian features	Odds ratio (95% CI)[a]
Age(years)	1(0.93–1.06)
Sex, men	0.61(0.24–1.54)
BMI(kg/m^2)	0.98(0.87–1.11)
eGFR	0.98(0.96–1.0)
HbA1c(%)	1.86(1.24–2.78)
Duration of diabetes(years)	1.06(1–1.14)
Systolic BP(mmHg)	1.06(1.03–1.10)
Ln(Daily step count)	1.22(0.61–2.46)
Percentage of carbohydrate	1.02(0.96–1.08)
Amplitude	0.81(0.68–0.96)
MESOR	1.06(1.01–1.11)
CGM metrics	**Odds ratio(95% CI)[b]**
$TIR^{70\text{–}180}$	0.97(0.94–0.99)
$LnTAR^{>250}$	1.49(1.01–1.07)
SD	1.03(0.99–1.07)
CV	0.98(0.90–1.07)

[a] All 11 variables were included as covariates in the logistic regression analysis.[b] Age, sex, BMI, eGFR, Hemoglobin A1c, duration of diabetes, systolic BP, daily step count, percentage of carbohydrate, amplitude, and MESOR were adjusted for each logistic regression analysis.

Difference between HbA1c and GMI

Javier Gómez Pino, Viyey Kishore Doulatram Gamgaram, Luis Ignacio Navas Vela, Mariana Jesús Gomes Porras & Monica Tomé García
Hospital Regional Universitario, Endocrinology and Nutrition

Introduction
Evidence suggests that, for the same mean glucose level, protein glycation may be different and that this may have an impact on the occurrence of complications. We

currently have GMI that estimates mean glucose measured with the FreeStyle Libre 2 and HbA1c determined in the laboratory.
Objectives
To analyse the proportion of "rapid glycaemic" patients in our clinical setting (HbA1c-GMI > 0.5) and to assess the prevalence of microvascular complications (retinopathy, nephropathy, and neuropathy) in these patients and compare with the rest of the sample.
Methods
Cross-sectional descriptive observational study in people with type 1 diabetes mellitus followed up in the Diabetes Unit of the Axarquia Hospital carrying the FreeStyle Libre 2 system. Variables collected: age, sex, presence of microvascular complications, GMI and HbA1c.
Results
291 patients were included, mean age 42.9 ±14.8 years, 40% female, time of evolution 20.4 ± 13 years. Prevalence of microvascular complications 36.3% (9.8% nephropathy, 32.4% retinopathy and 12.9% neuropathy). Mean IGM 7.4 ±0.941% and mean HbA1c 7.70±1.17%. HbA1c-GMI difference: 0.170± 0.708. Proportion of rapid glycators: 26.1%. A significantly higher prevalence of microvascular complications was found (47.4 vs 34 <% with *P* 0.038), with statistically significant difference in retinopathy (44 vs 29.3% with *P* 0.020), neuropathy (21.1 vs 10.2% with *P* 0.016). The difference in nephropathy was not statistically significant (14.5 vs 8.8% with *P* 0.165).
Conclusions
The proportion of rapid glycators in our sample is high (26.1%). Rapid glycators in our sample have a higher prevalence of microvascular complications (retinopathy and diabetic neuropathy).

Cellular immunity in type 1 diabetes: insights from comparative analysis with type 2 diabetes and healthy individuals by flow cytometry

Elena Zakharova, Anna Goncharenko, Ivan Golodnikov, Margarita Samsonova, Nadezhda Rusyaeva, Marina Shestakova & Marina Loginova
Endocrinology Research Centre, Moskva, Russian Federation

Goal
Type 1 diabetes (T1D) development involves intricate interactions between pancreatic β-cells and immune cells. Our study analyzed cellular immunity parameters in adult T1D patients' blood to identify factors influencing disease progression in comparison with healthy donors and type 2 diabetes (T2D) patients.
Methods
Three groups were studied - healthy volunteers ($n=13$), T1D patients ($n=10$), and T2D patients ($n=13$). Analysis included autoantibody measurement and flow cytometry (BD LSRFortessa) of peripheral blood.
Results
Analysis of the main populations of T cells ($CD3^+$-cells), B-cells ($CD19^+$-cells) and NK cells ($CD3^-CD19^-$-cells) did not reveal significant differences between the values in healthy donors and patients with T1D and T2D (Table 1). However, $CD3^+CD8^+$ T-cells and Immune Regulatory Index differed between healthy donors and T2D patients. In T1D, $CD3^-CD19^-CD8^-CD38^+$ NK-cells decreased compared to controls and T2D, with a negative correlation to insulin autoantibodies. On the other hand, there is a trend towards an increase in the quantity of $CD3^-CD19^-CD8^+CD38^+$ NK-cells compared to the control group (Table 1). Effector NK-cells ($CD3^-CD19^-CD16^{++}CD56^+$) decreased in T1D, while T2D had increased NK-cells with weak CD56 expression (Table 1). Correlation analysis did not reveal a connection between $CD3^-CD19^-CD8^-CD38^+$ NK-cells of the three studied groups and the levels of autoantibodies to GAD, islet cells, and tyrosine phosphatase (Table 1).
Conclusion
T2D shows reduced cytotoxic T-cells, while NK-cells play a crucial role in T1D. $CD8^-CD38^+$ NK-cells reduction in T1D correlates with insulin autoantibodies. Functional activity differences in NK-cells between early and long-term treatment stages may exist in T1D and T2D patients.

Glycemic variability assessed by continuous glucose monitoring system in insulin-treated diabetic patients on hemodialysis

Rihab Yamoun[1], Abdesslem Haifa[1], Aguerbi Sahar[2], Bornaz Emna[1], Boukhayatia Fatma[1], Ounaissa Kamilia[1], Ben Ayed Tasnim[2], Fattoum Safa[2,3], Bdrouchi Samara[2], Ben Hamida Fethi[2], Chargui Soumaya[2], Amrouche Chiraz[1] & Abderrahim Ezzeddine[2]
[1]National Institute of Nutrition and Food Technology, Department of Nutritional Diseases (D), Tunis, Tunisia; [2]Charles Nicolle Hospital, Internal Medicine department, Tunis, Tunisia; [3], Tunisia

Introduction
Glycemic control in diabetic patients undergoing hemodialysis is difficult to achieve because of the high glycemic variability in this population. The aim of our study was to assess the glycemic profile, using the continuous glucose monitoring system 'CGMS', in a group of insulin-treated diabetic patients on hemodialysis.
Methods
We conducted a descriptive, evaluative, longitudinal study involving insulin-treated diabetic patients undergoing hemodialysis. It was bi-centric in the National Institute of Nutrition and the Nephrology Department of Charles Nicolle Hospital between 2021 and 2022. We used a 7-day CGMS (Medtronic; Guardian 3) to monitor glucose levels including the dialysis days (HD) and the following inter-dialytic periods ('free' day [FD]).
Results
CGM data were available for 30 subjects (19 male) with a mean age of 57±15.5 years and mean diabetes duration of 21.4±6.9 years. The mean glucose management index (GMI) which provides an estimated glycated hemoglobin (A1c) level was 8.1±1.2%. The mean interstitial blood glucose was 210.7±50.5 mg/dl, with no significant difference between FD and HD (213.9±59.9 mg/dl vs. 217.6±52.4 mg/dl, $p=$NS). The mean coefficient of variation (CV) was 35± 8.7%. It was lower during FD (27.6±9.7% vs. 30.2±9.9%) with no significant difference ($p=$NS). However, the mean amplitude of glucose excursions (MAGE) and the standard deviation (SD) were significantly higher during the dialysis day than FD (93.7±35.8 mg/dl vs. 111.4±39.1 mg/dl, $P=0.01$ and 49.5±28.8 mg/dl vs. 62.4±18.8 mg/dl, $P=0.04$, respectively).
Conclusion
In this population of diabetic patients with end stage kidney disease undergoing hemodialysis, glycemic profile was shown differently between the HD and the FD. Therefore, the use of a CGMS to monitor glycemic control could improve the management of insulin therapy in these patients.

Night eating syndrome improvement after 3 months of liraglutide administration in obese diabetic 2 patients

Fedir Laniush, Alina Urbanovych & Khrystyna Moskva
Danylo Halytsky Lviv National Medical University, Endocrinology, L'viv

Background and aims
Night eating syndrome (NES) is one of the most common eating disorder in patients with obesity and diabetes type 2 (DT2). It may affect the management and outcome of DT2. Liraglutide is used for obesity and DT2 management. It controls glucose metabolism, suppresses hunger, and causes weight loss. Leptin is a hormone produced by adipose tissue after food intake in order to promote satiety and maintain fat storage. Our aim was to evaluate how liraglutide affects leptin levels after 3 months of administration in obese patients with NES and DT2.
Materials and methods
82 individuals (mean age – 61.3 ± 7.4 years; BMI - 33.7 ± 3.2 kg/m^2; history of diabetes < 5 years) with DT2 and obesity were recruited into the study. After completing Night Eating Questionnaire, 17 individuals (20,7%) were screened positive for NES. 1st study group ($n = 8$) with NES started therapy with metformin and liraglutide 1,8 mg daily. 2nd study group ($n = 9$) used metformin and SGLT2-inhibitors for DT2 management. Leptin levels were measured twice: at the start of the study and after 3 months of liraglutide administration.
Results
The initial level of leptin in the 1st study group decreased from 11.02 ± 5.2 ng/ml to 6.6 ± 3.7 ng/ml ($P < 0.05$); they also demonstarted greater weight loss and reduction in the number of night eating episodes. In the 2nd study group leptin levels also reduced (12.3 ± 6.4 ng/ml to 11.4 ± 5.7 ng/ml), but not significantly ($P > 0.05$); number of night eating episodes did not change.
Conclusion
Liraglutide provides multifunctional positive effects on individuals with obesity and DT2. Owing to suppression of hunger center in hypothalamus and promoting satiety, liraglutide improves NES by reducing number of night eating episodes. Leptin level changes reflect body weight loss as well as renovation of sensitivity in hypothalamus to peripheral appetite-controlling peptides and reducing of leptin resistance.

Microvascular changes using OCT Angiography in diabetic eyes without clinical evidence of retinopathy

Rekik Mona[1], Kammoun Sonda[1], Jallouli Aida[1], Nabila Rekik Majdoub[2] & Trigui Amira[1]
[1]Habib Bourguiba Hospital, Department of ophthalmology; [2]Hedi Chaker Hospital, Department of endocrinology

Introduction
Diabetic retinopathy (DR) is a common microvascular complication of diabetes mellitus, leading to visual impairment among individuals of working age. Optical coherence tomography angiography (OCTA) has been developed to visualize the retinal microvasculature and choriocapillaris based on the motion contrast of circulating blood cells.
Purpose
To investigate the qualitative microvascular changes in retinal vascular plexuses and choriocapillaris (CC) in patients with type 2 diabetes mellitus (DM2) without DR using swept-source optical coherence tomography angiography (SS-OCTA). hanges in retinal vascular plexuses and choriocapillaris in patients with type 2 diabetes mellitus (DM2) without diabetic retinopathy (DR)
Methods
An OCTA (DRI OCT Triton; Topcon Corp, Japan) system was used to collect 3 × 3-mm macular scans from diabetic patients without clinical evidence of diabetic retinopathy. We conducted a descriptive qualitative analysis of foveal and extrafoveal microcirculation at the level of the superficial (SCP), the deep (DCP) retinal capillary plexus and the choriocapillaris (CC) to identify microvascular changes in diabetic eyes without clinically detectable retinopathy.
Results
Thirty eyes from 15 diabetic patients without clinical evidence of retinopathy were analyzed. Microaneurysms seen in OCTA but not in fundus examination were found in 4 eyes. The presence of breaks in the perifoveal anastomotic circle is observed at the level of the SCP in 10 eyes. Within the DCP, there are vascular dilations in 8 eyes with an enlargement of the anastomotic circle in 10 eyes, which appears larger compared to its size in the SCP. Areas of hypo-perfusion are noted as hypo-signal zones within the CC in 8 eyes.
Conclusion
DM2 patients without DR have SCP, DCP and CC qualitative impairment. These study highlight that OCT A can identify preclinical microvascular abnormalities preceding the onset of clinically detectable DR, serving as potential biomarkers for the early detection of DR.

Relations of C-reactive protein to post-glucose load glucose in patients with prediabetes and coronary artery disease

Valentina Tankovic[1,1], Sinisa Stankovic[1], Snjezana Popovic Pejicic[1], Gabrijela Malesevic[1], Aleksandra Markovic[1] & Djuro P. Macut[2]
[1]Faculty, of medicine, University of Banja Luka, Internal Medicine, Banja Luka; [2]University of Belgrade - Faculty of Medicine, Internal Medicine, Beograd, Serbia

Introduction
The association between CRP and prediabetes has not been sufficiently investigated. The aim of the study was to determine the association of prediabetes with subclinical inflammation, as well as to examine the correlation of sensitive CRP (hsCRP) with fasting glycemia and 2 h glycemia during exercise during the OGTT test.
Methods
The study included 106 patients with angiographically diagnosed coronary artery disease, who, based on the oral glucose tolerance test (OGTT), were classified into a group with type 2 diabetes (T2D, $n = 34$), a group with impaired glycemia and glucose intolerance (IFG/IGT, $n = 38$) and a group with normal glucose tolerance (NGT, $n = 34$). The control group consisted of subjects with normal glucose tolerance and no coronary disease ($n = 100$), individually matched by age and body mass index (BMI) with coronary patients included in the study. The circulating level of lipids, insulin, hsCRP, the albumin level in the morning urine sample, and the insulin resistance index HOMA were determined in all of them.
Results
The level of hsCRP was elevated in the group of coronary patients with diabetes ($P < 0.05$), as well as in the group of patients with prediabetes ($P < 0.05$), compared to the control group. hsCRP values were not significantly different in coronary patients, regardless of glycemic status ($P > 0.05$). A significant correlation of hsCRP with glycemia in 120 min OGTT test was found. ($P < 0.05$), independent of existing obesity.
Conclusion
Chronic subclinical inflammation, detected by an elevated level of C-reactive protein, is more strongly associated with post load glycemia than with fasting glycemia. Prediabetes leads to an increase in markers of subclinical inflammation, which is associated with increased cardiovascular risk.
Key words: C-reactive protein, hyperglycemia, prediabetes, coronary disease

Self-perception of hypoglycemia symptoms in adolescents with type 1 diabetes

Meryem Chakir, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
Ibn Rochd University Hospital of Casablanca, Morocco Neurosciences and Mental Health Laboratory Faculty of Medicine and Pharmacy-University Hassan II-Casablanca-Morocco, Endocrinology, Diabetology, Nutrition and Metabolic Diseases Department, Casablanca, Morocco

Introduction
Hypoglycemia is a common complication of diabetes in cases of perfect glycemic balance, leading to a deterioration in the quality of life for diabetic patients. Early perception of hypoglycemia symptoms can improve the health status of diabetic adolescents.
Objective
The aim of our study is to evaluate the self-perception of hypoglycemia symptoms in adolescents with type 1 diabetes.
Materials and Methods
A prospective study conducted at the Endocrinology-Diabetology Department of Ibn Rochd University Hospital in Casablanca, involving adolescents with type 1 diabetes, based on the Clarke score. Data analysis was performed using SPSS.
Results
Sixty-seven patients were included in the study, of which 62.7% were female. The mean age was 16.5 years. The average duration of diabetes was 4.9 years. The mean body mass index was 21.1 kg/m^2. The average HbA1c was 9.3%. All patients were on a basal-bolus regimen, predominantly using analog insulins at a rate of 59.7%. The frequency of hypoglycemia was 86.5%, with an average of 2 episodes per week. Hypoglycemic episodes mostly occurred in the afternoon. Normal hypoglycemia

perception was noted in only 38% of patients. Self-perception of hypoglycemia symptoms was associated with the duration of diabetes ($P=0.01$)
Conclusion
Our study shows that the perception of hypoglycemia symptoms was normal in adolescents with longer-standing diabetes. Training patients to better perceive the signals their bodies send them represents a new perspective for therapeutic education.

Percutaneous radiological gastrostomy in our hospital: the key to improving nutritional status without complications
Maria Jose Vallejo Herrera, Veronica Vallejo Herrera & Maria Carmen Bautista Recio
Hospital Regional Málaga, Malaga

Background
Percutaneous radiological gastrostomy (PRG) is one of the techniques of choice for long-term enteral nutrition. Although safe and technically simple, it has been associated with relative morbidity and mortality.
Objective
We analyzed the results of the PRG insertion techniques with respect to morbidity and mortality, associated complications during the hospital stay, as well as nutritional results.
Methods
A cohort of 30 patients scheduled for PRG insertion from 08/2022 to 01/2023 was retrospectively evaluated. In 30 hospitalized patients, gastrostomy placement was scheduled during hospitalization in 30% (10 patients) and on an outpatient basis in 70% (20 patients). The mortality rate at one month was 16% (5 patients).
Results
We analyzed 30 PRGs in patients with a mean age of 60 (25-79) years in the referred period. 74% men and 26% women. The referral services for its implementation were Neurosurgery/Neurology, ENT, Maxillofacial and Endocrinology and other minority services. The underlying pathologies that indicated PRG were mainly neoplastic head and neck cancer, neurological diseases due to cerebrovascular disease and dementia, and patients with irreversible neurological lesions after multiple trauma. The average hospital stay of these patients was 53 days after admission. A 16F or 14F PRG tube was placed in most patients. There were no post-procedural complications, except for one case of transient paralytic ileus.
- The nutrition formulas prior to carrying out PRG corresponded to hyperprotein polymeric formulas. hypercaloric in all cases. The same nutritional formula was usually maintained at hospital discharge.
- The administration of enteral nutrition by PRG was in continuous perfusion during admission with transition to gravity upon discharge in the majority of cases. In prolonged admissions, after verifying good tolerance, the condition was changed to severity.
- The patients had an average BMI of 23. During the follow-up in the Nutrition consultations, 64% of the patients increased their BMI by an average of 2-4 and the remaining 26% maintained their initial BMI, with 16% (5 patients) loss of follow-up due to death.

Conclusion
The insertion of hospital PRG is a safe technique for long-term enteral nutrition, from which cancer patients or patients with neurological pathology mainly benefit, achieving maintenance or improvement of nutritional status in practically all patients through hyperprotein/hypercaloric formulas. cases, with a low rate of morbidity and mortality and associated complications.

Autoimmune hypoglycemia: a rare case of Hirata's disease
Evangelia-Ntaniella Dimopoulou[1], Paraskevi-Maria Bougiouka[1], Alexandra Giannou[1], Stavroula Paschou[2] & Vasiliki Vasileiou[1]
[1]Alexandra General Hospital, Athens, Greece; [2]Endocrine Unit, Department of Clinical Therapeutics, National and Kapodistrian University, Athens, Greece

Introduction
Insulin autoimmune syndrome (Hirata's disease) is a rare cause of hypoglycemia in Caucasians, with an estimated prevalence of 0,017 cases per 100.000 in general population. It is characterized by mostly postprandial hypoglycemia and the presence of autoantibodies against insulin. Treatment options include dietary modifications, glucocorticoids, azathioprine, rituximab and plasmapheresis.
Case report
A 72-year-old woman with no medical history of Diabetes Mellitus (HbA1c 5,6%) presented to our outpatient department reporting episodes of hypoglycemia (glu 40-60 mg/dl) since 2 months, the majority of which postprandially, accompanied by early post-meal hyperglycemia (glu 250-300 mg/dl). She presented an OGTT with glucose values compatible with DM (glu 0': 104, glu 60': 311, glu 120': 256 mg/dl), concurrently with extremely high insulin values (ins 0': 181, ins 60': 1474, ins 120': 5340 mIU/l). Such a combination raised the suspicion that insulin could not act properly. Prolonged OGTT was performed and hypoglycemia was recorded at 220' (glu 33), while both insulin and C-peptide levels where profoundly increased (ins 220': 169 μIU/ml, C-pept 220': 11,3 ng/ml) simultaneously. After excluding some common causes of hypoglycemia (adrenal insufficiency, medications, alcohol abuse, malignancy), we proceeded with measurement of her insulin autoantibodies (anti-IAA), which turned out positive (>20 IU/ml – normal values <2,4). Our diagnosis was Hirata's disease. Our patient's medical history was free of exposure to susceptible drugs or recent infection. Treatment with methylprednisolone 15 mg daily was started and within a month her hypoglycemic episodes were significantly reduced. Two months later her antibody titre was within normal range (2 IU/ml), and remained within normal limits (1 IU/ml) at follow-up measurement 4 months later, even after treatment discontinuation. She reports no hypoglycemic episodes.
Conclusion
Despite the rarity of this condition, Hirata's disease is important to be considered early in the differential diagnosis of hypoglycemia. This case report aims to raise awareness of this clinical condition to the physicians, since a high titre of insulin autoantibodies would help avoid costly and complicated examinations.

Exceptional observation of congenital hyperinsulinism with variable phenotypic expression
Hana Charfi, Dhoha Ben Salah, Yassmine Abdelkafi, Nesrine Dhieb, Mouna Elleuch, Fatma Mnif, Nadia Charfi, Mouna Mnif, Mohamed Abid & Nabila Rekik Majdoub
Hedi Chaker Hospital, Sfax, Tunisia

Introduction
Congenital hyperinsulinism (CHI) is a rare disease with an incidence of 1 in 30,000. It is the most common cause of persistent neonatal hypoglycemia, primarily due to inhibitory mutations in genes encoding the ATP-sensitive potassium channel in pancreatic beta cells, with ABCC8 (SUR1) and KCNJ11 (Kir6.2) mutations being the most frequent. In this context, we report a highly unusual case in terms of phenotypic and evolutionary aspects.
Clinical Case
A 17-year-old female presented with severe organic hypoglycemia related to endogenous CHI diagnosed since neonatal age. She had been treated with Diazoxide since childhood, but experienced recurrent hypoglycemia and therapeutic escape. The diagnosis of focal CHI was established based on pancreatic MRI and endoscopic ultrasound findings revealing hyperplasia in the pancreatic tail. A caudal pancreatectomy was performed, paradoxically leading to severe and persistent hyperglycemia reaching 8 g/l for 20 hours, accompanied by a significant decrease in insulin levels during its kinetic evaluation, dropping from 400 μIU/ml to 25 μIU/ml (concurrent blood glucose at 3 g/l). Subsequent postoperative evolution showed a gradual spontaneous normalization of blood glucose to 1 g/l, followed by the recurrence of hypoglycemia with a rise in insulin levels. Histopathological data confirmed the diffuse nature of pancreatic hyperplasia, indicating the need for total pancreatectomy. Molecular analysis of candidate genes involved in CHI was negative for ABCC8 and KCNJ11 genes. However, involvement of a molecular anomaly in the enzymatic chain of insulin secretion process was considered.
Conclusion
CHI, seemingly a straightforward entity, exhibits a highly complex etiopathogenesis, making the correlation between phenotypic and genotypic expression challenging. High-throughput sequencing techniques have provided insights into insulin secretion signaling pathways, but the involvement of environmental factors opens up a new research avenue, highlighting the Gene-Environment interrelation.

Long term use of closed-loop systems in patients with type 1 diabetes and risk of hypoglycemia

Beatriz Torres Torres[1,2], Paloma Pérez López[1,2], Ainhoa Alcelai Uribeecheverría[2], Pablo Fernández Velasco[1,2], Jaime González Gutiérrez[1,2], Lucía Estévez Asensio[1,2], Esther Delgado García[1,2], Emilia Gómez Hoyos[1,2], Gonzalo Díaz Soto[1,2] & Daniel De Luis Román[1,2]
[1]Hospital Clínico Valladolid, Endocrinology, Valladolid, Spain; [2]Facultad de Ciencias de la Salud, IEN, Valladolid, Spain

Background and Aim
Data support the use of hybrid closed-loop systems, because of it positive impact in the management of patients with type 1 diabetes (T1D). The aim was to evaluate the impact of an hybrid closed-loop system in patients with T1D at high risk of hypoglycemia.
Methods
Retrospective study of patients with T1D controlled in a Endocrinology department older than 17 years old, who were carriers of an Insulin Pump (MiniMed™640G) and Flash Glucose Monitoring System. They switched to a MiniMed™780G Hybrid closed-loop system (Medtronic), at least two years before the study. At baseline, patients had a Coefficient of Variation(CV) $>$ 36% and/or a Time below 70 mg/dl (TBR)greater than or equal to 4%. Data of Time in Range (TIR), Time above 180 mg/dl (TAR), TBR, CV and Glucose Management Indicator(GMI) were collected at baseline and 3 months and 2 two years after change.
Results
18 patients were included. The age was 33.5 (28-43) years old, the evolution of their T1D was on 18.6 (15-24) years and 56% were women.
10 patients (55%) had an TIR $>$70% at baseline, compared to 100% of patients at both 3 and 24 months ($P<0.001$)
Conclusions
The use of hybrid closed-loop systems, in our series, has shown an increase in TBR due to a decrease in TAR, TBR and CV. Improvement in glycometric parameters was observed at 3 months and it was maintained after 2 years of follow-up.

Table 1. Summary of data outcome

	TIR	TBR	TAR	CV	GMI
Baseline	68,5% (56.7-76.0)	5% (3,5-7)	20% (16-29)	38.2 (33.7-41.5)	6.6% (6.5-7)
3 months	86.3% (80.0-89.0)	3% (2-4)	11% (7-16)	31.3% (27.8-34)	6.4% (6.4-6.6)
24 months	83.1% (80-87.5)	2% (1-4)	14% (9.5-18.5)	30.3% (28-33.1)	6.6% (6.4-6.8)

Mody-3 diabetes: is there a place for GLP-1 receptor agonists use?

Valentim Lopes, Patrícia Brito, Rita Ribeiro & Adriana Lages
ULS de Braga, Endocrinology, Braga, Portugal

Introduction
Maturity-onset diabetes of the young (MODY) represents 1 to 2% of all cases of diabetes. MODY-3 is the most prevalent subtype and is characterized by a high sensitivity to sulfonylurea (SU) therapy. To date, we have scarce evidence about the efficacy of other therapies in this population, namely GLP-1 receptor agonists (GLP-1ra).
Objective
Evaluate the metabolic impact of GLP-1ra use in MODY-3 patients.
Methods
Retrospective descriptive study including patients with genetically confirmed MODY-3 followed at the Endocrinology Department of a tertiary referral centre. Data were analysed using SPSS v.27. Results were considered significant if $P <$ 0.05.
Results
From a total of 53 patients with genetically confirmed MODY diagnosis followed at our centre, we selected 16 patients with MODY-3 for the final analysis (30.2%). We divided the patients in two groups: patients treated with GLP-1ra - group 1 – ($n = 9$, 56%) and patients not treated with – group 2 ($n = 7$, 44%). 12 (75%) of the patients of the total sample were female, with a median age at diagnosis of 23 (Q1 19 – Q3 26.5) and 18 (Q1 18 – Q3 24) years and a median disease duration of 29 (Q1 12.5 – Q3 36.5) and 17 (Q1 14 – Q3 27) years, respectively for the group 1 and 2. Patients of the group 1 (vs patients of the group 2) presented more weight loss – -7 ([-10.5]-[-4.5]) vs 0 ([-3]-2) kg, $P = 0.011$ – and a higher C-peptide/serum glucose ratio - 1.1 (0.7-2.4) vs 0.4 (0.3-0.5) ng/ml:mg/dl, $P = 0.006$. We did not find statistically significant differences between the two groups regarding total daily dosage of SU and insulin, frequency of usage of other pharmacological classes (namely metformin and SGLT-2 inhibitors), HbA1c and prevalence of micro and macrovascular complications.
Conclusion
Patients treated with GLP-1ra (group 1) presented a significantly higher weight loss and evidence of preservation of residual endogenous pancreatic secretion of insulin, highlighting the potential benefit of this pharmacological class in patients with MODY-3 diabetes mellitus.

Evaluation of nutritional knowledge in Tunisian adolescents

Ben Othman Rym, Amorri Amani, Salma Abadlia, Ben Zina Baya, Ben Mansour Nadia, Kasraoui Sabeh, Gamoudi Amel & Jamoussi Henda
National Institute of Nutrition and Food Technology, Nutrition A, tunis

Introduction
The inequity in energy balance is the most common cause of obesity throughout adolescence. Thus, evaluating nutritional knowledge is crucial for effective planning of targeted preventive interventions, by identifying specific areas that require improvement. Our study was undertaken in order to assess the levels of dietary awareness in a sample of Tunisian adolescents aged 12 to 15 years.
Methods
It was a multicenter cross-sectional study including 315 adolescents aged from 12 to 15 years. Our study was conducted at the National Center for School and University Medicine in Tunis and five randomly selected nurseries in Ariana governorate from December 2021 to June 2022. Participants' nutritional knowledge was evaluated using an Arabic version of the validated French nutritional questionnaire QuesCA 12-15 with a maximum score of 9/9. We developed the Arabic version following established translation and questionnaire validation guidelines.
Results
The average age of adolescents was 13.1 ± 1 years. The sex ratio was 1.15. Three-quarts of the sample (76%) had a normal weight, 13% were obese and 9% were underweight. The mean score on the questionnaire was 5.814 ± 0.4/9. The majority of participants (79%) obtained a fair score (i.e. score ranging between 4 and 6/9). None of the participants answered all items correctly. Nevertheless, thirteen percent achieved a good score (i.e. score $\geq$ 7/9) indicating a robust understanding of nutrition. On the other hand, 8% received a poor score (i.e. score $\leq$ 3/9). Worth noting, one child had a score of 0/9. Moreover, correct responses exceeded 75% for items related to the themes of breakfast, beverages, proteins, fruits and vegetables, and sweets. In contrast, items related to themes of balanced diet, starchy foods, calcium-rich foods, and fats had correct response rates below 25%.
Conclusion
These insights provide a foundation for developing tailored interventions to enhance dietary awareness and combat the rising challenges of obesity among Tunisian adolescents.

Indices of carbohydrate metabolism in patients during the acute period of covid-19

Umida Mirzaeva
Tashkent Pediatric medical institute, Endocrinology, Tashkent, Uzbekistan

Introduction
The World Health Organization has recognized a new coronavirus infection as a pandemic[1]. As of early October 2020, the number of infected people worldwide amounted to more than 37 million[2]. According to WHO data, the structure of morbidity of new coronavirus infection is dominated by elderly people and patients with comorbidities, among which the most frequent are diseases of the cardiovascular system, diabetes mellitus (DM), obesity, chronic lung diseases, and oncologic pathology[3].
Objective
To determine the indices of carbohydrate metabolism in patients with COVID-19 in the acute phase of the disease.

Materials and methods
The object of research were 31 patients in the acute period of coronavirus infection caused by COVID-19. The age of the patients ranged from 32 to 80 years. Of these, there were 13 (41.9%) males and 18 (58.1%) females. All patients underwent standard clinical and anamnestic examinations: anthropometric, hemodynamic, laboratory examination included general and biochemical blood analysis, liver function indices, coagulogram, lipid spectrum parameters, fasting glycemia, HbA1c, fasting insulin levels, with HOMA-IR index determination, urea, creatinine with calculation of SCF and CRP.
Results of the study
Carbohydrate metabolism disorder in the form of increased fasting glucose level was revealed in 6 (19,4%) patients, mainly older than 50 years old with concomitant arterial hypertension, excessive body weight and obesity. In 4 patients with type 2 DM in anamnesis the duration of the disease was on average 6.8 ± 1.7 years. In the majority of patients fasting glucose level was within the range of normal values (mean 4.4 ± 0.7 mmol/l). HbA1c above the reference interval was observed in 32.3% of patients. When analyzing insulin resistance indices, increased insulin level was noted in 22.6% of cases, HOMA IR ≥ 2.7 was found in 35.5% of patients, mostly with coronavirus infection of moderate severity.
Conclusions
Thus, the presence of impaired carbohydrate metabolism is associated with a more severe course of coronavirus infection. At the time of admission, the group with a moderate course of coronavirus infection had more co-morbidities than patients in the group with a mild course.

The impact of diet on rheumatoid arthritis disease activity
Rym Ben Othman[1], Khaoula Zouaoui[2], Maryam Naifar[1], Ramla Mizouri[1], Ikhlas Trabelsi[1], Olfa Berriche[1] & Henda Jamoussi[1]
[1]national institute of nutrition; [2]La Rabta, Tunis, Tunisia

Introduction
Rheumatoid arthritis (RA) is a chronic autoimmune disease that may cause nutritional impairment. The aim of the present study was to assess differences in nutritional status and Mediterranean diet (MD) adherence among patients with rheumatoid arthritis (RA), according to disease activity.
Methods
A comparative cross-sectional study, conducted among patients consulting the rheumatology department of La Rabta University hospital for RA. To assess disease activity and adherence to Mediterranean diet, we opted for the subjective disease activity score28 (DAS28) and MedDietScore. The dietary survey data were subsequently analyzed using the NUTRILOG software.
Results
This study included 52 patients. Patients were subdivided into 2 groups: G1 includes 35 patients with low activity RA and G2 with very active RA according to DAS28. The median age was 56.26 ± 13.12 years. The mean Body Mass Index (BMI) was 28.84 kg/m^2 in G1 vs 28.20 kg/m^2 in G2 ($P=0.74$) and 52.9% of patients in G2 were obese (BMI ≥ 30 kg/m^2) Vs 48,6%; $P=0,76$. waist circumference was higher in G2 with no statistically significant association; $P=0,86$. the two groups ($P=0.22$). The eating pattern of G2 patients was more regular than that of patients in G1, with a P-value of 0.7. The frequency of consumption of certain foods such as Walnuts, Rapeseed Oil, Soybean Oil, Fish, Cinnamon, Garlic, Ginger, Sesame, and Turmeric did not differ significantly between the two groups. Patients in G1 adhered more to the Mediterranean diet without significant difference (7.26 vs 7.18; $P=0.88$). The calorie surplus was higher for patients in the low-activity PR group (404 kcal vs 52.09 kcal; $P=0.55$). Spontaneous macronutrient intake did not differ significantly between the two groups. Only the percentage of daily intake of polyunsaturated fatty acids (PUFA) was significantly higher in G2 ($P=0.03$). Regarding micronutrient and fiber intake, only the sodium intake was significantly higher in patients from G1 (6059,31 mg vs 4604,59 mg; P-value$= 0,01$.
Conclusion
Specialized nutritional management should be instituted in patients with RA to avoid disruption of their nutritional status.

Weight reduction in patients with hypothalamic obesity treated with setmelanotide for 12 months
Christian L. Roth[1], Ashley Shoemaker[2], Michael Gottschalk[3], Jennifer Miller[4], Guojun Yuan[5], Sonali Malhotra[6], Cecilia Scimia[5] & M. Jennifer Abuzzahab[7]
[1]Seattle Children's Research Institute; Division of Endocrinology, Department of Pediatrics, University of Washington, Seattle, Seattle, United States; [2]Ian Burr Division of Endocrinology and Diabetes, Vanderbilt University Medical Center, Nashville, United States; [3]Pediatric Endocrinology, University of California San Diego/Rady Children's Hospital, San Diego, United States; [4]Pediatric Endocrinology, Department of Pediatrics, College of Medicine, University of Florida, Gainesville, United States; [5]Rhythm Pharmaceuticals, Inc., Boston, United States; [6]Rhythm Pharmaceuticals, Inc.; Harvard Medical School; Massachussetts General Hospital, Boston, United States; [7]Pediatric Endocrinology and Diabetes, Children's Minnesota, Saint Paul, United States

Background
Hypothalamic obesity (HO) is an acquired form of severe obesity characterized by rapid and excessive weight gain resulting from insult to the hypothalamus—primarily caused by tumor invasion, resection, or radiotherapy—that can impair melanocortin-4 receptor (MC4R) pathway signaling. Treatment with setmelanotide, an MC4R agonist, resulted in weight and hunger reduction at 16 weeks in a Phase 2 trial of patients with HO. Here, we report changes in weight-related parameters after 12 months of setmelanotide treatment in patients with HO who entered a long-term extension (LTE) trial.
Methods
The Phase 2, multicenter, open-label study (NCT04725240) was a 16-week trial in patients aged ≥ 6 to ≤ 40 years with a clinical diagnosis of HO. Patients who demonstrated adequate safety and meaningful clinical benefit were eligible to enroll in the LTE trial (NCT03651765). Mean (standard deviation [SD]) percent change in body mass index (BMI) for all patients and mean (SD) change in percent of the 95th BMI percentile (%BMI$_{95}$) for children (aged <18 years) from index trial baseline to Month 12 of setmelanotide treatment were assessed.
Results
Of 14 patients who entered the LTE, 12 (86%) received ≥ 12 months of setmelanotide at the time of analysis. One adult who experienced nausea discontinued study drug at 7 months and 1 child who had been lost to follow-up reconsented and reentered the LTE but did not have 12-month data. At Month 12, the mean (SD) percent BMI change from baseline was -24.9% (13.0%) across all patients ($n=12$) and in children ($n=11$), the mean (SD) change in %BMI$_{95}$ was -39.5 (19.4) percentage points. No new safety signals were identified.
Conclusions
In a heterogeneous population of patients with HO secondary to treatment of hypothalamic tumors, 12 months of setmelanotide treatment was associated with sustained meaningful BMI improvement with no new safety signals.

Impact of setmelanotide on metabolic syndrome risk in patients with POMC and LEPR deficiency
Martin Wabitsch[1], Wendy Chung[2], Peter Kühnen[3], James Swain[4], Jill Garrison[5], Nicolas Touchot[5], Jesús Argente[6] & Karine Clément[7]
[1]Division of Pediatric Endocrinology and Diabetes, Department of Pediatrics and Adolescent Medicine, University of Ulm, Ulm, Germany; [2]Division of Molecular Genetics, Department of Pediatrics, Columbia University, New York, United States; [3]Charité - Universitätsmedizin Berlin, Corporate Member of Freie Universität Berlin und Humboldt-Universität zu Berlin, Institute for Experimental Pediatric Endocrinology, Berlin, Germany; [4]Honor Health Research Institute, Scottsdale, United States; [5]Rhythm Pharmaceuticals, Inc., Boston, United States; [6]Department of Pediatrics and Pediatric Endocrinology, Universidad Autónoma de Madrid, University Hospital Niño Jesús, CIBER 'Fisiopatología de la obesidad y nutrición' (CIBEROBN), Instituto de Salud Carlos III; IMDEA Food Institute, Madrid, Spain; [7]Assistance Publique Hôpitaux de Paris, Nutrition Department, Pitié-Salpêtrière Hospital; Sorbonne University, Inserm, Nutrition and Obesity, Systemic Approaches (NutriOmique) Research Group, Paris, France

Background
Proopiomelanocortin (POMC; including biallelic variants in *PCSK1*) and leptin receptor (LEPR) deficiency are associated with hyperphagia and early-onset,

severe obesity. Treatment with the melanocortin-4 receptor agonist setmelanotide for 1 year results in significant and sustained improvements in weight (POMC, −25.6%; LEPR, −12.5%), hunger, and quality of life. We used the metabolic syndrome Z score based on body mass index (MetS-Z-BMI) to assess the effect of setmelanotide treatment on long-term risk of cardiovascular disease (CVD) and type 2 diabetes mellitus (T2DM). Each 1.0-point increase in MetS-Z-BMI increases the odds of future CVD and T2DM by 9.8 and 2.7, respectively, when assessed in children and by 2.4 and 2.8, respectively, when assessed in adults.
Methods
Parameters from Phase 3 trials of patients with POMC (NCT02896192) or LEPR (NCT03287960) deficiency were used to calculate MetS-Z-BMI score change after 1 year of setmelanotide. Long-term clinical responders to setmelanotide were defined as achieving ≥10% weight loss (if ≥18 years old) or ≥0.3-point BMI Z score reduction (if <18 years old) after 1 year.
Results
Eighteen patients (56% female, 11-36 years old) were evaluated. A decrease in mean (SD) MetS-Z-BMI was observed in clinical responders after 1 year of setmelanotide ($n=14$; −1.31 [0.84]). Nonresponders ($n=4$) achieved minimal decrease in MetS-Z-BMI (−0.17 [0.23]; difference between groups, −1.13, $P=0.0187$). Responders with POMC ($n=9$) and LEPR deficiency ($n=5$) had changes in MetS-Z-BMI of −1.63 (0.84) and −0.72 (0.48), respectively. MetS-Z-BMI change was similar in female and male responders.
Conclusions
Clinical response to setmelanotide led to decreases in MetS-Z-BMI in patients with POMC and LEPR deficiency associated with reduced risk of developing CVD and T2DM in other populations. These data suggest that early initiation of setmelanotide may reduce future risk of T2DM and CVD.

Fibroblast growth factor 21 in health and diseases

Hassan Heshmati[1] & Haitham Abu-Lebdeh[2]
[1]Endocrinology Metabolism Consulting, LLC, Hassan Heshmati and Valerie Shaw Endocrine Research, Anthem, AZ, United States; [2]Mayo Clinic, Division of Endocrinology, Diabetes, Metabolism and Nutrition, Rochester, MN, United States

Introduction
Fibroblast growth factor 21 (FGF21), a 181 amino acid peptide hormone predominantly produced by the liver, is a member of the endocrine FGF subfamily. It is involved in multiple physiological regulations and plays an important role in several pathological conditions. This literature analysis provides an update on the relevance of FGF21 in health and diseases.
Methods
A systematic search of literature was conducted using the search terms fibroblast growth factor 21, health, diseases, role, and analog.
Results
FGF21 is a stress hormone with various functions. It is involved in the regulation of energy expenditure and metabolism of lipids and glucose by acting on the adipose tissue and central nervous system. In normal subjects, serum FGF21 levels increase gradually with aging. There is an increase in FGF21 secretion under stressful conditions (e.g., fasting status, protein restriction, exercise, several metabolic disorders, kidney diseases, cardiovascular diseases, and sepsis). The increased serum FGF21 levels observed in metabolic disorders (e.g., obesity, nonalcoholic fatty liver disease 'NAFLD', and type 2 diabetes) and other conditions (e.g., kidney failure, heart failure, and sepsis) can be associated with a state of FGF21 resistance that is related in part to the presence of high circulating levels of fibroblast activation protein, a protease that inactivates FGF21. In contrast, low serum FGF21 levels have been reported in anorexia nervosa. Serum FGF21 level has the potential to be used as a biomarker in several metabolic disorders (e.g., NAFLD and type 2 diabetes) and other conditions (e.g., heart failure). In view of the multiple FGF21 functions related to energy expenditure and metabolism of lipids and glucose, long-acting FGF21 analogs (e.g., LY2405319, PF-05231023, pegozafermin, AKR-001, and LLF580) have been used in clinical trials for the treatment of various conditions such as obesity, NAFLD, dyslipidemia, and type 2 diabetes. The results of these trials show that FGF21 analogs can reduce body weight, liver fat, circulating lipids, and fasting insulin/insulin resistance. Thus far, these analogs are considered safe and well tolerated.
Conclusions
FGF21 is a peptide hormone synthesized predominantly by the liver and involved in the maintenance of metabolic homeostasis. FGF21 plays an important role in multiple pathological conditions. Serum FGF21 levels are increased in several diseases in a setting of FGF21 resistance. Although FGF21-based therapy appears to be an attractive approach to treat metabolic disorders, additional clinical studies are necessary before practical recommendations can be made for the use of FGF21 analogs.

Introduction
Metabolically associated fatty liver disease (MAFLD), prevalent in the Western world and a leading cause of liver transplantation among U.S. women, ranges from intra-hepatocyte lipid accumulation to cirrhosis. Fibrosis severity is crucial for prognosis, correlating with risks of advanced cirrhosis, portal hypertension, and hepatocellular carcinoma. 5-10% weight loss is associated with improvement of liver steatosis, but achieving >10% weight loss is usually necessary to improve NASH. Ketogenic diets, regardless of calorie intake, seem effective in treating steatosis, but there is very little evidence on their impact on liver fibrosis. The objective of this study is to evaluate the effect of a moderately low calorie, high-fat ketogenic diet (HFKD) on liver health in patients with MAFLD.
Methods
This prospective, pilot study involved patients with a confirmed MAFLD diagnosis through Magnetic Resonance Imaging (MRE) and Proton Density Fat Fraction (PDFF). Inclusion criteria included age over 18, and BMI ≥ 30 kg/m^2, while exclusion criteria included decompensated liver failure, pregnancy/lactation, type 1 diabetes mellitus, chronic renal disease, alcoholism, hepatotropic viral infection. The primary outcome was reduction of liver steatosis, while secondary outcomes focused on safety, improvements in liver fibrosis, metabolic profile, and body composition. The patients underwent a moderately hypocaloric HFKD for 90 days and Magnetic Resonance Imaging (MRE) was employed to evaluate steatosis (PDFF %) and stiffness (kPa). Baseline and post-intervention assessments included anthropometric measurements, biochemical analysis, and body composition evaluation (DEXA).
Results
Seven patients with MAFLD (mean age 61.3 ± 8.14 years and mean BMI 38.84 ± 6.62 kg/m^2) were included. Following the dietary intervention, weight loss (-8.14 kg, $P=0.03$) and a decrease in mean BMI (-2.92 kg/m^2, $P=0.02$) and fat mass percentage (-3.57%, $P=0.02$) were reported. As expected given the small calorie deficit, none had >10% weight loss, allowing for better evaluation of the impact of macronutrient composition beyond calorie deficit/weight loss *per se*. MRE revealed a significant reduction in steatosis (PDFF -6.16%, $P=0.03$). Although no statistical reduction in liver fibrosis was observed overall likely due to the small sample size, three out of seven patients exhibited clinically relevant stiffness decrease. Notably, two patients achieved complete resolution of NASH, while another, despite remaining cirrhotic, demonstrated significant improvement. Safety parameters were unchanged.
Conclusion
Despite modest weight loss, preliminary data indicate a role for HFKD in managing MAFLD, not only in mitigating steatosis but potentially in more advanced stages characterized by liver fibrosis. MRE emerges as a sensitive tool for assessing MAFLD changes over time.

The effects of multi-strain probiotics in patients with obesity and metabolic syndrome

Ivaylo Bogomilov[1], Vesela MIhneva[2] & Branimira Mihaylova[3]
[1]Medical University Of Sofia, Sofia, Bulgaria, Pharmacology and toxicology, Sofia, Bulgaria; [2]Military Medical Academy Sofia, Pharmacology and toxicology, Sofia, Bulgaria; [3]Medical University Of Sofia, Sofia, Bulgaria, Sofia, Bulgaria

Introduction
Obesity and metabolic syndrome (MS) to which it can lead are diseases that have become very important in recent decades. Understanding the complex mechanisms leading to the development of obesity and metabolic syndrome would give us the answers on how to properly manage these important socially significant diseases. The criteria for metabolic syndrome in recent years have changed a little bit, but invariably they include - visceral type of obesity - measured by waist circumference, arterial hypertension, dyslipidemia - characterized by low levels of HDL-cholesterol and increased levels of triglycerides, diabetes mellitus (DM) type 2 or impaired fasting glycemia. However, insulin resistance is both a consequence of obesity and one of the causes of the development of metabolic syndrome. In recent years, different groups of medications have proven their effect on insulin resistance and are used in the treatment of obesity and metabolic syndrome. Recent studies have shown that the gut microbiome is also extremely important in the development of insulin resistance and may be one of the keys to treating MS and obesity.
Methods
Forty patients with obesity, MS and HOMA-index above 5 were tracked during the study. The patients were given a probiotic - 2.5×10^9 cfu/g of Ecologic®Barrier (multi-strain probiotics) and a standard diet for 6 months. After 6 months, we followed the value of fasting blood sugar, fasting insulin and HOMA index.
Results
In all patients using probiotics, there was a decrease in the levels of fasting insulin, as well as in the levels of fasting glucose, respectively the levels of the HOMA-index, and this reached statistically significant values $P<0.05$. In thirty of the patients, there was a decrease in body weight of 5 ± 1 kg.
Conclusion
Usage of specialized probiotics and regulation of the gut microbiome may lead to improvement in metabolic parameters in MS and obesity. Extensive studies on the impact of probiotics on components of MS and obesity are needed to fully understand their effect in the treatment of these diseases.

The influence of metabolic and hormonal changes in the treatment of obesity

Vesela Mihneva[1], Ivaylo Bogomilov[2] & Tzvetelina Totomirova[1]
[1]Military Medical Academy Sofia, Endocrinology and metabolic diseases, Sofia, Bulgaria; [2]Medical University Of Sofia, Sofia, Bulgaria, Pharmacology and toxicology, Sofia, Bulgaria

Introduction
Obesity is a chronic relapsing disease that has acquired pandemic dimensions in recent years. Obesity is not just a disease that is associated with an increase in body weight, but a condition that leads to a complete change in the hormonal status of patients.
Methods
In the Clinic of "Endocrinology and Metabolic Diseases" of the Military Medical Academy - Sofia, we tracked 100 people with obesity with a BMI over 30 kg/m2 for 6 months. Patients were divided into 5 different groups depending on the therapy they received-with metformin, with liraglutide up to 3 mg, semaglutide up to 2.4 mg, treatment with specialized probiotics or only on a standard diet. We monitored the values of thyroid hormones - TSH, fT4 fT3; levels of TAT, MAT; total testosterone in men and women, fasting insulin levels, fasting glucose levels and insulin and glucose levels during oral glucose tolerance test (OGTT), before the start of treatment and 6 months later.
Results
We found statistically significant changes ($P<0.05$) in the hormone levels - in patients who reduced more than 5% of body weight regardless of the therapeutic approach-a decrease in TSH levels was found, in patients with subclinical hypothyroidism at the beginning of the follow-up, without levothyroxine replacement therapy and increased total testosterone levels in men with baseline low total testosterone. In patients with a reduction of more than 10% of body weight, a decrease in fasting insulin levels was found, as well as in fasting glucose levels and glucose levels at 120 min of the performed OGTT compared to the values at the beginning of the follow-up.
Conclusion
The reduction of body weight and the treatment of obesity leads to an improvement in the general hormonal status of patients, independently of the therapeutic approach, but in correlation with the percentage of reduced body weight.

Association study of obesity susceptibility gene polymorphisms in relation to 5 tunisian families

Hamdi Frikha[1], Hana Charfi[1], Yassmine Abdelkafi[1], Khouloud Boujelben[1], Dhoha Ben Salah[1], Faten Haj Kacem Akid[1], Nadia Charfi[1], Fatma Mnif[1], Mouna Mnif[1], Faiza Fakhfakh[2], Mouna Elleuch[1], Mohamed Abid[1] & Nabila Rekik Majdoub[1]
[1]Hedi Chaker University Hospital, Department of Endocrinology; [2]University of Sfax, Laboratory of Molecular and Functional Genetics, Tunisia

Introduction
Obesity, in its common form, exhibits extreme genetic heterogeneity, and its mode of transmission remains unknown. To investigate the impact of the genetic component, we conducted an association study between polymorphisms of functional and positional candidate genes: Leptin and its receptor gene (LEP, LEPR), Melanocortin 4 Receptor (MC4R), FTO gene: Fat mass and associated obesity, and Pro-opiomelanocortin gene (POMC); with obesity and associated phenotypes (anthropometric and metabolic parameters, insulin levels, leptin levels, Homeostatic Model Assessment of Insulin Resistance HOMA-IR).
Materials and Methods
Our study included 50 patients from 5 Tunisian families affected by obesity and 52 controls from the Tunisian population. Genotyping of candidate gene single nucleotide polymorphisms (SNPs) was performed using PCR-RFLP and automatic sequencing. The association study was conducted using the Family-Based Association Test (FBAT).
Results
Statistical analysis of the genotyping results for different polymorphisms of the LEP gene showed that the SNPs (H1328084 A>G and +19 G>A), located in the 5' region of the gene, are associated with hyperleptinemia. In silico analyses demonstrated that these two polymorphisms could affect potential binding sites for certain transcription factors (c-Myb for A19G and NF-1 for H1328084) and consequently could play an important role in the regulation of plasma leptin levels. Regarding the LEPR gene, we found that the G allele of the c.A668G (Q223R) polymorphism is significantly associated with hyperinsulinemia and hyperleptinemia. Our results also showed that the RsaI variant of the POMC gene is associated with anthropometric parameters, plasma cholesterol levels, and blood pressure. Additionally, an association was detected with diastolic blood pressure and the Homeostatic Model Assessment of Insulin Resistance (HOMA-IR) for another 3'UTR polymorphism of the POMC gene (C8246T). Finally, no significant association was detected for the MC4R and FTO genes.
Discussion and Conclusion
The study of the genetic variability of the candidate genes in 5 Tunisian families confirms the association between the two functional leptin gene polymorphisms (H1328084 A/G and A19G) and the Q223R polymorphism of the leptin receptor gene LEPR with hormonal parameters. Only the C8246T polymorphism of the POMC gene seems to be associated with insulin resistance. A larger sample size study and inclusion of sporadic cases could better establish the impact of various genetic variants, particularly the MC4R and FTO genes.

EP63

Difference in impact of flash glucose monitoring in patients with type 1 diabetes mellitus and pancreatogenic diabetes

Ana Ortolá Buigues[1], Carla Valles Valverde[2], Emilia Gómez Hoyos[1], Rebeca Jiménez Sahagún[1], Juan José López Gómez[1], Beatriz Torres Torres[1], Esther Delgado García[1], Gonzalo Díaz Soto[1], Beatriz Ramos Bachiller[1] & Daniel de Luis Román[1]
[1]Hospital Clínico Universitario Valladolid; [2]Facultad de Medicina. Universidad de Valladolid

Introduction
Diabetes mellitus secondary to exocrine pancreas diseases (pancreatogenic DM) is a heterogeneous type of DM that usually requires treatment with multiple doses of insulin (MDI), like type 1 DM (DM1). Our objective was to evaluate the difference in the impact of Flash glucose monitoring (FGM) on glycemic control in pancreatogenic DM and DM1.
Methods
Prospective, observational study in Spanish hospital. We included the first patients with DM1 who started FGM from June 2019 to April 2020 and patients

with pancretogenic DM from January 2021 to June 2023, all on treatment with MDI. Patient data collected included demographic, clinical, anthropometric variables, as well as etiology, duration and treatment of DM. In addition, blood glucose control variables from the Abbott FreeStyle Libre the first 14 days and at 3 months were recorded: glucose management indicator (GMI), coefficient of variation (CV), percentage of time in range (TIR) (70-180 mg/dl), and hypoglycaemic events in 14 days.
Results
86 patients with DM1 vs 26 patients with pancreatogenic DM were included. Of DM1 61.6% were male vs 50% in pancreatogenic DM ($P=0.291$). Their age was 37.4 (SD 13.0) vs 59.7 (SD 16.4) years ($P<0.001$). DM duration was 18.1 (SD 11.3) vs 8.8 (SD 6.8) years ($P<0.001$). Total insulin dose/kg/day at the first visit was 0.62 (SD 0.20) vs 0.52 (SD 0.29) IU/kg/day ($P=0.045$). Of the pancreatogenic DM, 53.8% were secondary to pancreatectomy (26.9% total and 26.9% partial), and 30.8% due to chronic pancreatitis. In the first 2 weeks of FGM, there were no significant differences in the number of scans, TIR or GMI, in the two types of DM. There was a significant higher CV in DM1 patients [41.3 (SD 7.4) vs 31.7 (SD 5.7) $P<0.001$] and hypoglycemia events [13.5 (SD 9.1) vs 2.5 (SD 2.9) $P<0.001$] and their duration [95.7 (SD 44.9) vs 56.8 (SD 56.3) min, $P<0.001$]. At 3 months, there were only improvements in DM1 glucometry in decrease of hypoglycemia events [10.7 (SD 6.7) vs 13.5 (SD 9.1) $P=0.001$], with no changes in pancreatogenic DM. Regarding treatment, there was no change at 3 months in DM1, while in pancreatogenic DM an increase in bolus insulin use was observed [13.9 (SD 9.5) vs 11.0 (SD 7.1) IU/day, $P=0.009$], with no change in basal insulin.
Conclusion
Pancreatogenic DM patients have lower risk of hypoglycemia than DM1 patients, and the decrease in hypoglycemia events described in DM1s with GMF is not observed in them.

Progressive hyperparathyroidism post simultaneous pancreas-kidney transplantation in a long-term type 1 diabetes mellitus remission patient

Alexandra Zueva[1,2]
[1]Endocrinology Research Center, Moscow, Russian Federation; [2]The University of Sheffield, Sheffield, United Kingdom

Background
Simultaneous pancreas-kidney transplantation is an effective intervention for selected patients with insulin-dependent diabetes and end-stage chronic kidney disease (CKD), offering freedom from dialysis, insulin injections, and daily blood glucose monitoring. However, limited data exists on the impact of CKD complications on patient survival post-transplantation.
Case Presentation
A 58-year-old woman with Type 1 Diabetes (T1D) diagnosed in 1987 at the age of 22, end-stage CKD diagnosed in 2006, who underwent simultaneous pancreas-kidney transplantation in 2014, presented to our clinic for an annual check-up. It was known from her medical history that the patient had developed multiple diabetic complications such as diabetic kidney disease, diabetic retinopathy, and diabetes-related foot disease as a result of poor early glycemic control. Additionally, severe osteoporosis has developed since 2010 due to secondary hyperparathyroidism (HPT), treated with denosumab and cinacalcet. In 2022, she was diagnosed with tertiary HPT based on ultrasound signs of parathyroid glands hyperplasia, a decrease of bone mineral density (BMD), and multiple vertebral fractures on X-ray, although surgical intervention was not pursued, and alfacalcidol was added. A primary laboratory survey performed in our clinic showed HbA1c at 6.4%, C-peptide at 1.95 ng/ml, and normoglycemia without insulin. Under this treatment, creatinine clearance measured 49 mL/min, PTH and corrected total serum calcium remained within the normal range. While both transplants function appeared satisfactory, BMD remained stable since 2022 without any improvement despite treatment. Ophthalmic examination revealed no progression of retinopathy. Considering the limited impact of nonsurgical HPT treatment on skeletal health, parathyroidectomy was recommended.
Conclusions
This case highlights a nine-year remission period following successful simultaneous pancreas-kidney transplantation in a T1D patient. However, it also underscores the progressive nature of complications post-transplantation, necessitating careful monitoring and timely intervention to prevent further complications.

Prevalence and risk factors for steatosis and liver fibrosis measured by magnetic resonance elastography in adults with cystic fibrosis-related diabetes

Ana Piñar Gutiérrez, Silvia García Rey, María del Carmen Roque Cuéllar, Andrés Jiménez Sánchez, Ángeles Pizarro, Esther Quintana Gallego, Francisco Javier Castell, Manuel Romero-Gomez, Alfonso Soto & Pedro Pablo Garcia-Luna
Virgen del Rocío University Hospital, Sevilla, Spain

Introduction
Cystic fibrosis-related diabetes (CFRD) has a prevalence of 40-50% in adults. Given what we know about metabolic liver disease, studies are needed to assess whether CFRD is also related to steatosis (LS) and liver fibrosis (LF).
Objectives
To determine the prevalence of LS and LF by magnetic resonance elastography (Mre) in a cohort of adults with CFRD. Secondary: to determine the diagnostic yield of transitional elastography (Fibroscan®) and the factors associated with both entities.
Methods
Cross-sectional study of adults with CFRD in a multidisciplinary unit. Clinical evaluation, morphofunctional assessment, MRe, transitional elastography and noninvasive markers were performed. Quantitative variables are expressed as n(%); qualitative variables as P50(P25-P75). Diagnostic accuracy tests were performed. Logistic regression was performed to study risk factors.
Results
$n=28$. Women$n=15(53.6\%)$. Age$=34(28.7\text{-}40.5)$years. Time of evolution$=28(19.5\text{-}34)$years. Malnutrition(GLIM)$=15(53.6\%)$. Exocrine pancreatic insufficiency$=26(92.9\%)$. BMI$=23.2(19.7\text{-}24.5)$kg/m^2. Insulin treatment$=20(71.4\%)$. The prevalence of LS was 25% and of LF 32.1%. In Fibroscan® it was 28.6% (71.4% sensitivity and 85.7% specificity) and 17.9% (55.5% sensitivity and 100% specificity) respectively. The AUROC of the Fibroscan® was 0.915(0.81-1) in HD and 0.936(0.838-1) in FH. We did not find any factors associated with LS. Those associated with LF are shown in the Table. Multivariate analysis could not be performed due to the low sample size.
Conclusions
This is the first study of LS and LF in adults with CFRD performed with MRe. The prevalence was 25% and 31.1% respectively. FibroScan® demonstrated excellent diagnostic accuracy. Alterations in blood count and transaminases, as well as fat-soluble vitamin deficiencies seem to be associated with increased risk of LF.

Enavogliflozin, an sglt2 inhibitor, improves nonalcoholic steatohepatitis induced by high-fat high-cholesterol diet

Heesung Kim[1], Haein Hwang[1], Thi Minh Phuc Pham[2], Seon Mee Kang[3] & Eun-Hee Cho[3]
[1]Kangwon National University Hospital, Internal medicine, chuncheon, Korea, Rep. of South; [2]Kangwon National University, chuncheon, Korea, Rep. of South; [3]Kangwon National University Hospital, Endocrinology, chuncheon, Korea, Rep. of South

Objective
Non-alcoholic fatty liver disease (NAFLD) is a progressive disease caused by a build-up of fat in the liver and onsets with simple steatosis, potentially advancing to non-alcoholic steatohepatitis (NASH) in the presence of inflammation and fibrosis, severely leading to cirrhosis or hepatocellular carcinoma. There is increasing cumulative evidence indicating that sodium-glucose cotransport 2 (SGLT2) inhibitor agents efficaciously alleviate NASH in a novel mouse model, but there is no study mentioning the effect of Enavogliflozin on liver disease. Consequently, in this present study, we investigated the impact of this sodium-glucose cotransport 2 inhibitor on high-fat high-cholesterol diet (HFHCD)-induced NASH mice.

Methods
Male C57BL/6 mice were fed a chow diet, HFHCD, or HFHCD with Enavogliflozin for 12 weeks. Enavogliflozin was administered at a dose of 1.28 mg/kg/day in these experiments. *In vitro*, human hepatic stellate cells (LX-2 cells) were treated with transforming growth factor beta 1 (TGF-β1) in the presence or absence of Enavogliflozin.
Results
HFHCD induced excessive hepatic lipid accumulation, immune cell infiltration, and severe fibrosis. Enavogliflozin administration not only ameliorated hepatic steatosis and fibrotic condition but also suppressed the production of inflammatory cytokines (IL-6, IL-1β). In the *in vitro* study, in addition to decreasing SGLT2 expression induced by TGF-β1, enavogliflozin inhibited hepatic stellate cell activation by reducing proliferation, wound healing migration, and suppressing the expression of αSMA.
Conclusion
Our results suggest that enavogliflozin shows efficacy in a mouse model of NASH and liver fibrosis by attenuating hepatic steatosis, suppressing inflammation, and inhibiting hepatic stellate cell activation *in vitro*.

Assessment of dietary patterns in patients with type 2 diabetes mellitus and different expressed insulin resistance
Diana Simoniene
Lithuanian University of Health Sciences, Endocrinology, Kaunas, Lithuania

What factors contribute to the development and progression of insulin resistance in diabetes is not fully understood.
The aim was to evaluate the intake of carbohydrates, vegetables and meat intake according to sex, age, BMI, duration of diabetes, diabetes complications and HOMA - IR scores in the groups with different IR.
Methods
This was a case-control study. Total of 122 subjects were enrolled. Subjects matched by age and sex were divided into two groups. Subjects with high insulin doses (> 1–2 IU/kg/day) and poor diabetes control (HbA1c > 9%) were referred to the case group (60 participants). Subjects with low insulin requirement (< 1 IU/kg/day) and HbA1c < 8 % were referred to control group. Usual dietary intake was assessed by using semiquantitative FFQ (unique, created by study author). Participants were asked to report their frequency of consumption of a given serving of each food item during the previous month on a daily basis.
Results
A significantly higher proportion of control group subjects consumed slow-release carbohydrates (≥ 2 times per week) and had a lower HOMA-IR < 10 (70.6%), compared with the case group subjects, who consumed more fast-acting carbs and had a high HOMA-IR ≥ 10 (29.4%) ($P=0.041$). Younger than 60 years case group participants consumed vegetables less frequently than control subjects (61.9% in the case group vs 100% in the control group, $P = 0.043$). Case group women (82.1%, $P=0.033$), subjects over 60 years (85.3%, $P=0.020$) and subjects with diabetes duration >10 years (84.8%, $P=0.017$) consumed red meat more often than 1 time per week. Irrespective of BMI, subjects in the control group were statistically significantly more likely to report no or infrequent intake of the red meat (16.1% vs. 3.6% in the case group, $P=0.006$). A higher proportion of subjects who rarely ate red meat (less than 1 time a week) had no diabetes complications (33.3%) compared to 8.6% of subjects who rarely ate red meat and had diabetes complications ($P=0.051$).
Conclusions
Subjects who frequently consumed slow carbohydrates were more likely to have lower HOMA-IR. Vegetables were less frequently consumed by case group subjects, younger than 60 years. Red meat was consumed more frequently by female, subjects over 60 years, obese and long diabetes duration subjects. The rate of chronic diabetes complications was lower in subjects who consumed red meat less than 1 time a week.

Painful diabetic peripheral neuropathy among Tunisian geriatric patients suffering from diabetes mellitus
Dhoha Ben Salah, Mariem Abdelmouleh, Siddiqa Soomauroo, Mona Elleuch, Khouloud Boujelben, Faten Hadjkacem, Nadia Charfi, Fatma Mnif, Mouna Mnif, Mohamed Abid & Nabila Rekik
Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Introduction
Distal and symmetrical peripheral polyneuropathy is the most frequent type of diabetic neuropathy. Its painful form (PDN) is the most common cause of non-traumatic neuropathic pain and can place a heavy burden on elderly patients' lives. Despite the major impact that it can have on the quality of life, PDN is generally underdiagnosed because of a large interindividual variability of symptoms and in the absence of well-established diagnostic criteria.
Aim
To determine the prevalence of PDN and to identify the different risk factors of its occurrence within Tunisian geriatric patients.
Methods
This was a cross-sectional study conducted in the endocrinology-diabetology department of Hedi Chaker hospital Sfax Tunisia, in which we collected elderly patients with diabetes. The DN4 Questionnaire was used to diagnose PDN.
Results
A total of 52 elderly patients were recruited. The mean age of patients was 70.6 years with a slight female predominance (55.8% Vs 44.2%). All the patients had type 2 diabetes. The mean duration of diabetes' evolution was 13.54 years. The average of HbA1c level was 10.35%. Among diabetes' complications, PDN was the most frequent in our study (53.8%). The mean DN4 score was 3.83. Significant predictors of PDN included long history of diabetes ($P=0.04$), high levels of glycated hemoglobin (HbA1c) ($P=0.04$) and insulin therapy within type 2 diabetic patients ($P=0.029$), in addition to some comorbidities such as sweating disorders and history of leg ulcer. Some features of foot examination were also found to be risk factors of PDN namely trophic disorders ($P=0.05$), dry skin ($P=0.004$), hyperkeratosis ($P<0.001$), abolition of Achilles reflexes ($P<0.001$) and positive monofilament test ($P<0.005$).
Conclusion
The present study demonstrated that the prevalence of PDN is high among our geriatric population. This emphasizes the need to screen periodically diabetic elderly patients using a simple instrument such as the DN4 questionnaire and to educate at risk patients about predictors of PDN regularly.

Analysis of the work of the office of diabetic foot care "minsk city clinical endocrinilogy center" for 2019-2023
Hanna Bliznets, Volha Shyshko, Inesa Pukita & Alena Yurenia
Minsk City Clinical Endocrinology Center, Minsk, Belarus

Objectives
Analysis of the work of the diabetic foot office (DFO), the number of amputations and the causes that led to this complication of diabetic foot syndrome (DFS) underlies the development of preventive measures that help to reduce the level of disability and lethality, which is an urgent and socially significant medical problem.
Objective
To study the indicators characterizing the provision of medical care to patients with diabetes and lower limb lesions in Minsk from 2019 to 2023 and the relationship of these indicators with the developed regulatory documentation determining the optimal routing of this group of patients.
Materials and Methods
Annual reports were analyzed according to the database of the "Diabetic Foot" department of the health care institution "Minsk City Clinical Endocrinology Center" (MCCEC). Indicators for 2019-2023 of adult patients with diabetes were evaluated.
Results
After implementation of a regulatory document defining the sequence of patient referral and routing the number of patients per year admitted to the MCCEC increased from 6883 in 2019 to 7633 in 2023. The percentage of patients initially admitted with DFS in 2019 was 19% and increased to 35.7% in 2023. There is a decrease in high amputations: at the hip level from 17.9% in 2019 to 15.2% in 2023, at the tibial level from 10.5% in 2019 to 8.9% in 2023. There is a gradual increase in the percentage of finger-level amputations from 61% in 2019 to 67% in 2023.
Conclusions
The analysis of statistics of specialized care for patients with DFS for 5 years has shown that the development of thematic documents and optimization of patient routing significantly increase the capacity of specialized care, which leads to early

detection of patients with DFS, and as a result - a decrease in the frequency of high amputations, which may reflect the improvement of the quality of patient management by endocrinologists and surgeons at the outpatient stage, and increase the effectiveness of prevention of lower limb lesions.

Mitochondrial diabetes in relation to 40 patients from 30 tunisian families: phenotypic and genotypic heterogeneity

Hamdi Frikha, Yesmine Elloumi, Souhir Maalej, Khouloud Boujelben, Dhoha Ben Salah, Faten Haj Kacem Akid, fatma mnif, nadia charfi, mouna mnif, mouna elleuch, Mohamed Abid & Nabila Rekik Majdoub
Hedi Chaker University Hospital, Department of Endocrinology, Tunisia

Introduction
Mitochondrial diabetes (MD) is characterized by a wide spectrum of phenotypic and genotypic manifestations. Through a cohort study of 40 patients with MD, we attempted to establish a correlation between this diversity of phenotypic expression and the biomolecular substrate of the mitochondrial genome within the Tunisian population.
Results
Epidemiologically and anthropometrically, our series aligns with literature data, with an onset age of 31.6 years (5-52), a female predominance (82.5%), and a normal BMI in 60% of cases. Diabetes had a MIDD2 phenotype in % of cases, with a significantly higher frequency of diabetic retinopathy (42.5%) compared to 8-13% in the literature. Regarding extra-pancreatic manifestations, the reticulated macular dystrophy, highly characteristic of MD, was absent in all our patients, as well as retinitis pigmentosa (15% vs 57-86%). Perceptive deafness, classically almost constant, was present in only half of the cases. Dilated cardiomyopathy was found in only one case vs 18-34% in the literature. The biomolecular study of the mitochondrial genome revealed the absence of the most frequently described mutation associated with MD: m.3243A>G (tRNA Leu). This led us to investigate the m.14709T>C (tRNA Glu) mutation, found in 6 patients from 3 different families; however, the study of heteroplasmy levels within 2 families did not reveal a correlation with the phenotypic spectrum. Moreover, whole mitochondrial genome sequencing revealed other polymorphisms not described in the literature, playing a key role in the functioning of the mitochondrial respiratory chain.
Conclusion
Our cohort is characterized by phenotypic and genotypic heterogeneity within a sample of the Tunisian population. It appears that the m.3243A>G mutation is not specific to our Tunisian population, and the m.14709T>C mutation was more frequent. A larger-scale study is necessary to establish the impact of heteroplasmy levels on the phenotypic spectrum.

Impact of socio-economic status on glycemic control in type 2 diabetic patients: a study of 216 cases

Nabil Skouta, Nassim Essabah Haraj, Siham El aziz & Asma Chadli
UHC Ibn Rochd, Casablanca, Morocco, Department of Endocrinology, Diabetology and Metabolic Diseases, Casablanca

Introduction
Type 2 diabetes constitutes a major public health problem. In 2017, the International Diabetes Federation estimated that 425 million people worldwide suffer from diabetes, and by 2045, this number is projected to rise to 629 million.
Objectives
The aim of our study is to assess the impact of patient's socio-economic status (SES) on their glycemic control.
Patients Et Methods
This is a descriptive cross-sectional study involving 216 type 2 diabetic patients, followed in the Diabetology department at Ibn Rochd University Hospital in Casablanca from March 2023 to November 2023. The classification used for socio-economic status is provided by the High commission for planning of Morocco: Low SES (income < 350$/month), Moderate SES (income between 350-2300$/month), High SES (income > 2300$/month). Data were collected using an exploitation form and analyzed using IBM SPSS Statistics 27.0.
Results
Our study included 216 patients with a mean age of 59 years and a M/F ratio of 2.48. The average duration of diabetes was 13 years. Regarding cardiovascular risk factors, 67% were hypertensive, 39% were obese, 41% had dyslipidemia, and 13% had toxic habits. Ischemic heart disease and peripheral arterial disease were found in 15% and 16% of cases, respectively, while retinopathy and diabetic nephropathy were present in 54% and 20% of cases, respectively. In our series, 20% of patients had a moderate SES with an average HbA1c of 7.02%, while 80% had a low SES with an average HbA1c of 11.25%. The mean difference in HbA1c levels between low and moderate SES individuals was 4.22% (95% CI 3.83;4.61) ($P < 0.0001$).
Conclusion
Our study indicates that socio-economic status influences the stability of individuals with type 2 diabetes. Individuals with a higher socio-economic status face fewer challenges in adhering to treatments such as GLP-1 agonists, SGLT2 inhibitors, or the latest-generation insulins, which are costly but more effective.

DOI: 10.1530/endoabs.99.EP73

EP74

Predictors of carbohydrate metabolism disorders within 1 year after COVID-19

Zilya Kalmykova, Marina Shestakova, Irina Kononenko & Natalia Mokrysheva
Endocrinology Research Centre, Moskva, Russian Federation

Background
The potential impact of SARS-CoV-2 on glucose metabolism has been discussed since the first days of the COVID-19 pandemic, and now has been confirmed by research results and clinical practice data about new-onset carbohydrate metabolism disorders after COVID-19. Determining the predictors of their development will help to determine the best treatment tactics.
Aim
To determine predictors of carbohydrate metabolism disorders within 1 year after COVID-19.
Materials and methods
We included consecutive patients hospitalized with viral pneumonia caused by COVID-19. All underwent a clinical and laboratory examination, including assessment of carbohydrate metabolism indicators (blood glucose on admission, fasting plasma glucose, HbA1c, proinsulin, insulin, C-peptide, HOMA-IR). The prospective part of the study included patients without previous history of diabetes mellitus, who had HbA1c > 6.0% during the acute period of the COVID-19. In this group, patients underwent an oral glucose tolerance test (OGTT) 6-8 weeks and 1 year after discharge. In patients, which developed prediabetes and diabetes after COVID-19, we performed a comparative analysis of clinical and laboratory parameters.
Results
We included 155 hospitalized patients with acute phase of COVID-19: median age 59 years [47;72], male/female ratio (%) - 49,4/50,6, BMI – 28,9 kg/m2 [25,4;32,9]. Among these patients, 55 had elevated HbA1c values without previous DM history: HbA1c 6,1-6,4% - 36 patients, HbA1c ≥ 6,5% - 27 patients. During the follow-up 1 year after COVID-19, 33 patients were lost to follow-up, 12 patients developed carbohydrate metabolism disorders, and 10 were euglycemic. We found differences in baseline proinsulin levels between groups with and without carbohydrate metabolism disorders on follow-up: 0,58 mIU/l [0,26; 0,94] and 1,16 mIU/l [0,98; 2,47], respectively ($P < 0,001$). AUC for baseline proinsulin levels estimated 0,906 (95% CI, 0.784-1.000, $P < 0.001$), with cut-off 1,10 mIU/l to distinguish patients with/without carbohydrate metabolism disorders at follow-up. The model had acceptable NPV, 93,8% (83,5%- 99,6%), however, PPV was low, 54,4% (14,1%- 77,2%).
Conclusion
Baseline proinsulin levels with a cut-off at 1,10 mIU/l could be potential predictor of long-term carbohydrate metabolism disorders in patients without previous DM history after COVID-19. However, further studies with extended groups and longer follow-up are needed to confirm this finding.

EP75

Fournier's gangrene in diabetic women: 2 case reports

Ilham Midhat, Mennani Fatimaeezzahra, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Centre Hospitalo-Universitaire Mohammed Vi Marrakech, Endocrinology, Marrakech, Morocco

Introduction
Fournier's gangrene is a rare and serious poly-microbial necrotizing fasciitis of the perineum and external genitalia, characterized by a fulminant evolution and a high morbidity and mortality. Annual incidence is between 1.6 and 3.3 cases/100,000 patients, with type 2 diabetics accounting for 30% to over 50% of cases, and 66% in women.
Observations
Case 1: 48-year-old female, diabetic for 8 years on Metformin, admitted for diabetic ketosis on Fournier's gangrene, revealed by a swelling associated with pain in the perianal and gluteal region, rapidly complicated by perianal necrosis extending to the left thigh, evolving for 7 days in a context of fever quantified at 39°c. Biological work-up revealed a frank infectious syndrome with Enterococcus Feacalis on pus sampling.
Case 2: Patient aged 43, admitted for diabetic ketoacidosis inaugurated by Fournier's gangrene, revealed by an ulcerated lesion in the left perianal area 4 months previously. The lesion was manipulated, and rapidly spread to the left buttock area, evolving in a context of fever at 39.4°c. Biological tests revealed a frank infectious syndrome with Streptococcus Agalactiae in the pus sample. Both patients received triple broad-spectrum probabilistic antibiotic therapy, then adapted to the antibiogram, and underwent immediate broad-spectrum surgical debridement with insulin initiation followed by intensification. The average hospital stay was 20 days. One patient had a favorable outcome after a stay in intensive care, with good progress in directed healing. After stabilization, patients received therapeutic education on the need for hygiene and early consultation in the event of any injury to the perineal region.
Discussion and conclusion
Necrotizing skin and soft-tissue infections are characterized by rapid, deep-seated spread along the fascia and destruction of the skin, hypodermis and muscles. Clinical presentations vary according to the location and extent of lesions, the bacteria involved and predisposing factors linked to the infected subjects. They may be monomicrobial (especially streptococci/staphylococci) or polymicrobial. Fournier's gangrene most often occurs in an immunocompromised environment: diabetes (40-60% of cases), alcoholism, malnutrition and poor sanitary conditions are frequent predisposing factors, as are immune deficiencies: chemotherapy, AIDS, advanced age.... Women are affected much more rarely, and the starting point of the disease is often gynecological. Treatment must be initiated urgently, based on broad-spectrum antibiotic therapy, hemodynamic stabilization measures and, above all, rapid surgical cure by debridement and radical excision of necrotic tissue, in order to reduce the still high mortality rate, as well as aesthetic and functional sequelae.

Complications and metabolic control in adults with diabetes aged 16-25 years old

Francisca Leitão[1], Sae Zambre[2], Lucy Du[2], Maria Carlos Cordeiro[1] & Ana Quitalo
[1]Hospital Garcia de Orta; [2]Translational Research Institute

Introduction
Diabetes mellitus (DM) is a chronic disease with increasing incidence worldwide, mostly in younger ages. Diabetic kidney disease (DKD) is a main complication, with a prevalence of 20-40%, associated with high cardiovascular mortality. Despite the association of type 2 diabetes (T2D) in young adults with rapid progression to DKD, in type 1 diabetes (T1D) this is not well established. Other complications have also a high impact on life quality.
Objective
Evaluate the difference in the metabolic control and incidence of complications associated with T1D and T2D in young adults.
Methods
Retrospective cohort study including all cases of patients with DM aged 16 to 25 who attended MYAHC (Mater Young Adult Health Centre, Brisbane), between 2016-2020. Cases with less than 2 GFR measurements were excluded. Values of glycated haemoglobin (HgA1c) were collected.
Results
Were analysed 576 patients, 548 with T1D and 28 with T2D. In total, 59% were female, the mean age at first visit was 19.3 and the median time since diagnosis was 16 years. CKD of diabetic aetiology was found in 14.4% of T1D group, 2 of them with ESKD (0.3%), compared with 71.4% in T2D group, none with end-stage kidney disease (ESKD). Cases of CKD of another aetiology were found only in T2D group (10.7%). GFR was lower than 90 ml/min/1.73 m^2 in 19.9% of T1D group, compared to 7.1% in T2D group. GFR below 60ml/min/1.73 m^2 was only found in 0.7% of T1D group. Overall, the decrease in GFR per year was an average of 2.11 ml/min/1.73 m^2 in T1D group compared to 0.98 ml/min/1.73 m^2 in T2D group. For other chronic complications: peripheral neuropathy was found only in T1D group (3.1%); 12.2% of T1D presented with retinopathy compared to 7.1% in T2D group; autonomic neuropathy was present in 64.3% of T2D group, compared with 2.2% in T1D group. Better metabolic control was noted in T2D, with a HgA1c of 7.2 compared to 7.8 in T1D group.
Conclusion
Regardless higher incidence of DKD in the T2D group, there was higher incidence of ESRD along with greater decline in eGFR/year in T1D group. Also, overall incidence of other complications was higher in T1D. Although these can possibly be explained by the small number of young people diagnosed with T2D, these results suggests that the progression rate towards DKD is higher and more abrupt in young adults with T1D. Better metabolic control in T2D reinforces the importance of intensive treatment in T1D.

Common disease rare complication: diabetic myonecrosis

Selin Çetin[1], Alperen Onur İşler[2], Büşra Torun Alp[1], Adalet Elçin Yıldız[3], Tolga Yıldırım[4] & Uğur Ünlütürk[2]
[1]Hacettepe University School of Medicine, Department of Internal Medicine, Ankara, Turkey; [2]Hacettepe University School of Medicine, Division of Endocrinology and Metabolism, Department of Internal Medicine, Ankara, Turkey; [3]Hacettepe University School of Medicine, Department of Radiology, Ankara, Turkey; [4]Hacettepe University School of Medicine, Division of Nephrology, Department of Internal Medicine, Ankara, Turkey

Background
Diabetic myonecrosis is a rare complication associated particularly with prolonged dysregulation of blood glucose in diabetes. While the exact pathophysiology remains not fully understood, it is suggested that atherosclerosis, diabetic microangiopathy, vasculitis, ischemia-reperfusion injury and hypercoagulability might contribute to this condition. Diabetic nephropathy is the most blamed risk factor. Here, we present a case of diabetic myonecrosis followed up after renal transplantation due to diabetic nephropathy.
Case Presentation
A 40-year-old female patient with known type 1 diabetes, situs inversus and hypertension, who had a kidney transplant from a living donor due to diabetic nephropathy, was admitted to the internal medicine clinic due to progressive decrease in glomerular filtration rate (9 ml/dk). She had uncontrolled type 1 diabetes for 30 years with retinopathy, neuropathy, hypertension and nephropathy leading to ESRD. She had a diabetic foot arthroplasty in her history. HbA1c value was 11.7%. One week before the patient's admission, she developed swelling, pain, and restricted mobility in the upper left thigh. The findings were significant in terms of infectious-inflammatory processes. WBC was $14.54 \times 10^3/\mu L$ (4.49-12.68×10^3), sedimentation rate was 15 mm/hour (0-25), CRP was 17.9 mg/l ($<$ 0.5) creatine kinase total was 58 U/l ($<$145) in laboratory examination. A lower extremity Doppler ultrasound was performed and didn't reveal any evidence of deep vein thrombosis (DVT). The skin ultrasound result showed edematous changes and thickening in the subcutaneous tissue of the symptomatic area with no significant drainable abscess or collection detected. In a contrast-free MRI imaging performed for differential diagnosis, myositis and fascial edema were observed in the vastus medialis and intermedius muscles on the left, along with a focal area suggesting necrosis within the vastus medialis. MRI findings indicated diabetic myonecrosis. During this period, blood glucose control was achieved with insulin glargine and insulin aspart. In the treatment of diabetic myonecrosis, bed rest and elevation of the extremity were applied. NSAIDs could not be given because her kidney functions were impaired. Oxycodone 10 mg/day was given for pain palliation. The patient's complaints and symptoms regressed in 15 days.
Conclusions
Despite diabetes being a common disease, diabetic myonecrosis is an uncommon and challenging complication to diagnose. In the diabetic patients especially who have diabetic nephropathy, in situations of sudden onset pain and swelling in the lower extremities, diabetic myonecrosis, should be considered in the differential diagnosis and MRI should be performed.

Analysis of glycated hemoglobin trajectories in chd patients with dm 2

Raisa Trigulova[1] & Shahnoza Mukhtarova[2,2]
[1]Republican Specialized Scientific and Practical Medical Center for Cardiology, Tashkent, Uzbekistan; [2]Tashkent Pediatric Medical Institute, Tashkent, The Republic of Uzbekistan, Tashkent

Introduction
The stability of glycated hemoglobin (HbA1c) as a key to the prevention of micro-and macrovascular complications continues to be discussed.
Purpose
to analyze the interrelations between HbAc trajectories and clinical and biochemical parameters in patients with CHD and DM 2.
Material and methods
130 patients with CAD and DM-2 aged 63.9±8.8 years. Therapy: DPP-4 inhibitors, GLP agonists. Groups: HbA1c <7.0 (n-27; A); 7.0<HbA1c<8.0 (n-25; B); HbA1c > 8.0 (n-78; C). 2 years of observation.
Results
In patients with unchanged HbA1c, there is an increase in vitamin D: with HbA1c<8, n-47 Δ 6.54 ng/ml, $P=0.003$; HbA1c>8.1, n-50 Δ 8.24 ng/ml, $P=0.004$. CRP and BNP in dynamics: HbA1c<8, n-47 Δ 4.18 ng/ml, $P=0.002$ and Δ 363.0 pg/ml, $P=0.01$, respectively. HbA1c > 8.1 CRP and BNP n-50 Δ 2.75 ng/ml, $P=0.02$ and Δ 432.2 pg/ml, $P=0.02$. A high content of UA is recorded in group C and Ć (with HbA1c > 8.1) ($P=0.02$). With HbA1c<8, there is a decrease in vitamin D 16.65[10.00-22.50] and a high BNP 2052.78 [1247.50-2977.50] pg/ml. A direct correlation was established between PPG and the metabolic index ($r=0.367$; $P=0.009$); vitamin D and BNP ($r=0.336$; $P=0.017$) and vitamin D with eGFR ($r=0.429$; $P=0.002$) in group C (HbA1c remained >8.1).
Conclusion
A two-year follow-up of HbA1c showed that alternating target values were recorded. Correlations of vitamin D in the blood (both deficiency and insufficiency) with high BNP in patients with HbA1>8.1 were revealed, which confirms the role of vitamin D in the progression of heart failure and renal dysfunction.

Resilience in patients with fabry disease and its association with disease course, psychosocial factors and quality of life: a multicentre cross-sectional study

Albina Nowak[1,2] & Yaroslav Winter[3]
[1]university Hospital Zurich, Endocrinology, Zurich, Switzerland; [2]University Hospital of Zürich, Zürich, Switzerland; [3]University Hospital Mainz, Neurology

Fabry disease (FD) is an X-linked lysosomal storage disorder originating from mutations in the GLA-gene causing deficiency in alpha-Galactosidase A (GLA) which leads to the accumulation of glycosphingolipids, particularly globotriaosylceramide (Gb3) and globotriaosylsphingosine (Lyso-Gb3). The classic phenotype is characterized by neuropathic pains and pain crises, anhidrosis, abdominal cramping. With advancing age, the disease leads to life-threatening complications such as renal dysfunction, left ventricular hypertrophy, hypertrophic cardiomyopathy or cryptogenic stroke. These debilitating symptoms are associated with depression and impaired quality of life. Resilience is known as an individual's ability of coping with stressors and is characterized as high self-esteem, optimism and self-efficacy. Resilience enhancement programmes were shown to have a benefit on resilience, depression, anxiety and quality of life. 122 genetically confirmed FD patients from the university hospitals of Zurich Switzerland and Mainz Germany completed self-report questionnaires Resilience Scale 11 (RS-11), Beck Depression Inventory (BDI), Pain Disability Index (PDI), Pittsburgh Sleep Quality Index (PSQI), Trierer Inventory for Chronic (TICS-SSCS). Women indicated higher resilience scores than men (59 ± 14.4 vs 54.4 ± 19.2) and patients without enzyme replacement therapy (ERT) higher than on ERT (64.5 ± 15.9 vs 55.8 ± 16.5). Among females, resilience was higher if the FD diagnose was made at younger age ($r=-0.40$, $P=0.02$), while resilience declined with increasing age ($r=-0.26$, $P=0.04$). More symptomatic patients showed lower resilience scores ($r=-0.24$, $P=0.01$). The RS-11 showed a significant adverse correlation with BDI ($r=-0.59$; $P=0.001$), PDI ($r=-0.31$, $P=0.006$), PSQI ($r=-0.53$, $P=0.001$) and TICS-SSCS ($r=-0.42$, $P=0.001$). Our analyses show that impaired resilience is associated with depression, pains, poor sleep and chronic stress. All these factors are modifiable and treatable. Importantly, resilience enhancement programs should be offered to Fabry patients.

Association between eating behavior and post-operative diabetes mellitus remission

Paula Sprovera, Carolina Monteiro Antunes, Maria Leonor Guia Lopes, Margarida Oliveira, Catarina Gama, Bruna Pimentel, Catarina Saraiva & João Manuel Sequeira Duarte
Egas Moniz Hospital, Endocrinology, diabetes and metabolism, Lisbon, Portugal

Introduction
Type 2 Diabetes Mellitus (DM2) remission after bariatric surgery can be achieved in 72% of cases. This mechanism is not fully dilucidated; however, it could be caused by the action of glucose direct deposit in the jejunum.
Objective
To assess the preoperative eating behavior impact in postoperative DM2 remission.
Materials and methods
A retrospective chart review among obese and type 2 diabetic patients that underwent bariatric surgery in a tertiary hospital center. Preoperative BMI and eating behavior were evaluated, as well as postoperative diabetes status and BMI.
Results
A total of 198 patients underwent bariatric surgery, of which 128 presented an altered glucose metabolism, corresponding to 64 cases of DM2 and 64 pre-diabetic patients. Most diabetic patients were women (78%), with initial mean weight of 114.7 kg, while male patients presented 154.5 kg. The mean BMI was 42.1 kg/m2 and 49 kg/m^2, respectively. In the eating behavior evaluation, 28% of the diabetic patients were classified as 'volume-eater', 15.6% as 'sweet-eater' and 6.25% as 'snack-eater'. Half of the sample presented a mixed-pattern eating behavior, being the most frequent combination the 'Volume-sweet-eater' mixture. Most diabetic patients (71.8%) underwent a gastric bypass (GBP) and 28.2% underwent a vertical sleeve gastrectomy (VSG). In the GBP group, 46% of patients achieved diabetic remission at 5 years of assessment and there were no cases of remission in the VSG group. The eating behavior that presented most cases of remission was the 'volume-sweet-eater' pattern with 100% of cases of normoglycemia after bariatric surgery ($P=0.004$). The other patterns did not present statistically significant remission.
Conclusion
It seems that therés an association between the 'volume-sweet-eater' behavior and post-operative DM2 remission.

Exogenous insulin antibodies syndrome: challenges in management

Sahar Abidi, Manel Jemel, Emna Naccache, Marwa Chiboub & ines Kammoun
Departement of Endocrinology, National Institute of Nutrition, Tunis, Tunisia

Introduction
Exogenous insulin antibodies syndrome (EIAS) is a clinical syndrome associated with insulin antibodies induced by exogenous insulin in diabetic patients. It represents a rare cause of hyperinsulinemic hypoglycemia and glycemic instability. The management of EIAS remains a challenge.
Case presentation
We present the case of a 12-year-old female with type 1 diabetes for 6 years treated with insulin analogues (Glrargen and Aspart). She experienced significant glycemic instability, leading to frequent hospitalizations for diabetic ketosis and ketoacidosis with no apparent cause, resulting in an average HbA1c of 14%. Her mother reported discontinuation of rapid insulin due to recurrent hypoglycemia. The patient weighed 32 kg, had a height of 145 cm (-2DS), and investigations revealed an isolated growth hormone deficiency. The anti-exogenous insulin antibody titer was elevated at 24 UI/ml (VN <0.4). Treatment with a high dose of corticosteroids (30g of prednisolone) resulted in a favorable response, marked by a significant improvement in glucose stability and no unexplained hypoglycemia. Corticosteroids were maintained for 4 months and then gradually tapered. However, after discontinuation, a recurrence of glycemic instability was observed.
Discussion
EIAS typically manifests months or years after initiating insulin treatment and can affect both type I and II diabetes patients. It is a rare cause of glycemic instability, characterized by daytime hyperglycemia due to insulin uptake by anti-insulin antibodies and nocturnal hypoglycemia due to insulin release. The initial treatment of EIAS involves glucocorticoids. In our case, we initiated treatment with 2 UI/kg of prednisolone for 4 months, with a gradual dose reduction. The

literature suggests alternative treatments, including oral or IV immunosuppression such as mycophenolate mofetil, cyclophosphamide, and azathioprine, although outcomes vary. Plasmapheresis can serve as effective therapy in patients who are refractory to other therapeutic modalities based on the results of literature review and case reports.
Conclusions
EIAS should be considered in T1D patients with unexplained glycemic instability and hypoglycemia. The laboratory plays an integral diagnostic role. The management of EIAS is poorly codified. Longer-term follow-up is necessary, as recurrence is classic in this type of pathology

EP101

Side effects of mesenchymal stem cell transplantation in type 1 diabetics department of endocrinology, diabetology, metabolic

Mennani Fatima Ezzahra, Sana Rafi, Ghizlane EL Mghari & Nawal EL Ansari
Centre Hospitalo-Universitaire Mohammed VI Marrakech, Endocrinolgy, Marrakech

Introduction
According to numerous studies, mesenchymal stem cell therapy is one of the best therapeutic approaches for the treatment of type 1 diabetes. The aim of our study is to provide an update on the contribution of mesenchymal stem cells to glycaemic control and the screening of short-and long-term side effects.
Results
We included 5 patients who met our inclusion criteria. The mean age was 21.2 years, with a sex ratio of 0.6. The average duration of diabetes in our patients was 2 years and 3 months. Minor incidents in the immediate postoperative period were nausea and vomiting in 30% of patients, pain at the sampling site in 10%, and no patient presented a major incident in the immediate postoperative period. In terms of glycaemia: GAJ and GPP fell from 1.63 and 2.01 pre-transplant to 1.28 and 1.52 respectively after 18 months post-transplant, the mean daily dose of basal insulin fell from 0.46 IU/Kg/d pre-transplant to 0. 37 IU/Kg/d after 18 months' follow-up, for rapid insulin requirements fell from 17.5 IU/d pre-transplant to 11.5 IU/d, and marked weight gain was observed in 40% of patients after 18 months' post-transplant follow-up.
Discussion
Dave and trivedi published in 2013 their results of post-MSC transplant follow-up in 2 T1DM patients, insulin requirements reduced from 64 and 56 IU/day to 18 and 22 IU/day after 23 months of follow-up, HbA1c levels reduced from 9.1%, to 6.3% in the 1st patient and 12.4%, to 6.8% in the 2nd patient, without any side effects. Another review published in China in March 2022 by Xin Xing Wan showed that stem cell transplantation had beneficial effects in newly diagnosed type 1 diabetics, with no obvious adverse effects.
Conclusions
Mesenchymal stem cells represent an avenue for the future that will open up new therapeutic prospects in T1DM because of their immunomodulatory properties, ease of isolation, abundance and safety of use.

EP104

Quality of life of patients with diabetes type 1 and type 2 in the conditions of military conflict

Oksana Khyzhnyak, Miroslava Mykytyk & Urii Karachentsev
V. Danilevsky' Institute of Endocrine Pathology Problems, Clinical Endocrinology, Kharkiv, Ukraine

The military conflict in Ukraine triggered the internal migration of millions of Ukrainians. Internally displaced persons (IDPs) and residents of territorial communities (RTCs) located in zones of war with Diabetes mellitus (DM) are at high risk of developing post-traumatic stress disorder (PTSD), anxiety and depression.
The aim of the study was to assess the health-related quality of life (HRQoL) of patients with DM type 1 (DM T1) and type 2 (DM T2) in the context of military conflict.
Materials and methods
26 patients with DMT1 ((34.7 $\pm$ 8.79) yrs, disease duration (DD) (11.0 $\pm$ 10.5) yrs) and 65 patients with DMT2 ((56.5 $\pm$ 10.79) yrs, DD (6.9 $\pm$ 5.1) yrs) were examined. 43.9% ($n=40$) were IDPs and 56.1% ($n=51$) RTCs located in the war zone. The Ukrainian-language version of the "SF-36®Health Survey" questionnaire was used to assess the health care system. Subjective feelings of patients were analyzed using the HADS Hospital Anxiety and Depression Assessment Scale. Statistical processing of the results was performed using Package for Social Sciences v.16.0 (SPSS Inc, Chicago, Il, USA).
Results and discussion
It was found that the physical activity of patients with DM was significantly limited by their health status. Patients with DM T1 rated their general health status higher on the 'general health status' scale than patients with DMT2. In patients with DMT2, the average score on the 'mental health' scale was significantly lower than in patients with DMT1, which indicated the possible development of PTRs. It was determined that the physical activity of MTG-patients is significantly limited by their health status compared to the IDPs group. Assessment of the severity of depressive symptoms on the HADS-D subscale showed that in 46.2% ($n=42$) of the examined the total score was within the normal range, in 24.2% ($n=22$) it corresponded to subclinical depression and in 29.7% ($n=27$) – clinically significant depression. The total score on the HADS-D subscale in MTG-patients is significantly higher than in the IDPs group ((7.81 $\pm$ 0.34) and (4.86 $\pm$ 0.29), respectively; $P < 0.04$).
Conclusion
In conditions of war conflict, patients with DMT2 compared to patients with DMT1 experienced a more significant deterioration in PCH and mental component of health (MCH). MTH-patients with DM due to the deterioration of PCH and MCH, have more significant restrictions in daily activities, social contacts, and a decrease in the level of communication than IDPs. 53.9% of patients with DM in the conditions of a military conflict develop clinical depression of varying severity, 50.6% - clinical anxiety.

Comorbidity of autoimmune diseases in pediatric patients with type 1 diabetes mellitus: a retrospective analysis

Irina Bojoga[1,2], Sorin Ioacara[1,2] & Simona Fica[1,2]
[1]'Elias' University Emergency Hospital, Endocrinology and Diabetes, Bucharest, Romania; [2]'Carol Davila' University of Medicine and Pharmacy, Bucharest, Romania

Background and Aims
The concurrent presentation of Type 1 diabetes mellitus (T1DM) with other autoimmune disorders, notably autoimmune thyroiditis and celiac disease, has been substantiated in numerous studies. Established guidelines advocate for routine screenings for these disorders at the onset of T1DM diagnosis, followed by periodic evaluations — biennially for thyroid pathologies and every 2-5 years for celiac disease. This research endeavours to elucidate the prevalence of these autoimmune comorbidities in pediatric patients with T1DM receiving care at our Endocrinology and Diabetes Department.
Methods
We engaged in a meticulous retrospective analysis encompassing pediatric patients diagnosed with T1DM and monitored systematically for associated autoimmune pathologies within our facility. Thyroid anomalies were scrutinized through assessments of TSH, anti-thyroid peroxidase antibodies, and antithyroglobulin antibodies, supplemented by examinations for thyroid stimulating hormone receptor antibodies in instances of suppressed TSH to preclude Basedow-Graves disease. Meanwhile, the prevalence of celiac disease was determined through the measurement of anti-transglutaminase IgA antibodies alongside the total IgA level.
Results
The cohort incorporated 565 patients characterized by a median age of 7.3 $\pm$ 4 years at the time of T1DM diagnosis, with a slight male predominance (50.8%). A substantial fraction, 25.6%, manifested at least one additional autoimmune disorder, itemized as follows: autoimmune thyroid disease (20%), differentiated further into Hashimoto thyroiditis (19.2%) and Basedow-Graves Disease (0.8%); celiac disease (2.65%); and other autoimmune maladies, including psoriasis and megaloblastic anemia (0.7%). Moreover, a smaller segment encountered dual diagnoses: Hashimoto thyroiditis and celiac disease (2.1%), and a singular case exhibited coexistence of thyroiditis and psoriasis. Of those diagnosed with Hashimoto Disease, a noteworthy 27.6% necessitated substitution therapy with levothyroxine.
Conclusions
The data delineates a significant incidence of autoimmune comorbidities in pediatric patients with T1DM treated at our department, with one in four patients afflicted. The findings underscore the imperative of regular screenings to facilitate timely diagnosis and intervention, a practice integral in fostering the well-being and normative development of pediatric patients.

Chrono-type of obese patients

Mouna Elleuch, Wissal Ghamgui, Nadia Charfi, Feten Hadj Kacem, Nabila Rekik & Mohammed Abid
Hedi Chaker Hospital, Endocrinology and Diabetology department, Sfax, Tunisia

Introduction
The chrono-type, intrinsic to each individual, is the tendency of an individual to prefer activities carried out in the morning or evening. The aim of our study was to determine the chronotype of our obese patients.
Materials and methods
This is a descriptive cross-sectional study involving obese adults consulting the service of Endocrinology of Sfax, Hedi Chaker University Hospital, during the period extending from December 2022 until March 2023. Our patients were subject to the typology questionnaire circadian of Horne and Ostberg.
Results
We recruited 40 obese patients. The average age was 43.47 years × 16.56. The sex ratio was 0.21. Fifteen percent of patients were smokers. The average duration of obesity was 20 years × 13.25. The average weight was 95.17 kg. BMI average was 35.96 × 5.04 kg/m^2. The average score of Horne's circadian typology and Ostberg was 55.93 × 11.28. The chrono-type of our patients was distributed as follows: 5% were very morning, 47% were moderate morning, 32% were neutral, 15% were moderate evening and no patient was entirely in the evening.
Conclusions
Only 15% of patients had an evening chronotype. According to several authors, people with an 'evening' chrono-type are more at risk of developing overweight or obesity mechanisms to explain this association are not yet fully elucidated, which must push us to carry out more research on this subject.

Diabetic pregnancy: adherence and benefits of regular physical activity on blood sugar control in diabetic pregnant women

Rakia Bachir Moctar, Salma Bensba, Nassim Essabah Haraj, EL Aziz Siham & Asma Chadli
CHU Ibn Rochd, Casablanca, Morocco, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Casablanca, Morocco

Introduction
Regular physical activity, the right diet and medication can help diabetics achieve optimal glycemic and mental balance.
The objective of the study is to assess the prevalence of regular physical activity (APR: ≥30 min/day, 3 times/week) and its effect on glycemic control.
Patients and methods
Our work is a retrospective study, including 449 patients with diabetic pregnancies followed at the Endocrinology-Diabetology department between January 2016 and January 2022. To do this work, we used SPSS software.
Results
The study included 449 patients with a mean age of 32 years. The prevalence of patients engaged in regular physical activity was 42.14% (n = 189). Two groups of patients, G1: patients with regular physical activity and G2: "sedentary" patients. The mean BMI of the G1 was 25.4 kg/m^2 compared to 29.8 kg/m^2 for the G2. G2 had an average fasting blood glucose of 1.8 g/l vs G1: 0.86g/l. Glycemic control was significantly better in G1: mean HbA1C = 6.8% vs 7.2% G2. This, with less severe hypoglycemia in the G1 but not significant.
Discussion and Conclusion
Our study showed the importance of APR on glycemic control. As a result, it is an inexpensive and effective prevention of cardiovascular disease. Hence the need for therapeutic education to encourage RPA.

Phospholipid composition of hippocampal membranes in rats with the induced sporadic neurodegenerative condition

Talat Saatov, Gulnora Artykbaeva, Tokhir Ishankhodjaev & Mukhammadjon Mustafakulov[1,1]
Institute of Biophysics and Biochemistry, Mirzo Ulugbek National University of Uzbekistan, lab of metabolomics, Tashkent, Uzbekistan

Alzheimer's disease is closely associated with type 2 diabetes mellitus (DM); being considered as type 3 DM due to common molecular peculiarities of type 2 DM and insulin resistance associated with the memory deficit and decline in the cognitive functions in elderly persons. We generated a model of sporadic neurodegenerative condition (NDC) or type 3 DM. The work was initiated to study profile of phospholipids in the hippocampal membranes of rats with the induced sporadic NDC.
Materials and methods
Within long period of time, the animals have been kept on the high calorie diet subsequently administered with neurotoxin. The phospholipids were fractionated by thin-layer chromatography. All experiments with animals were conducted in compliance with the regulations of the Committee on bioethics at the Institute of Biophysics and Biochemistry.
Results and discussion
Monitoring of the type 3DM was conducted by regular testing of behavior functions of animals, as well as their blood biochemical examination. The sporadic model of NDC with symptoms of Alzheimer's disease or type 3 DM induced, the lysoforms of phospholipids (14.1 ± 0.6 vs 10.3 ± 0.5 μg of phosphorus/g of tissue in the controls), phosphatidic acid (18.2 ± 1.2 vs 14.9 ± 0.8 μg of phosphorus/g of tissue) and cholesterol (22.6 ± 0.3 vs 19.0 ± 0.3 μg of phosphorus/g of tissue, P < 0.05) were found increased next to insignificant reduction in macro-components, to name phosphatidylcholine (542.0 ± 21.6 vs 559.8 ± 25.6 μg of phosphorus/g of tissue), sphingomyelin (108.1 ± 3.221 vs125.2 ± 3.8 μg of phosphorus/g of tissue), phosphatidylethanolamine (488.3 ± 19.1 vs 491.4 ± 21.4 μg of phosphorus/g of tissue), in micro-components, such as phosphatidylserine (147.4 ± 6.1 vs 187.5 ± 9.5 μg of phosphorus/g of tissue), phosphatidylinositol (83.5 ± 3.5 vs 88.7 ± 4.8 μg of phosphorus/g of tissue), as well as in total phospholipids (1464.7 ± 32.3 vs 1537.4 ± 31.3 μg of phosphorus/g of tissue). As the components of intermediate part of bio-membranes, phospholipids make impact on the condition and functionality of a cell, as a whole. Phospholipids maintain functioning of the essential cell mechanisms, to name ion exchange, inner reparation, bio-oxidation, influencing fixation of enzymes in mitochondria and oxidative phosphorylation. Increase in lysoforms of phospholipids and phosphatidic acid under induction of the NDC model indicates activation of phospholipases, possibly producing effects on the microenvironment of acetyl choline receptors of the brain cells and neuroplasticity of the nerve cells.

EP120

Association of AGEs and alcohol consumption with the incidence of diabetic neuropathy

Deimante Paskeviciene, Rasa Verkauskiene & Lina Radzeviciene
Lithuanian University of Health Sciences, Institute of Endocrinology, Kaunas, Lithuania

Background
Diabetic neuropathy (DN) is a major complication of diabetes, affecting one in three people with diabetes. The presence of peripheral neuropathy increases their risks of developing foot ulceration and subsequent necrosis that results in lower limb amputation. Good diabetes control helps to lower the risk of diabetic complications, which can be accelerated by advanced glycation end-products (AGEs) or alcohol consumption. AGEs are heterogeneous group of molecules, that normally accumulate slowly and in healthy people with natural ageing. Higher AGEs levels were associated with metabolic syndrome, cardiovascular disease, and diabetes-related complications such as DN. Alcohol consumption by persons with diabetes can worsen glucose control and diabetes-related medical complications, such as disturbances in fat metabolism or nerve damage. This study aimed to analyze the relationship between AGEs levels, patients' alcohol consumption and the presence of DN.
Materials and methods
AGEs concentration in the skin was non-invasively measured using ultra-violet light to excite autofluorescence with AGE Reader in 151 patients (age 18-85): no DN (78), with DN (73). Data on patients' clinical characteristics were collected from medical records and used to investigate associations between the presence of DN and the patients' AGEs concentration and alcohol consumption.
Results
The median diabetes duration was 14 years, age – 55 years. The study cohort consisted of 83 (55.0%) women and 68 (45.0%) men. The presence of DN significantly depended on alcohol consumption ($r_{cramer's}$ = 0.232, P < 0.01). Patients who consume alcohol are more likely to have complications of DN than patients who do not consume alcohol (P < 0.01). There were no significant associations between AGEs concentration and alcohol consumption (P = 0.232) and the presence of DN complication (P = 0.575). However, there was a positive correlation between AGEs concentration and age (r = 0.474, P < 0.001), BMI (r =

0.161, $P<0.05$), duration of diabetes ($r=0.293$, $P<0.001$). The odds of developing DN is 2.57 (CI 1.33 – 4.96) times greater for people, who consume alcohol ($P<0.01$).
Conclusions
Patients consuming alcohol were more likely to have a DN complication. Alcohol consumption did not have any influence on the levels of AGEs.
Funding
The work was supported by the EEA Financial Mechanism 2014-2021 'The Baltic Research Programme'.

Comparison of admissions for diabetic ketoacidosis in patients with autoimmune diabetes and type 2 diabetes in the san cecilio clinic university hospital

Javier García Sánchez, Elena Martínez Silla, Raúl Rodríguez Juárez, Laura Cánovas Noguera, Enrique Redondo & Pablo José López-Ibarra Lozano
San Cecilio Clinical University Hospital, Endocrinology and Nutrition, Granada

Introduction and objectives
Diabetic ketoacidosis (DKA) is a severe acute complication of Diabetes Mellitus (DM) and may require hospital admission. Our aim was to compare the characteristics of DKA occurring in patients with autoimmune DM (AMD) and type 2 DM (DM2) in our setting.
Methods
Retrospective observational study. Patients with AMD and DM2 admitted for DKA at the Hospital Universitario San Cecilio de Granada between January 2019 and December 2023 were compared. Variables related to the disease and to the episode of CAD were analyzed. Analyses were carried out with SPSS 25.0.
Results
85 patients with AMD and 16 with DM2 were included (48.5% women, with no significant differences between the two groups). The mean age was significantly higher in DM2 (35.21 vs. 56.13 years, $P<0.05$) and the time of evolution was similar in both groups (15.37 $\pm$ 11.53 and 14.77 $\pm$ 9.97 respectively). BMI was significantly higher in the DM2 category (31.47 vs 21.4 kg/m^2, $P<0.05$). Admission for CAD was the manner of debut in 25.9% of patients with AMD and in 31.25% of DM2. Of the patients with AMD, 64.5% had previously presented an episode of DKA. The most important precipitating factor in AMD was omission of treatment while in DM2 it was concomitant infections. No significant differences were found in terms of the need for ICU stay or the number of days in the ICU and on the hospital ward between the two groups. In those patients with DM debut, patients with DM2 have higher basal and rapid insulin needs (31 vs 15.6 IU, $P<0.05$; and 34.67 vs 21.6 IU, $P<0.05$; respectively). Metabolic control in terms of HbA1c was worse, with a tendency to significance, in the AMD group (11.01 vs 10.02%, $P=0.064$). No significant differences were observed in analytical parameters (blood glucose, pH, HCO3 and lactic acid) at admission.
Conclusions
In our work, it was observed that admissions for DKA in our center were more frequent in patients with AMD, despite the fact that these present better metabolic control and lower insulin requirements at debut. On the other hand, there is a tendency for most episodes of DKA in DM2 to be associated with infections, while the main risk factor in patients with AMD is the omission of treatment.

Type 1 diabetes mellitus and metabolic syndrome

Dhoha Ben Salah, Siddiqa Soomauroo, Mouna Elleuch, Khouloud Boujelben, Faten Hadjkacem, Nadia Charfi, Fatma Mnif, Mouna Mnif, Mohamed Abid & Nabila Rekik
Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Introduction
Metabolic syndrome (MS) is responsible for the increased cardiovascular risk in type 2 diabetics. There is a scarcity of research on the metabolic syndrome among individuals diagnosed with type 1 diabetes (T1DM). The aim of this study is to describe clinical, biochemical and therapeutic characteristics of T1DM with MS.
Materials and Methods
Retrospective study including 36 patients, with T1DM and MS, hospitalized in the department of Endocrinology in Hedi-Chaker Universital Hospital in Sfax/Tunisia, from 1997 to 2020. MS was defined according to the NCEP-ATP III criteria.
Results
The average age of our patients was 53 years (extremes: 26-80). A male predominance was noted with a sex ratio of H/F to 1,4. The average duration of diabetes was 15 years. Metabolic syndrome occurred after an average duration of diabetes of 13.7 years. Hypertension was noted in 21 patients (58.3%). The mean BMI was 26 kg/m^2, 19.7% of patients were obese. The average waist circumference was 95.5 cm $\pm$ 10.7. An android distribution of fat was present in 14 women. The mean total cholesterol level was 4.59 mmol/l $\pm$ 1.18 and mean triglycerides level was 1.67 mmol/l $\pm$ 0.81. Hypertriglyceridemia was present in 17 cases. The average HDL cholesterol level was 0,96 mmol/l $\pm$0.29. Low HDL-cholesterol level was present in 20 cases. The MS comprised of 3 criteria in 22 cases, 4 criteria in 11cases and 5 criteria in 3 cases. In the majority of cases, it was the combination of dyslipidemia, hypertension and diabetes (80%). Therapeutically, the average dose of insulin used was 0.8 IU/kg/day. The association of metformin was required in 18 cases (50%). Microvascular complications were present in all patients consisting of retinopathy (55.6%) and nephropathy (41.7%) and neuropathy (63.9%). Macrovascular complications, such as coronary insufficiency, were present in 20% of cases. The Cardiovascular risk was very high in all patients.
Conclusions
The prevalence of metabolic syndrome during type 1 diabetes is increasing. It indicates an increased risk for micro-and macrovascular complications.

Insulin resistance and body composition in a pediatric population of acute lymphoblastic leukemia survivors

Iustina Grosu[1], Luminita Nicoleta Cima[1,2], Sabina Maria Dumitrache[1], Raluca Stan[1], Ana Zubaci[1], Marina Iliescu[1], Diana Puscasu[1], Cristina Jercan[3], Andreea Serbanica[3], Anca Colita[2,3] & Simona Fica[1,2]
[1]Elias Emergency University Hospital, Endocrinology and Diabetes, Nutrition and Metabolic Diseases, Bucharest; [2]Carol Davila University of Medicine and Pharmacy, Bucharest, Romania; [3]Fundeni Clinical Institute, Pediatrics, Bucharest, Romania

Background
Childhood acute lymphoblastic leukemia (ALL) is no longer a death sentence. With survival rates approaching 90%, focus needs to shift towards improving long-term quality of life. Compared to the general population, adult survivors have four-fold excess risk of mortality secondary to cardiovascular diseases. Thus, modifiable risk factors, such as altered glucose metabolism, are of great importance and should be actively sought after. Studies show high prevalences of insulin resistance(IR) from an early age in this population, but its pathophysiology is poorly understood. Proposed mechanisms include body compostion alterations, with increased fat mass, fat redistribution and decreased lean mass.
Study aim
We aimed to investigate the early development of glucose homeostasis disturbances in ALL survivors while still children and to determine the relationship of IR with body composition.
Methods
We registered 20 ALL survivors, aged under 18, in remission for at least one year, evaluated in the Pediatric Endocrinology Department between 2016 and 2022 (mean age 9.85 +/-3.68 years, range 4-17; average time from diagnosis 4.7 years). Anthropometric measurements (BMI, waist circumference, waist-to-hip ratio) and glycemic indices (fasting glucose and insulin, HbA1c, OGTT) were collected and compared with results from 12 healthy children matched for age and sex. IR was evaluated using HOMA-IR and QUICKI. DXA was performed to assess body composition in 12 survivors.
Results
Glycemic profile (fasting glucose, HbA1c, OGTT) was normal in both groups. However, ALL survivors were 50% more likely to have IR compared to healthy subjects (RR=1.5, 95%CI 1-2.23, $P=0.047$), despite no significant difference in BMI (mean z-score 0.26 $\pm$ 1.38 vs 0.05 $\pm$ 1.24, $P=0.7$). Higher mean HOMA-IR (2.76 $\pm$ 1.88 vs 0.97 $\pm$ 0.73, $P=0.0095$) and lower mean QUIKI (0.34 $\pm$ 0.04 vs 0.425 $\pm$ 0.08, $P=0.02$) were observed in ALL survivors. In the study population, HOMA-IR correlated with BMI ($r=0.57$, 95%CI 0.06-0.84, $P=0.03$), android-gynoid fat ratio ($r=0.65$, 95%CI 0.09-0.90, $P=0.02$) and appendicular lean mass index(ALMI) ($r=0.75$, 95%CI 0.24-0.93, $P=0.01$).
Conclusions
As children in remission after ALL are 50% more likely to have IR compared to healthy subjects, an early and regular screening for metabolic disturbances should

be implemented in order to diminish cardiovascular risk among the growing population of survivors. Surprinsingly, in our study group, IR had a positive relationship not only with fat distribution, but aslo with ALMI, a surrogate for skeletal muscle mass. This is contrary to the general belief that high lean mass is beneficial for glucose regulation. Further studies are needed to clarify the effect of muscle mass on glucose homeostasis in ALL survivors.

Perioperative management of diabetes

Belhadi Leila, Nassim Essabah Haraj, El Aziz Siham & Chadli Asma
University Hospital Center Ibn Rochd, Department of Endocrinology and Metabolic Diseases, Casablanca, Morocco

Introduction
Perioperative hyperglycemia is associated with several adverse effects, including infection and cardiovascular events. Glycemic control is likely to be beneficial in reducing postoperative mortality.
Objectives
Our study aims to assess glycemic balance in the perioperative period and the impact of glycemic imbalance on postoperative complications.
Patients and Methods
A retrospective descriptive study was conducted on 185 patients hospitalized in the surgical departments of CHU Ibn Rochd Casablanca, from January 2022 to January 2023. The analysis was performed using the SPSS software.
Results
The average age was 60.2 years, with a female predominance (sex ratio: 1.26). The average duration of diabetes was 9.6 years. Type 2 diabetes accounted for 94.7% of cases, and type 1 diabetes for 4.9% of cases. An endocrinologist's opinion was sought preoperatively in 76.8% of cases and postoperatively in 23.2% of cases. The glycemic imbalance was judged based on HbA1C in 35.7% of cases and on a glycemic cycle with an average blood glucose level of 2.6 g/l in 55.7% of patients. The average HbA1C was 9.5%. Regarding treatment, 37.8% of patients were on oral antidiabetic drugs (ADO), 52.6% were on insulin therapy, and 2% were on a diet. All patients were put on insulin therapy (basal-bolus in 84.2% of cases and rapid bolus in 14.7% of cases). Surgical management was urgent in 89.4% of patients. Glycemic control was achieved in an average of 5.2 days. Among our patients, 6.3% experienced postoperative infectious complications, and one patient died from a pulmonary embolism.
Conclusion
Preoperative identification of patients with poorly controlled diabetes and intensification of treatment improve glycemic control, reduce the risk of complications, and shorten hospital stays.

EP125

Impact of travel on diabetes: a cross sectional study

Zayneb Sassi, Houcem Elomma Mrabet, Asma Ben Mabrouk, boubaker Fadia, Haifa Sfar, Ghofrane Belaabed, Amine Bayoudh, Najoua Lassoued, zantour baha, alaya wafa & Sfar Mohamed Habib
University Hospital Tahar Sfar, the Endocrinology Department, Mahdia, Tunisia

Introduction
The prevalence of diabetes has risen in recent years, leading to a growing number of travellers with diabetes. While travel can be therapeutic, it poses specific challenges for diabetic patients, requiring meticulous precautions.
Objective
To assess the occurrence of complications during travel and diabetes control after travel.
Methods
Cross-sectional study using a questionnaire, including out-patients with type 1 (T1DM) or type 2 diabetes (T2DM) aged $\geq$ 18 years and who had past travel experiences while diagnosed with diabetes at the Endocrinology Department at Tahar Sfar University Hospital Mahdia between October and December 2023.
Results
Twenty-one patients were included. The mean age was 57 years ranging from 35 to 73 years. Eighteen patients (85%) had T2DM. Among them, eight patients (44%) were on insulin therapy. The onset of diabetes occurred at 10 $\pm$ 6 years. The duration of travel had an average of 30 days and a median of 15 days. Ten patients (47 %) traveled alone, while 11 patients (52%) traveled with their families ($n=11$). Fifteen patients went on a pilgrimage to Saudi Arabia. Only six patients (28%) sought pre-travel advice and had a pre-travel consultation. None of the patients brought a medical prescription for their diabetes treatment during travel. Eleven patients (52%) were non-adherent to treatment. This was attributed to the lack of time and organization in 4 cases (36%), episodes of hypoglycemia resulting from changes in exercise patterns in 3 cases (27%), a shortage of rapid insulin analogs in one case, and a lack of therapeutic education, along with deviation from dietary measures in the remaining cases. Acute metabolic complications occurred in 4 cases (19%) during the trip, with two cases of hyperglycemia and two cases of ketoacidosis. A three-day hospitalization for ketoacidosis was reported in a patient with T1DM who had a shortage of rapid insulin analogs for 2 days. A significant decline in diabetes control after traveling was observed in 61% of the patients ($n=13$), as determined by comparing HbA1C levels before and after the trip, with an average increase of 1.08 % (t= -2, $P=0.028$).
Conclusion
Our series was characterized by a high frequency of altered diabetes control during and after traveling. This can be attributed to the absence of pre-travel advice, insufficient education regarding potential emergencies, and a lack of thorough review of diabetes. Diabetic patients must be guided in understanding that they can travel with diabetes, not from diabetes.

EP127

ENT mucormycosis in diabetic patients: report of 5 cases

Rachida Bouattay, nawres bouaziz, Hela Guizeni, Mahdi Ferjaoui, Amel El Korbi, Naourez Kolsi, Khaled Harrathi & Jamel Koubaa
مستشفى فطومة بورقيبة بالمنستير, Monastir, Tunisia

Objectives
Mucormycosis is an opportunist infection usually affecting immunocompromised patients. It is rare and often fatal. The pathogen is filamentous fungus of the mucorales order. Transmission is air-borne, with predominantly sinonasal tropism (40% of cases). Other locations are possible but much rarer. Diagnosis is founded on anatomopathologic and mycologic examination. Prognosis is severe, depending essentially on early diagnosis and treatment. The present study and review of the literature updates clinical, paraclinical, evolutive and therapeutic aspects of ENT mucormycosis.
Material and methods
A retrospective study included 5 patients with ENT mucormycosis diagnosed over a 14-year period, from January 2006 to December 2019.
Results
The study included 2 male and 3 female patients, with a mean age of 45.6 years (range: 27-61 years). All patients were diabetic. Mean duration of diabetes was 10.6 years, with extremes ranging from 3 to 24 years. Complications related to diabetes were observed in 3 cases. A patient had advanced kidney failure and another had systemic lupus erythematosus. A glycaemic imbalance was noted in 100% of patients with a mean HbA1C of 8.78. All five patients had sinonasal mucormycosis. Imaging was performed for all patients. Computed tomography was performed in all cases and imagnetic resonance imaging in one case. Mucorales filaments were founded on anatomopathologic and mycologic examination. Liposomal amphotericin B was progressively initiated for many weeks, with surgical curettage in all cases. The equilibration of diabetes was obtained. Subsequent evolution was unfavorable in four cases and the patients died a few days after surgery, from severe sepsis and multi-organ failure.
Conclusions
Otorhinolaryngologic mucormycosis is a rare fungal infection, which needs to be borne in mind. Rhinocerebral lesions are the most common clinical manifestations. Diagnosis is often difficult, but should be as early as possible. Treatment, initiated urgently, associates antifungal treatment, surgical resection and control of risk factors. The prognosis remains in all cases severe.

Self-assessment by type 2 diabetics of their knowledge about their disease

Mouna Elleuch[1], Insaf Nasri[1], Wissal Ghamgui[1], Younes Derbel[1], Mouna Mnif[1], Fatma Mnif[1], Dhouha Ben Salah[1], Charfi Nadia[1], Mohammed Abid[1], Feten Hadj Kacem[1] & Nabila Rekike[1]
[1]Hedi Chaker Hospital, Endocrinology and Diabetes Department, Sfax, Tunisia

Background
To be able to manage their disease and live with it, type 2 diabetic patients need to understand and be aware of their disease. Educational diagnosis should therefore assess patients' perception of their diabetes.
Aims
This study aims to carry out a self-assessment of diabetic patients' knowledge of their disease
Methods
Our study is a descriptive and analytical cross-sectional study which took place during the period from November 2022 to January 2023 among T2DM patients hospitalized in the endocrinology department in Sfax as well as patients followed at the basic health centre
Results
Our study find out that almost half of the patients did not know the origin of their disease. In terms of knowledge of the various complications, half of our patients said that they were aware of some of them. With regard to treatment (57.4%), they only recognized their current treatment and no longer knew about the other therapeutic alternatives for T2DM. The majority of patients admitted that diabetes aggravates underlying co morbidities. Only 31.1% of patients were aware of the use of insulin therapy. Patient autonomy was significantly associated with better knowledge of ADO intake (P-value = 0.021), hyperglycemia sign (P-value = 0.011) and glucometer use (P-value = 0.023); the more autonomous the patient, the better his or her knowledge of these areas. Knowledge of complications was strongly associated with diabetes control (HbA1c) (P-value = 0.003). The correlation was negative (-0.238). Furthermore, the higher the level of knowledge, the lower the HbA1c. There was an association between theoretical knowledge of the complications of the disease and the number of T2DM patients in the complication stage. A higher level of knowledge of the complications of T2DM was observed in patients who already had one of the complications of T2DM. Patients on ADO alone also appeared to have better knowledge of the disease than those on insulin. However, this did not reach statistical significance (P-value = 0.254).
Conclusion
Patients admitted that their knowledge of their illness was inadequate. Autonomy and the socio-economic conditions of the population meant that the quality of patient education depended on how well patients were educated.

Non-arteritic anterior ischemic optic neuropathy (NAION) in diabetic patients: A case report

Ilham Midhat, mennani fatimaeezzahra, Sana Rafi, Ghizlane EL Mghari & Nawal EL Ansari
Centre Hospitalo-Universitaire Mohammed VI Marrakech, Marrakech, Morocco

Introduction
Non-arteritic anterior ischemic optic neuropathy (NOIAN) is acute ischemia of the optic nerve head. It is one of the most common causes of blindness in diabetic patients, especially in the elderly. Visual impairment in NAION may be due to deterioration in visual acuity (VA) and/or visual field (VF) loss.
Observation
51-year-old female patient, diabetic for 14 years on insulin, not well controlled, and hypertensive for 15 years on treatment, who presented for one and a half months with a brutal and painless decrease in visual acuity of the right eye (RE), at the etiological investigation performed: fundus showed a drop in visual acuity in the (RE), with visual acuity in the left eye: 8/10th; normal papilla, flat retina, a few patchy haemorrhages at the posterior pole and punctiform, macula embedded in the chorioretinal anastomoses (ACR). Fluorescein angiography is in progress. Orbito-cerebral MRI: signal abnormalities in supratentorial white matter. Visual evoked potentials showed right axonal optic neuropathy. Lumbar puncture was normal. Biological workup revealed a slightly disturbed lipid profile and HBA1c 11.8%. Immunological tests revealed anti-SSA and anti-SSB autoantibodies, anti-native DNA antibodies, anti-phospholipid antibodies (IgG/IgM) and paraneoplastic antibodies. Serologies were negative. Patient received a bolus of 500 mg/day of Solumedrol for 3 days with slight improvement of decrease in visual acuity, responsible for major hyperglycemias suppressed by insulin therapy, with progressive attainment of optimal glycemic control, in order to avoid worsening of RE decrease in visual acuity and prevent contralateral damage.
Discussion et conclusion
Ischemic optic neuropathies include all vascular pathologies of the optic nerve. The classic distinction is between anterior ischemic optic neuropathy, in which there is papilledema, and posterior ischemic optic neuropathy, in which the optic disc appears normal. Non-arteritic acute anterior ischemic optic neuropathy is the most common form of ischemic optic nerve damage. Its exact physiopathology remains poorly understood. It is seen in patients with a papilla at risk (small and unexcavated). There is no effective preventive or curative treatment. In all cases of ischemic optic neuropathy, it is essential to eliminate an arteritic cause, both clinically and through further investigations. Treatment with methylprednisolone should then be started as a matter of urgency to limit visual decline and prevent damage to the adelphic eye. Optimal glycemic control remains an indispensable weapon in the prevention of NOIAN. When the condition has already set in, it can be stabilized or even corrected.

Diabetes mellitus in beckwith-wiedemann syndrome: an unusual co-occurence

Yesmine Elloumi, Abbes Wissal, Frikha Hamdi, Maalej Souhir, Ben Salah Dhoha, Boujelben Khouloud, Hadj Kacem Faten, Mnif Fatma, Nadia Charfi, Mnif Mouna, Elleuch Mouna, Mohamed Abid & Nabila Rekik Majdoub
Hospital of Hedi Chaker

Background
Beckwith–Wiedemann syndrome (BWS) is an imprinting disorder characterized by overgrowth, tumor predisposition, and congenital malformation(s). Diabetes mellitus is not characteristic of BWS. If anything, BWS is associated with hypoglycaemia which is believed to be related to hyperinsulinaemia due to an unknown mechanism. The presentation of concurrent BWS and permanent diabetes mellitus (DM) is uncommun.
Case Report
We report the case of a two year old girl with a past medical history of BWS. She was a term baby. She had earlobe crease, macroglossia and omphalocoele requiring immediate surgical repair. Genetic testing detected a decreased methylation intensity of the KvDMR1 (differentially methylated region) in the chromosome region 11p15.5, consistent with a diagnosis of BWS. Paternal uniparental isodisomy of 11p15 was unlikely but couldn't be excluded and her DNA methylation was normal at H19. At the age of two, she presented to her primary care physician with weight loss, polyuria, and polydipsia. She was diagnosed with new-onset diabetes and was started on a basal-bolus insulin regimen. At ten years old, she consulted with a poorly controlled DM. Lab results showed negative testing for the autoantibodies against Glutamic Acid Decarboxylase (GADA), insulinoma antigen-2 (IA-2A) and islet cells (ICA). Insulin blood level and c peptid level were respectively < 7 pmol/l and $< 0{,}03$ µg/l for a concomitant blood sugar at 5,13 g/l. We can postulate as a mechanism for such paradoxal association, a loss of imprinting control region (IC2) methylation that regulates the expression of CDKN1C which has been previously reported to be associated with permanent diabetes, as reported in 2023. A loss of methylation in imprinted PLAG1 locus on chromosomes 6q24 responsible for transient neonatal diabetes mellitus (TNDM) is the second hypothesis but it was described to be associated with transient DM as reported in 2015.
Conclusion
Our case illustrates the second case in the literature associating paradoxal permanent DM and BWS. Further biomolecular investigations are required to identify the possible interactions between BWS and glucose homeostasic abnormality.

Successful medical treatment of congenital hyperinsulinism with pasireotide: case-report

Kammoun Fatma, Ibtissem Ben Nacef, Sabrine Mekni, Sawsen Essayeh, Rihab Laamouri, Mchirgui Nadia, Karima Khiari & Imen Rojbi
Charles Nicolle Hospital, Endocrinology, Tunisia

Introduction
Congenital hyperinsulinism (CHI) is the most common cause of persistent hypoglycmia in neonatles and children. CHI causes persistent hypoglycemia due to inappropriate over-secretion of insulin. Promt diagnosis and immediate management is important to avoid long-term neurological damage. Medical therapy includes the use of the somatostatin analog octreotide as a second line-treatement in diazoxide-unresponsive cases. Here we report a case of a patient with CHI successfully treated with pasireotide, a somatostatin analog with high affinity for somatostatin receptor 5.

Case description
The patient presented at the age of 8 years with recurrent episodes of nonfasting hypoglycemia with neuroglycopenic symptoms. A diagnosis of autonomous insulin secretion was biochemically confirmed by identifying an elevated insulin level of 22,9 μ UI/ml > 3 μ UI/ml and C-peptide was elevated (3,43 ng/ml > 0,6 ng/ml) measured during hypoglycemia (glucose 2.03 mmol/l). Glucose infusion rate to maintain euglycemia was 7 (mg/kg/min). Abdominal ultrasound, computed tomography and magnetic resonance imaging (MRI) did not identify any pancreatic abnormalities. Endoscopic ultrasound and octreotide receptor scintigraphy revealed no pathological findings. The patient was initially treated with frequent feeding with carbohydrate-enriched formula and diazoxide 10 mg/kg/j. At the age of 12 years treatment with sc injections of octreotide was added because of recurrent hypoglycemia. At the age of 12 years 6 months and after parental consent, we started therapy with the long-acting somatostatin analog pasireotide at the dose of 40 mg every 28 days. Potential side effects of pasireotide (elevated liver enzymes, hypothyroidism, and adrenal insufficiency) were monitored and did not occur. With this therapy, the patient was normoglycemic with a good growth rate, normal weight gain, and excellent neurodevelopment.
Discussion
Pasireotide is a second-generation somatostatin analogue with a strong affinity for four of the five SSTRs especially SSTR5, followed by SSTR2, SSTR3, and SSTR1 receptors. Pasireotide was first introduced for treating Cushing disease and acromegaly and is known to cause hyperglycemia as a side effect due to inhibition of insulin secretion. It has been proposed as a new treatment for CHI. Pasireotide has a much higher affinity for SSTR5 than the first-generation somatostatin analogues) and might be more effective in controlling hyperinsulinism.

Oligoelements deficiency in adult patients consulting for underweight

Dorra Ben Salem[1], Emna Bornaz[1], Selma Mohsen[2], Haifa Abbassi[1], Sana Khamassi[1], Fatma Boukhayatia[1], Asma Ben Brahim[1], Rym Yahyeoui[1], Kamilia Ounaissa[1] & Chiraz Amrouche[1]
[1]National Institute of Nutrition, Outpatient Department and Functional Exploration, Tunis; [2]Tahar Sfar Hospital, Endocrinology, Mahdia, Tunisia

Introduction
Oligoelements are essential for body metabolism and normal physiological processes. Deficiency of these micronutrients is associated with multiple situations such as malnutrition. Despite numerous reports linking micronutrient deficiencies to serious health complications, attention to this issue is poor among clinicians.
Objective
We investigated the nature of oligoelements deficiencies that arose in underweight patients in order to determine the frequency of deficiency in each element in this situation and to identify associated factors.
Materials and methods
An assessment of the serum calcium (Ca), phosphorus (P) and magnesium (Mg) levels was done on adult patients with underweight consulting our specialized nutrition unit in the outpatient department of the National institute of Nutrition of Tunis. Socio-demographic and anthropometric parameters were collected. To diagnose undernutrition, we referred to the high health authority (HAS) 2021 definition.
Results
Thirty-five adult patient was included with a female predominance (80%). The mean age was 36.64 ±13.45 years [22; 69]. The average weight, BMI, weight loss and calf circumference were 47.45±12.34 kg, 17.14±3.3 kg/m^2, 15.88±9.63% and 30.82±4.11 cm respectively. The prevalence of undernutrition was 62.84%. Only a third of patients (33.32%) had a known disease explaining their malnutrition on admission to the unit. The average Mg, Ca and P were 0.8±0.07 mmol/l, 2.35±0.11 mmol/l and 1.13±0.16 mmol/l respectively. Hypomagnesemia was met in 20% of cases, hypocalcemia in 5.7% of cases and hypophosphoremia in 2.9% of them. No significant correlation was found between (Mg), gender, anthropometric and other biological parameters. (Ca) was neither correlated to weight nor to weight loss. (P) was significantly correlated with calf circumference ($P=0.05$).
Conclusion
Oligoelement deficiencies seem to be frequently found in undernutrition situations. Proper monitoring and tests are recommended whenever the diagnosis is established, followed by specific and individual nutritional supplementation treatments.

Severe hypertriglyceridemia in type 2 diabetes with systemic lupus accompanied by acute pancreatitis

Hemmat el Haddad, Rokaya Abdel Aziz, Heba Moustafa, Heba Murad, Nehal Hamdy, Ahmed Fayed, Ihab Sameeh, Randa Salam, Samar Amin, Mona Youssry & Fatma Fayed
Cairo University, Internal medicine, endocrinology, Cairo, Egypt

Introduction
Severe HTG usually occurs in a patient with genetic predisposition encoding various apolipoproteins (APOE, APOA5, APOC2, APOB), lipoprotein lipase (LPL), exacerbated by secondary factors as diabetes, obesity, high alcohol intake
Case report
35 yr old diabetic male presented with repeated vomiting with severe epigastric pain He had similar attack 1 year ago diagnosed as acute pancreatitis. 3 years ago he was diagnosed SLE with antiphospholipid on prednisone 5 mg, mycophenolate mofetil 1.5 mg, hydroxychloroquine 400 mg, warfarin 4 mg Upon admission, he was alert, Pulse: 140 beat/minute Blood pressure: 80/40 Respiratory rate: 32/minute. Temperature: 38ºC, tenderness over the epigastrium. Laboratory investigations; RBS 500 mg/dl, A1C: 14.7 %, ABG (PH: 7.38 HCO3: 26 Mm/l SaO2 98.0%) HB;12.4 g/dl, TLC: 24/ul PLT:77,000/uL/CRP: 265 mg/dl/Chol: 425 mg/dl, LDL: 257 mg/dl, HDL: 25 mg/dl, TG: 1547 mg/dl Amylase: 1323U/l, Lipase: 2278U/l/Na: 141mEq/l, K: 3.8 mEq/l, Urea: 100 mg/dl Creatinine: 2.1 mg/dl., ALT: 73 IU/l, AST: 73IU/l, Bil T: 4.5 mg/dl, Albumin: 4 g/dl Abdominopelvic sonar showed: Pancreatic edema with pancreatic cyst (9×7 cms). CT abdomen: Enlarged pancreatic head, perihepatic& peri pancreatic free fluid collection for pigtail insertion. Culture and sensitivity of collected fluid: E.coli, candida. The patient started, antifungal, fluids and insulin, NPO Icosapent Ethyl 2 gm and fenofibrate 320 mg, cholesterol dropped to 102 mg/dl, triglycerides to 293 mg/dl discharged on fibrates with life style modification
Conclusions
Patients with severe hypertricylcerideamia require fast and effective lowering of TG levels in order to reverse the lipotoxic effect

DOI: 10.1530/endoabs.99.EP165

Blood phospholipid profile in patients with type 1 diabetes mellitus combined with ischemic heart disease

Gulnora Artykbaeva & Talat Saatov
Institute of Biophysics and Biochemistry, Mirzo Ulugbek National University of Uzbekistan, lab of metabolomics, Tashkent, Uzbekistan

For quite a long period of time, diabetes mellitus (DM) has been considered as the carbohydrate metabolism disorder; to maintain blood glucose normal was believed to be the only mission of insulin. By now, findings from many studies have proved that DM is accompanied by the complex disorder of metabolism not only for carbohydrates, but also for lipids and proteins. Atherosclerotic injury of large vessels and ketoacidosis are known to be the main DM complications. The work was initiated to study disorders of phospholipid metabolism in patients with type 1 DM and its combination with ischemic heart disease (IHD).
Materials and methods
We examined 34 patients with type 1 DM. The group of DM+IHD included 25 patients. The control one consisted of 11 healthy persons. The blood phospholipids were fractionated by thin-layer chromatography.
Results and discussion
Significant increase in the concentrations of total phospholipids was found in fractions of these phospholipids in groups of patients with DM only and in those with DM and IHD combination. Phosphatidylinositol was found unchanged in the DM group (12.23 ± 3.59 vs 11.85 ± 3.38%), but it was significantly decreased in the DM+IHD group (3.74 ± 0.83 vs 11.85 ± 3.39, $P<0.05$). There was no difference between concentrations of phosphatidylcholine in patients with DM only (23.89 ± 4.41 vs 23.82 ± 5.12%), but significant reduction as compared to the normal concentrations was observed in the DM+IHD group (10.03 ± 2/07 vs 23.82 ± 5.12%, $P<0.05$). Phosphatidylethanolamine was found decreased both in the DM group (9.55 ± 3.44 vs 17.14 ± 3.14% in the controls), and in the DM+IHD group (11.62 ±4.5 vs 17.14 ± 3.14%, $P<0.05$). No significant differences could be seen in the concentrations of phosphatidic acid between the groups. Sphingomyelin was within normal limits in both groups of patients. Only traces of lysophosphatidylcholine could be observed in the controls. This was found in the DM group, but in the DM+IHD group significant increase of the parameter was seen (13.9 ±2.97%, $P<0.05$). Thus, the most significant alterations could be seen in the patients with the IHD-accompanied DM. In this group, increases in lysophospholipids next to the reduction in phosphatidylcholine, phosphatidylinositol and phosphatidylethanolamine, turned out the most sensitive ones. The sum

of phospholipids was most pronounced in DM, reducing in DM+IHD, but being significantly higher than the one in the controls. We have shown alterations in the phospholipid profile in patients with IHD-accompanied DM.

DOI: 10.1530/endoabs.99.EP166

EP167

Bempedoic acid role in treating familial hyperlipedemia

Aida Kanaan & Daniel Kannappan
Wrightington, Wigan & Leigh NHS Foundation Trust, Appley Bridge, United Kingdom

Bempedoic acid, an innovative medication targeting cholesterol synthesis through ATP citrate lyase inhibition, gained FDA and EMA approval in February 2020 for familial hypercholesterolemia and cardiovascular disease. UK NICE TA694, on April 28, 2021, extended its recommendation to include Bempedoic acid with ezetimibe for primary hypercholesterolaemia and mixed dyslipidaemia in adults, alongside dietary measures. This retrospective clinical audit assessed Bempedoic acid's effectiveness and safety, particularly in patients intolerant to statins, familial hyperlipidaemia, and atherosclerotic cardiovascular disease. Examining 16 patients from the Leigh Lipid Clinic (January 2021 to June 2023), results showed a significant reduction in LDL-C levels, with a peak percentage reduction of 18.98% at 6 months. Total cholesterol reached its lowest mean at 6 months, with a maximum reduction of 13.51%. However, a notable percentage of patients developed prediabetes or diabetes, warranting further exploration. Contrary to expectations, triglyceride levels increased by 30.4%, challenging previous literature suggesting Bempedoic acid's benefits in diabetes patients. In the audit of Bempedoic acid treatment for hypercholesterolemia in 16 patients, all participants experienced at least one treatment-emergent adverse event (TEAE), but none led to treatment discontinuation. New onset hypertension occurred in 12.5% of patients, while musculoskeletal symptoms and other specific adverse events, were reported in smaller percentages. Biochemical changes, such as elevated creatine kinase and alanine aminotransferase levels, as well as shifts in HbA1c with some patients transitioning to diabetes or prediabetes, were observed. Notably, 45.5% of patients had a significant drop in hemoglobin levels. Descriptive statistics of urea levels over time revealed a notable increase at the 1-year mark, reaching a mean of 7.75 mmol/l, with a maximum observed percentage increase of 30.64%. Triglyceride levels peaked at the 6-month interval with a mean of 2.6 mmol/l and a maximum observed percent increase of 30.4%. HDL-C levels showed the lowest mean at the 6-month interval (1.1725 mmol/l) with a maximum observed percent reduction of -28.08%. These findings highlight the prevalence of adverse events and biochemical changes associated with Bempedoic acid treatment, emphasizing the need for careful monitoring and further investigation. Acknowledging study limitations, such as a small sample size and missing data, this research provides valuable insights into Bempedoic acid's safety and side effects in a challenging patient population, advocating for a larger sample size in future evaluations.

Treatment with adalimumab and combined hormonal contraception as a cause of hypertriglyceridemia induced acute pancreatitis: a case report

Matej Rakusa[1,2] & Darko Siuka[2,3,4]
[1], Department of Endocrinology, Diabetes and Metabolic Disease, University Medical Centre Ljubljana, Ljubljana, Slovenia; [2]Department of Internal Medicine, Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia; [3], Department of Gastroenterology, University Medical Centre Ljubljana, Ljubljana, Slovenia; [4]Japljeva ulica 2, Department of Gastroenterology, University Medical Centre Ljubljana, Ljubljana, Slovenia

Introduction
Hidradenitis suppurativa (HS) is a chronic and debilitating inflammatory skin disease, that is characterised by painful lesions in apocrine gland-bearing areas. Patients also present with significantly increased rates of cardiovascular risk factors, such as dyslipidaemia, diabetes, metabolic syndrome. Adalimumab a fully human IgG1 monoclonal antibody that specifically binds to TNF-α is an established treatment for HS. Combined hormonal contraception is commonly used in general female population. Both medications are known to moderately increase cholesterol and triglycerides (TG).
Case report
We report a case of 34-year-old woman who was admitted to emergency department because of acute abdominal pain. Patient was treated with adalimumab 40 mg QW for previously diagnosed HS and used etonogestrel/ethinylestradiol vaginal ring (VR) for contraception. On admission she complained about sudden onset of nausea and dull abdominal pain, propagating to the back. She denied alcohol abuse. Blood pressure was 140/85 mmHg, height 158 cm, weight 93 kg, body mass index 37.3 kg/m^2. Abdominal examination revealed generalised tenderness on palpation. Bowel sounds were silent, but present. On admission blood was lipemic and could not be analysed. On abdominal ultrasound liver steatosis was present, cholecystolithiasis and cholecystitis were excluded. Computed tomography of abdomen revealed inflammation of the pancreas and retroperitoneal fat of 10 cm in diameter. We treated her with parenteral hydration, analgesics and plasmapheresis. Results of blood test after initial treatment were: white cell count 15.5×10^9/l (normal range $4\text{-}10\times10^9$/l), C-reactive protein (CRP) 135 mg/l (<5 mg/l), amylase 2.22 μkat/l (0.52-1.78 μkat/l), lipase 4.68 μkat/l (<1.07 μkat/l), cholesterol 19.5 mmol/l (<5 mmol/l), TG 49.1 mmol/l (<1.7 mmol/l). Liver function tests were normal. We discontinued treatment with adalimumab and removed VR. During hospitalisation TG level gradually decreased to 8.0 mmol/l, and CRP transiently increased to 368 mg/l and then normalised. No antibiotic treatment was necessary. On follow-up visit additional trend of normalisation of TG was noted.
Discussion and conclusion
To our knowledge this is the first case of hypertriglyceridemia induced pancreatitis, caused by combination of treatment with adalimumab for HS and with VR, without any other predisposing conditions. When combining treatment with known side effects on lipid metabolism, we should consider possible multiplicative effect, especially in patients prone to metabolic complications. Prior to initiating and during treatment regular laboratory test should be performed.

Myocardial infarction in patients with type 2 diabetes and coronary heart disease

Elena Brutskaya-Stempkovskaya, Lizaveta Tsitova & Karina Liahkova
Belarusian State Medical University, Belarus

Objective
Coronary heart disease (CHD) is one of the leading causes of death worldwide. According to WHO experts, one out of 4 deaths in the world is due to CHD (17.8 million people annually). Type 2 diabetes is an independent risk factor for CHD. Thrombotic complications of atherosclerosis are the main cause of death in 80% of patients with type 2 diabetes.
Materials and Methods
We studied the prevalence of myocardial infarction in patients with CHD and type 2 diabetes. A cross-sectional controlled study of 50 hospitalized cardialogical patients with chronic CHD was conducted. The main group - patients with chronic CHD and type 2 diabetes, average age was 68.5±9.63 years (women - 44.12%, men - 55.88%). The comparison group was patients with CHD without type 2 diabetes, averageage was 69.5±13.14 years (women – 43.75%, men – 56.25%).
Examination
ECG, HЬA1c, blood chemistry, glucose, heart ultrasound, coronary angiography.
Results
Patients of both groups were comparable in gender, age (U=243,5, P=0,56), laboratory data: cholesterol (4.62 (3.8-5.3) vs 4.78 (3.67-5.67) mmol/l, P=0.7), TG (1.55 (1.21-1.94) vs 1.60 (1.34-2.76) mmol/l, P=0.74), HDL (1.1 (0.9-1.3) vs 1.13 (0.87-1.38) mmol/l, P=0.88), LDL (2.4 (1.9-3.0) vs 3.0 (2.0- 3.7) mmol/l, P=0.12), VLDL (0.58 (0.37-0.72) vs 0.64 (0.54-1.03) mmol/l, P=0, 26), AST (23 (18-40) vs 24 (18-42) U/l, P=0.77), ALT (22 (15.9-41) vs 28 (23-40) U/l, P=0.14), creatinine (102.0 (77.5-144.6) vs 90.3 (75.3-132.9) μmol/l, P=0.47), total protein (71 (66-74) vs 71.35 (66-74) g/l, P=0.89) in blood serum. The blood glucose level in patients of the main group was significantly higher compared to the comparison group (6.8 (5.5-8.5) vs 5.5 (5.2-6.0) mmol/l, P=0.01). HbA1c = 7.7 ± 1.73% in patients of the main group, the experience of type 2 diabetes according to the anamnesis was 8.2 ± 3.14 years. According to the anamnesis data, acute myocardial infarction was diagnosed in 79.41% (n=27) of patients in the main group and in 56.25% (n=9) of patients in the comparison group. The prevalence of a history of myocardial infarction was 23.16% higher in patients of the main group ($\chi2$ = 2.9, P=0.089).
Conclusion
the results of the study indicate an increasing incidence of acute myocardial infarction by 23.16% in patients with coronary heart disease in combination with type 2 diabetes compared to patients with coronary heart disease without type 2 diabetes.

Predictors of antenatal insulin requirement in gestational diabetes mellitus

Sawsen Nouira, Taieb Ach, Asma Ben Abdelkrim, Amel Maaroufi, Yosra Hasni & Molka Chaieb
University Hospital Farhat Hached, Endocrinology, Sousse

Introduction
Gestational diabetes mellitus (GDM) arises from elevated glycemia during pregnancy, posing risks to both mother and fetus. Managing GDM involves close monitoring and dietary control, with antenatal insulin therapy (AIT). The aim of this study was to evaluate the efficiency of diverse maternal characteristics and biological indicators identified during GDM diagnosis in anticipating the inadequacy of dietary measures and the requirement for AIT to achieve glucose targets.
Materials
We conducted a retrospective longitudinal study that included women diagnosed with GDM and who were monitored at the Endocrinology Department of Farhad Hached Hospital in Sousse between January 2017 and March 2020.
Results
We analyzed 380 records of patients diagnosed with GDM. The average age in our patient group was 34 $\pm$ 5 years, ranging from 20 to 46 years. Among them, 73% (280 individuals) needed AIT, while 100 patients achieved glycemic goals solely through Medical Nutrition Therapy (MNT). Notably, those requiring insulin had prior history of obesity (24%), gestational diabetes (12%), and macrosomia (18%) ($P=10^{-3}$). Patients meeting glycemic targets via MNT had higher total carbohydrate intake upon GDM diagnosis ($P=0.02$). Those necessitating AIT were diagnosed at an average gestational age (GA) of 24 ± 6 weeks, significantly earlier than the 25 ± 6 weeks observed in patients following MNT ($P<10^{-3}$). Fasting glucose levels did not exhibit a notable difference between the two groups. Patients requiring insulin showed a median HbA1c level of 5.5%, surpassing levels observed in the group under MNT. Elevated HbA1C emerged as the only independent predictor for the necessity of AIT.
Conclusion
Recognizing the diverse spectrum of glucose intolerance severity among women with GDM necessitates a stratified classification for management strategies. This approach allows for the optimal allocation of human and financial resources. Notably, a higher HbA1C at diagnosis signals the potential need for intensified monitoring by specialized healthcare providers.

Frequency and risk factors of medication non-adherence in elderly diabetics

Dhoha Ben Salah[1], Abir Larayedh[2], Mouna Elleuch[1], Khouloud Boujelben[1], Faten Hadj Kacem[1], Fatma Mnif[1], Mouna Mnif[1], Nadia Charfi[1], Mohamed Abid[1] & Nabila Rekik Majdoub[1]
[1]Endocrinology Department, Hedi Chaker University Hospital, Sfax, Tunisia; [2]Department of Family Medicine, Faculty of Medicine, Sfax, Tunisia

Background
Low medication adherence is a frequent problem in elderly individuals with chronic diseases such as diabetes. The objective is to assess the level of medication adherence and identify predictive factors for poor adherence among elderly diabetic patients.
Methods
We conducted a descriptive, cross-sectional study among diabetic patients aged 65 years and older, who were attending the Endocrinology Department at Hedi Chaker University Hospital in Sfax from January to March 2022. Medication adherence was assessed using a validated Arabic version of the 8-item Morisky Medication Adherence Scale (MMAS-8). Univariate analysis followed by multivariate logistic regression was used to identify predictors of low medication adherence.
Results
This study included a sample of 137 elderly patients, with a mean age of 71.49 years ($\pm$6.2) and a sex-ratio of 0.9. The prevalence of low medication adherence was 56.2%, and it was independently and significantly correlated with five distinct factors: the absence of self-monitoring of blood glucose [OR = 2.987; 95% CI (1.295-6.889), $P=0.01$], irregular medical visits [OR = 5.383; 95% CI (1.353-21.419), $P=0.017$], non-adherence to prescribed treatments [OR = 4.644; 95% CI (1.457-14.804), $P=0.009$], high HbA1C levels (>7%) [OR = 3.008; 95% CI (1.194-7.580), $P=0.02$] and diabetic retinopathy[OR = 2.987; 95% CI (1.327-6.725), $P=0.008$].
Conclusions
Medication adherence was insufficient in our study. Therapeutic education programs are needed for patient management.

Feature of technology in therapeutic education of diabetes patient: 61 cases

Mouna Elleuch, Insaf Nasri, Wissal Ghamgui, Younes Derbel, Charfi Nadia, Feten Hadj Kacem, Mouna Mnif, Fatma Mnif, Mohammed Abid, Dhouha Ben Salah & Nabila Rekike
Hedi Chaker Hospital, Endocrinology and diabetology department, Sfax, Tunisia

Background
Interest health applications and networks for self-management of diabetes are growing. Furthermore, the potential influence of social media on health information spread is remarkable.
Aim
This study aims to determine the role of the new telecommunication technology in the dissemination of therapeutic education in our population.
Methods
Our study is an descriptive and analytical cross-sectional study which took place during the period from November 2022 to January 2023 among 61 T2DM patients hospitalized in the endocrinology department in Sfax as well as patients followed at the basic health centre.
Results
The involvement of new telecommunication technologies in the choice of therapeutic education's interface occupied the second priority in the different educational objectives, but in different proportions. Moreover, 24 patients (39.3%) preferred telephone applications for disseminating instructions on dietary hygiene measures. The role of the media was also in demand, especially for general information (26.2%), diet (24.6%) and how to use current treatment (21.3%). Internet platforms dedicated to diabetic patients were among the choices of 10 patients (16.4%) in the area of preventing complications of the disease. Social networks were also integrated into the development for health care resources, especially to prevent complications (23%). The correlation between patients' objective assessment of their knowledge and their possession of telecommunication resources (smart phones, computers…) was significant (0.316, $P=0.006$). The statistical study showed a positive correlation between the use of new technologies and patients' level of knowledge. This relationship was significant for glucometer use ($P=0.002$).
Conclusion
In our study, we recognized that whatever the integration of new telecommunication technologies that patients needed, the medical and paramedical staff were always involved in the dissemination of therapeutic education.

Impact of obesity and android fat distribution on the progression of hepatic fibrosis in metabolic steatopathy

Ahmed Mohamed Nefzi, Bouchabou Bochra, El Mouldi Yosr, Nakhli Abdelwahab, Hemdani Nesrine, Benzarti Zeineb, Ben Nejma Houda & Ennaifer Rym
Hôpital Mongi Slim, Hepato-gastroenterology, Marsa, Tunisia

Introduction
Metabolic steatopathy is a public health problem, and its therapeutic management remains a challenge primarily relying on lifestyle and dietary measures. The degree of liver fibrosis represents the major prognostic factor for this condition. The objective of this study was to investigate the impact of obesity and android fat distribution on the progression of hepatic fibrosis in metabolic steatopathy.
Patients and Methods
We conducted a prospective, descriptive study including patients diagnosed with metabolic steatopathy between March 2021 and December 2022. Age and various medical histories were collected. Anthropometric measurements were taken, and a biological assessment, including metabolic and hepatic panels, was performed. liver fibrosis assessment using transient elastography was conducted, with advanced fibrosis defined as liver elasticity $\geq$ 9.7 kPa.
Results
We included 139 patients with an average age of 54.2 ± 10.7 years and a gender ratio of 0.53. Histories of type 2 diabetes, hypertension, and dyslipidemia were

noted in 43.5%, 46.4%, and 31.2% of patients, respectively. Obesity was found in 52.6%, and android fat distribution was observed in 87.3% of patients. Advanced hepatic fibrosis was noted in 15.6% of patients. In analytical study, patients with advanced fibrosis had significantly higher body mass index (BMI) and waist circumference (WC) with *P*-values of 0.03 and 0.024, respectively. The study of BMI and WC performance in predicting advanced fibrosis showed the superiority of WC with areas under the ROC curve of 0.63 (95% CI 0.5–0.779) and 0.7 (95% CI 0.6–0.833), respectively. The BMI cutoff was 30.6 kg/m^2 with a sensitivity of 65% and specificity of 50%. The WC cutoff was 103.5 cm with a sensitivity of 82.4% and specificity of 40%.
Conclusion
Android-type obesity has a more pronounced correlation with advanced fibrosis than overall obesity. Therefore, it is imperative to systematically include the assessment of this parameter in the management of this pathology.

Postnatal growth and weight gain in term and near-term infants with severe neonatal hypoglycemia: a comparison between offspring of diabetic and non-diabetic mothers

Nada Alaaraj, Ashraf Soliman, Fawzia Alyafei, Noor Hamed, Shayma Mohamed & Hamdy Ali
Department of Pediatrics Hamad Medical Centre, Doha, Qatar

Introduction
Hypoglycemia occurs more frequently in infants of diabetic mothers as well as in preterm and small for gestational age babies (SGA). Severe neonatal hypoglycemia can adversely affect the neurodevelopment and metabolism of the infant on the long run. Postnatal growth of these infants has not been studied in depth.
Objective
This study aimed to evaluate postnatal growth patterns in infants with neonatal hypoglycemia, comparing infants of diabetic mothers (IDM) with infants of non-diabetic mothers (INDM) from birth to 3 years of age.
Methods
We retrospectively analyzed the growth data of 79 IDM and 51 INDM infants who were treated for severe neonatal hypoglycemia at a single center. Anthropometric measurements, including weight-for-age Z score (WAZ), length-for-age Z score (LAZ), and weight-for-length Z score (WLZ), were collected at birth and at several intervals up to 36 months.
Results
IDM were born at a higher gestational age and with better growth indices than INDM. During the first year, IDM had a progressive increase in WAZ, which stabilized thereafter, while INDM demonstrated a significant catch-up in WAZ and LAZ, particularly in the first 18 months. After 2 months, IDM maintained higher WLZ scores than INDM. By 36 months, IDM had significantly higher WAZ and WLZ, suggesting a tendency towards increased weight relative to length.
Discussion
IDM exhibited a distinct growth pattern, characterized by larger size at birth and slower postnatal catch-up growth compared to INDM. Despite severe neonatal hypoglycemia, IDM and INDM infants showed the ability to reach normal growth velocity by 18 months, although IDM had a higher risk of increased adiposity. These findings align with previous research, highlighting the impact of maternal diabetes on the growth trajectory of infants and the potential for long-term metabolic implications.
Conclusion
The growth patterns of infants with neonatal hypoglycemia are influenced by maternal diabetes status. While IDMs are at risk for increased adiposity, both groups show resilience in growth, underscoring the need for ongoing monitoring to support their growth needs.

A case of rhino-orbital mucormycosis precipitated by a state of diabetic keto-acidosis

Najoua Lassoued[1], Bougossa Rebeh[2], Bayoudh Amine[1], Larbi Fatma[2] & Sfar Habib[1]
[1]Taher Sfar University Hospital, Endocrinology Department, Mahdia, Tunisia; [2]Taher Sfar University Hospital, Department of Infectious Diseases, Mahdia, Tunisia

Background
Mucormycosis, also known as black fungus, is a rare, aggressive, locally invasive, and life-threatening fungal infection that can occur in healthy individuals but that is more frequently seen in immuno-compromised patients especially in diabetics in the context of diabetic keto-acidosis. Early diagnosis is a key for good prognosis.
Case Presentation
We report the case of a 66-year-old Tunisian male, with a history of uncontrolled type 2 diabetes treated with metformin, who presented with fever, acute hemifacial and palpebral oedema and right unilateral epistaxis. The patient reported a 10-day history of dental pain initially diagnosed as a dental abscess and treated with amoxicillin. The initial presentation revealed a state of Keto-acidosis, adequate insulin therapy, as well as fluid and electrolyte replacement were initiated. An emergency CT scan revealed orbital cellulitis stage 2 of Chandler associated with cervical-facial extension without signs of collection, along with right maxillary and ethmoidal sinusitis, the patient was admitted and the diagnosis of dental-origin cellulitis with orbital extension was initially retained, the patient was placed under a triple antibiotic treatment, in 24 hours rapid lesion extension was noted with central necrotisation of skin lesions along with necrosis of the lateral wall of the right nasal cavity and ulceration of the right vestibular grove in nasal fibroscopy. Tissue samples were taken and an urgent pathological examination confirmed the diagnosis of Rhino-orbital mucormycosis precipitated by the state of keto-acidosis the patient was placed under anti-fungal treatment and surgical removal and care for necrotic lesions were done in the ENT department. Glycemia targets were met with intensive intravenous insulin treatment followed by a basal-bolus insulin regimen. Clinical improvement was noted in a few weeks and the patient benefited from a facial skin graft;
Conclusions
This case shows a rare case of rhinorobital mucormycosis precipitated by diabetic ketoacidosis and uncontrolled type 2 diabetes. This case highlights the need for an early diagnosis of mucormycosis as well as the need for optimal control of diabetes and rapid treatment of acute metabolic complications.

Mauriac syndrome in poorly controlled type 1 diabetes: case report

Rokia Abd Al Aziz, Ghada Rabie, Dina Farouk & Randa Salam
Cairo University, Internal medicine, endocrinology, Cairo, Egypt

Introduction
Mauriac syndrome (MS) is considered a glycogenic hepatopathy characterized by growth failure, delayed puberty, hepatomegaly with abnormal liver enzymes, hypercholesterolemia. These features were attributed mainly to insulin deficiency and sub-optimal diabetic management
Case report
18 years old male, presented with short stature and delayed puberty. The patient was diagnosed to have type 1 DM at the age of 6. He was on a premixed insulin regimen but non compliant to treatment. His disease course was complicated by diabetic retinopathy, and neuropathy frequent admissions for recurrent diabetic ketoacidosis (DKA) There was a history of right hypochondrial dragging pain with no jaundice
Physical examination
Height was 145 cm, $<$3rd percentile, proportionate. BMI was 19.9 kg/m^2, mid-parental height was 168 cm. Blood pressure: 110/70 mm Hg, Pulse: 80/mint, normal RR and temperature. Absent secondary sexual characters and infantile male genitalia tanner stage 1 The abdominal examination showed soft hepatomegaly. liver span of 22 cm Cardiac and chest examination were normal
Investigations
HbA1c was 9.9%, A/C ratio: 500 mg/g His hepatic panel revealed high ALP: 490 U/l (N: 40-150 U/l), high liver transaminases. ALT: 235 U/l(10-50 U/l), AST: 259 U/l (N: 0-38 U/l) cholesterol: 319 mg/dl, LDL: 233 mg/dl, Serum triglycerides: 191 mg/dl Thyroid function test was normal LH: 0.22 mIU/ml (1.7-8.6 mIU/ml) FSH: 1.9 mIU/ml(N: 1.5-12.1) Total testosterone: $<$0.025 ng/ml (2.5 -8.4) indicative of hypogonadotropic hypogonadism ANA: 29 IU/ml, Anti -DNA, Anti–LKM, ASMA, anti-TTG IgA: negative Normal Ceruloplasmin: 24 hr urinary copper, HbsAg and HCV Ab: negative Abdominal ultrasound: Enlarged liver with uniform soft fatty echo pattern, span of right lobe 22 cm, bone age: 13 years The patient was prescribed a basal-bolus insulin regimen With improvement of his blood glucose, liver enzymes. And liver size decreased significantly. follow-up labs after 6 weeks: ALT: 54 U/l, AST: 40 U/l, ALP: 292 U/l, GGT: 44 U/l LH: 2.8 mIU/ml, FSH: 4.3 mIU/ml, Total testosterone: 0.2 ng/ml During his follow-up, he got his puberty, and his final height was 149 cm.
Conclusion
In spite of advancement in diabetic management, MS a rare complication in poorly controlled T1DM still exists. A high index of suspicion is needed in T1DM

with delayed growth and puberty since good metabolic control could reverse this rare condition.

EP192

Infrared thermography may be considered a new tool for the early detection of diabetic neuropathy

Mahmoud Younis
Egypt Ministry of Health, كفر الشيخ, Egypt

Introduction
Diabetes mellitus is a multifaceted condition that involves both metabolic and inflammatory processes. Diabetic neuropathy is a progressive disorder that affects the nerves throughout the body. Thermography is a non-invasive, painless, and radiation-free test that uses infrared light to detect changes in the surface temperature of the body. Thermography can be used to monitor the progression of diabetic neuropathy. Thermography can be utilized to assess the effectiveness of treatment for diabetic neuropathy. Thermography can be used to monitor the progression of diabetic neuropathy. Thermography can be utilized to assess the effectiveness of treatment for diabetic neuropathy.
Materials and Methods
Grouping: 60 Participants with type 2 diabetes and mild diabetic peripheral neuropathy (DPN) and 60 healthy controls were divided into 2 groups: The first group: patients with type 2 diabetes mellitus with mild neuropathy and mild scoring on biothesiometer measurements from 16 to 20.30 female patients and 30 male patients. The second group are controlled healthy peoples not having diabetes mellitus.30 female patients and 30 male patients. This study used medical infrared imaging to visualize the temperature distribution of the feet of participants with diabetes mellitus (DM) and healthy controls. An infrared thermal imaging camera (BENETECH GT3251) was used to measure the temperature of the dorsal surface. The room temperature was kept at 25 degrees Celsius. Before the measurement, participants were required to remove their shoes and socks. Each participant was in a supine position, with the knee joint fully extended. This posture was maintained for 5 minutes so that the epidermal temperature could adapt to the standard room temperature.
Results
The results show that infrared thermography shows increased dorsum of the foot temperature compared to controls with pvalue <0.0001. The results show a direct correlation between the temperature of the dorsum of the foot and the vibration perception threshold of diabetic neuropathic patients with P-value <0.0001.
Conclusion
Infrared imaging can detect changes in skin temperature, which can indicate nerve damage. This technology has been used to identify early signs of diabetic neuropathy before symptoms become severe. By detecting neuropathy early, clinicians can intervene with treatments that may slow the progression of the disease.

Fatal rhinosinus disease in diabetic patients: about 8 cases

El Omri Malika[1], Jemli S[1], Lazid Sarra[1], Bellakhdher Mouna[1], Meherzi Abir[1], Houas Jihene[1], Ghammem Monia[1], Ach Taieb[2], Kermani Wassim[1] & Abdelkefi Mohamed[1]
[1]ENT department Farhat Hached hospital, Sousse, Tunisia; [2]Endocrinology department Farhat Hached hospital, Sousse, Tunisia

Introduction
Mucormycosis is a rare opportunistic aggressive fungal infection usually occurs patients with immune deficiency especially in diabetic. Extension is rapid, with a high rate of mortality. The pathogen is a filamentous fungus of the zygomycete class of the Mucorales order. The aim of this study to reveal clinical, paraclinical manifestations of this entity and its prognosis.
Material and methods
A retrospective study about 8 cases of mucormycosis diagnosed and treated in our ENT department between January 2000 and December 2023
Results
The mean age was 49 years with male predominance, the average duration of diabetes follow up was over 12 years. We noticed an orbital involvement in one case. Rhinocerebral mucormycosis was diagnosed in one patient. The infection was limited to the rhinosinus space in 6 cases. The causative agent was, exclusively, *Rhizopusarrhizus*. In all cases, surgical evaluation was immediately performed for debridement of the necrotic tissues, and multiple biopsies were performed for diagnostic purposes. The medical treatment was based in intravenous liposomal amphotericin B. The main complication was septicemia, seen in one case, after one week of evolution. We noted a complete recovery in 5 cases. Outcomes had been marked by the death of one patient who had a cerebral involvement.
Conclusion
ENT mucormycosis is a rare and severe fungal infection, to be borne in mind in diabetic patients. Late diagnosis and treatment inevitably incurs severe or even fatal complications. Only adequate early treatment, associating amphotericin B, necrotic tissue resection and control of risk factors can improve prognosis.

Immune checkpoint inhibitor (ICPi)-induced de novo type 1 diabetes mellitus: a case report

Maria Borg[1], Zachary Busuttil[1], Simon Mifsud[1], Arlène Gatt[1], Kelly Mifsud Taliana[2] & Sandro Vella[1]
[1]Mater Dei Hospital, L-Imsida, Malta; [2]Sir Anthony Mamo Oncology Centre, L-Imsida, Malta

Background
Immune checkpoint inhibitors (ICPis) have become a cornerstone of cancer management. Whilst endocrine-related adverse effects are one of the most common immune-related adverse events, ICPi-induced *de novo* diabetes occurs at low frequencies[1]. We describe a case of ICPi-induced *de novo* type 1 diabetes presenting with severe diabetic ketoacidosis (DKA) in a female with metastatic melanoma.
Case report
A 50-year-old lady was being treated with ICPis for metastatic melanoma. She initially received four cycles of combined ipilimumab (a cytotoxic T-lymphocyte-associated protein 4 [CTLA-4] checkpoint inhibitor), and nivolumab (a programmed cell death-1 [PD-1] checkpoint inhibitor) therapy followed by maintenance nivolumab. After the tenth cycle of nivolumab, she presented to the emergency department with fatigue, abdominal pain, vomiting, and polyuria. Laboratory investigations confirmed severe DKA as evidenced by plasma glucose of 67 mmol/l, blood ketones >7 mmol/l, and metabolic acidosis (pH:6.91, serum bicarbonate:8mmol/l). Treatment with intravenous fluids, a fixed rate of intravenous insulin infusion at 0.1 units/kg/hour, and electrolyte replacement was commenced immediately. Low-molecular-weight heparin was also prescribed for thromboprophylaxis. Further investigations including liver function tests, amylase, and inflammatory markers were normal. A septic screen excluded an infectious source. Antibodies to glutamic acid decarboxylase, tyrosine phosphatase-related islet antigen 2, islet cell, and insulin were negative. Following resolution of her DKA and review by the diabetologists, diabetes specialist nurses, and caring oncologist the patient was discharged on daily insulin glargine and thrice daily insulin aspart. She remained well upon review at her follow-up appointment where in the interim she was recommenced on nivolumab.
Conclusions
The use of PD-1 inhibitors is associated with an increased risk of type 1 diabetes when compared to CTLA-4 inhibitors, but when PD-1 inhibitors are combined with CTLA-4 inhibitors, this leads to an increased risk of diabetes at an earlier stage[1,2]. This case highlights how DKA is the most common presentation of ICPi-induced type 1 diabetes as a result of swift β-cell destruction and resultant insulin deficiency[2]. ICPi-induced type 1 diabetes is irreversible. Hence, such patients require life-long insulin treatment regardless of whether ICPi therapy is withheld[2]. Patients receiving ICPis, especially PD-1 inhibitors, should be informed about the symptoms and signs of diabetes, and to monitor their glucose levels.

Evaluation of the prevalence phenotypic criteria of GLIM on hospitalized patients in a third-level hospital: a cross-sectional study

Laura Mola Reyes, Rosa María García Moreno, Mary Llaro, Gonzalo Miñon Sanchez, Bricia López Plaza & Samara Palma Milla
La Paz University Hospital, Madrid, Spain

Rationale
The Global Leadership Initiative on Malnutrition (GLIM) criteria was recently proposed as the world's first diagnostic criteria for malnutrition in adults in hospital settings. The GLIM approach is based on the assessment of three phenotypic and two etiologic criteria, with diagnosis confirmed by any combination of one phenotypic and one etiologic criterion fulfilled. The purpose of this study was to evaluate the prevalence phenotypic criteria of GLIM in hospitalized patients.
Methods
A cross-sectional study was performed on adult patients admitted to Hospital Universitario La Paz who were assessed by the Nutrition Unit staff through interconsultation between August 2019 and November 2020 ($n=1036$) GLIM criteria were applied. The phenotypic criteria (unintentional weight loss [UWL] defined as weight loss $>5\%$ within the last 6 months or $>10\%$ beyond 6 months; low BMI defined as <20 kg/m^2 or <22 kg/m^2 in participants younger and older than 70 years, respectively; and reduced muscle mass [RMM] from mid-upper arm circumference) were analyzed according to the age group, sex, and underlying pathology. The Chi-square test was used in statistical analysis.
Results
The prevalence of GLIM phenotypic criteria in the population was: 56.7% UWL, 30.1% low BMI, and 23.4% RMM. Regarding age, we found significant differences in RMM, with a greater prevalence of RMM in those <70 years ($P<0.001$). In relation to sex, there was a higher prevalence of UWL and RMM in men ($P<0.001$ and $P<0.001$, respectively), while low BMI criterion was more common in women ($P=0.043$). The underlying pathology had a significant effect on the phenotypic criteria of low BMI and RMM ($P=0.001$ and $P=0.002$, respectively), with the higher prevalence of low BMI in patients admitted for gastrointestinal diseases and RMM in those admitted for infections.
Conclusion
Our results suggest that the age and gender of the hospitalized patients and their underlying pathology may have an impact on the prevalence of phenotypic GLIM criteria in this population.

Osteomielitis enfisematosa en pacientes diabéticos

Maria Jose Vallejo Herrera & Veronica Vallejo Herrera
Hospital Regional Málaga, Malaga

Introduction/Objectives
Emphysematous osteomyelitis is a rare disease, characterized by the presence of intraosseous gas associated with an infectious process. It occurs in patients with chronic pathologies such as diabetes mellitus, and has high mortality. The most common location is the vertebral, sacral, femur, pelvis, tibia and fibula, while it is extremely rare in the foot.
Material/Method
With the help of the Radiology service of our hospital, we collected cases of emphysematous osteomyelitis diagnosed by imaging (CT or MRI) in diabetic patients at the Regional Hospital of Malaga during the year 2023: one in the pubis and two in the foot. 2 men and 1 woman with an average age of 60-70 years and diabetes with poor metabolic control, case 1 died during admission. Case 1 70-year-old man, ex-smoker, type 2 diabetes and dyslipidemia. He was admitted for grade IV peripheral arterial disease with dry necrotic plaque on both forefeet of MMII and dry necrosis in the toes of the left foot, leukocytosis and elevated CRP. In Angio - CT of the Lower Limbs, he presented radiological signs of osteomyelitis in both feet, affecting the left calcaneus (emphysematous osteomyelitis) and phalanges bilaterally. Subcutaneous emphysema and collections adjacent to both calcaneus. EXITUS Case 2: A 62-year-old man, poorly controlled type 2 diabetes, poor adherence to treatment, diabetic polyneuropathy, previous amputations and peripheral arterial disease with ulcers in both lower limbs. He went to the emergency room due to metabolic decompensation and poor progress of a left plantar ulcer. Computed tomography and magnetic resonance imaging showed emphysematous osteomyelitis in the midfoot and forefoot, with extensive abscessed inflammatory involvement of adjacent soft tissues. Intravenous antibiotic treatment was initiated with subsequent infratuberosal amputation. HOSPITAL DISCHARGE Case 3. 63-year-old woman, DM on insulin. Cutaneous lupus. He was admitted for left pyelonephritis with areas of abscessation, with probable superinfection of the cortical cyst in the upper pole complicated with emphysematous osteomyelitis affecting the pubis. Complicated evolution with pelvic collections and emphysematous osteomyelitis of the pubis. Percutaneous drainage was performed, isolating E. coli, the same germ isolated in urine and blood cultures. HOSPITAL DISCHARGE
Conclusion
Imaging tests play an essential role in making early diagnosis and treatment, and reducing the mortality rate. CT can evaluate bone gas and MRI can evaluate soft tissues. Treatment is based on surgical debridement, amputation and intravenous antibiotic therapy.

A comprehensive assessment of some pathogenetic aspects of sarcopenic obesity

Svitlana Opalenyk[1], Olga Oleksyk[2] & Oksana Khyzhnyak[3,3]
[1]Uzhhorod National University, Medical faculty 2, Department of Internal Medicine, Uzhhorod, Ukraine; [2]A. Novak' Transcarpathian Clinical Regional Hospital, Endocrinology, Uzhhorod, Ukraine; [3]V. Danilevsky' Institute of Endocrine Pathology Problems, Clinical Endocrinology, Kharkiv, Ukraine

Introduction
Early diagnosis of obesity, as well as prevention of its occurrence in high-risk patients, plays an important role in the prevention of severe cardiovascular and cerebrovascular diseases. The study of leptin and ghrelin are one of important pathogenetic aspect of obesity. At the same time, such factors as hypodynamia, low physical activity and insulin resistance contribute to the formation of sarcopenic obesity, which is characterized by the loss of muscle tissue and muscle strength with replacement by adipose tissue.
The aim of the study was to carry out a comprehensive assessment of some pathogenetic aspects of diagnosis of sarcopenic obesity.
Materials and methods
68 obese and overweight patients were examined: 32 men and 36 women. The average age of the patients was 45 ± 11.73 years. Depending on the body mass index, all patients were divided into 2 groups: group I -31 overweight patients, group II - 37 patients with obesity I and II degrees. The control group - 20 healthy people. All patients underwent a bioimpedance examination with a study of the component composition of the body. Determination of the serum levels of ghrelin and leptin was carried out by the ELISA method. Statistical data processing was performed using the STATISTICA 10.0 computer program (StatSoftInc, USA).
Results
According to the results of the bioimpedance examination, all patients had a deficiency of muscle. The level of leptin in overweight patients was higher compared to the control group (3.1 ± 0.28 ng/ml), but was within the reference values (6.57 ± 0.39 ng/ml). At the same time, a significant statistically significant increase in the level of leptin was observed in obese patients compared to both studied groups (up to 41.72 ± 5.22 ng/ml). Ghrelin levels were increased in both groups and were highest in group 1 (up to 247.5 ± 10.09 ng/ml) and moderately increased in patients in group 2 (up to 120.93 ± 5.57 ng/ml), $P=0.005$ compared to controls. A positive correlation between serum leptin and the content of fat mass was also established ($r=0.89203$; $p=0.01303$). At the same time, a negative correlation between the level of ghrelin and fat mass ($r=-0.70641$; $P=0.030251$) was found in all studied patients.
Conclusion
Determining the level of ghrelin in blood serum is a more sensitive and informative pathogenetic marker for detecting the sarcopenic form of obesity at an early stage of the disease.

Estimated glucose disposal rate as a predictor of chronic complications in type 1 diabetes – a cross-sectional study

Nuno Jesus, Patrícia Tavares, Henrique Alexandrino, José Silva, Margarida Gonçalves, Ana Sousa, Gustavo Rocha, Marta Ferreira, Sara Correia, Sara Monteiro & Maria Oliveira
ULS Gaia e Espinho, Endocrinology Department, Vila Nova de Gaia, Portugal

Introduction
Insulin resistance, often implicated in the pathophysiology of Type 2 Diabetes Mellitus, can also occur in patients with Type 1 Diabetes Mellitus (T1DM), giving rise to a distinct phenotype that some authors describe as Double Diabetes - a population with a higher risk of developing chronic complications. The estimated glucose disposal rate (eGDR) is a validated marker of insulin resistance

in Type 1 Diabetes (T1DM), based on data obtained from the hyperinsulinemic-euglycemic clamp method. The eGDR formula uses common predictor variables in clinical practice: body mass index (BMI), glycated hemoglobin (HbA1c), and the presence of arterial hypertension (HTN). Insulin resistance is often reported as eGDR <8 mg/kg/min, and its relationship with macro-and microvascular complications is unclear. This study aims to investigate the relationship between eGDR and macro-and microvascular complications in T1DM patients from our Endocrinology – Diabetes outpatient clinic.

Methods

Patients with T1DM followed in the Endocrinology – Diabetes outpatient clinic were included, excluding those with hemoglobinopathies, pregnant individuals, and those with less than 5 years of disease duration. The eGDR was calculated using the formula: 19.02 - [0.22 $\times$ BMI (kg/m^2)] - [(3.26 x HTN (0 = absent; 1 = present)] - [0.61 $\times$ HbA1c(%)]. Prevalences of complications and comorbidities were compared between insulin-resistant and insulin-sensitive groups, and odds ratios were calculated for three eGDR categories (<6; 6-7.99; ≥ 8 mg/kg/min), defined according to an observational study that related eGDR to mortality differences, whenever possible.

Results

A total of 182 individuals with T1DM were included, with 51% being male. The average age was 38.5 years, and the average disease duration was 18.5 years. Approximately 30.9% of the sample was overweight, and 12.6% had obesity. The eGDR was less than 8 mg/kg/min in about 44% of individuals, and this group was associated with the presence of at least one chronic complication of T1DM (OR 5.344 [95% CI 2.824–10.112], *P*-value <0.001). The eGDR inversely varied with the prevalence of microvascular complications, with statistical significance for diabetic kidney disease, diabetic retinopathy, and peripheral neuropathy. Due to the low prevalence of macrovascular complications in the sample, it was not possible to calculate statistically significant odds ratios.

Conclusions

The eGDR is a validated tool for estimating insulin resistance. It is associated with the prevalence of chronic complications of T1DM, making it a potentially helpful tool for personalized therapy in T1DM patients.

before and during hospitalization, the severity of SARS-CoV-2 infection, and mortality in patients with type 2 diabetes
Methods
The 857 patients were divided into four groups according to blood glucose control. The first group included 365 patients with an average blood glucose ≤ 140 mg/dl, the second group included 201 patients with an average blood glucose of -140-180 mg/dl, the third group included 198 patients with an average blood glucose of 180-250 mg/dl, and 93 patients in the fourth group had an average blood glucose >250 mg/dl. In all subjects, we assessed preadmission diabetes treatment and prior diagnoses of major comorbidities (atherosclerotic cardiovascular disease, congestive heart failure, chronic renal disease, chronic pulmonary diseases, and dementia). Glucose control during hospitalization, diabetes medications before and during hospitalization, renal function, and glucocorticoid treatment were retrieved from electronic health data. COVID-19 death at 30 days was assessed in the four groups.
Results
Among patients with poor preadmission glucose control (Hba1c>9%), one-third had average blood glucose >250 mg/dl during hospitalization and only 8% had adequate blood glucose control. The overall 30-day mortality rate was 19% (192 patients out of 857) and was highest among patients with uncontrolled blood glucose during hospitalization compared to well-controlled blood glucose (32% vs. 14%). Significant predictors of mortality were the severity of COVID-19, acute renal failure, and a diagnosis of congestive heart failure before hospitalization
Conclusion
In patients with type 2 diabetes hospitalized with COVID-19, poor long-term glycemic control is associated with the level of hyperglycemia during hospitalization, and the COVID-19 severity.

Non-alcoholic fatty liver disease. change from F3 to F1 fibrosis after 12 months of combined pioglitazone and dulaglutide treatment

Luisa Lener[1], Marco Chianelli[2], Filomena Graziano[2], Irene Misischi[2], Lucilla Petrucci[2], Roberta Rinaldi[2], Enrico Papini[2] & Rinaldo Guglielmi[2]
[1]Catholic University of Sacred Heart, University Hospital 'A. Gemelli', IRCCS, Internal Medicine, Endocrinology and Diabetology, Rome, Italy; [2]Regina Apostolorum Hospital, Unit of Endocrinology and Metabolism, Albano, Italy

Background
Liver fibrosis is the result of the chronic hepatocyte damage due to different causes. Among them, Non-alcoholic Fatty Liver Disease (NAFLD) is estimated to account for nearly 30% of cases, representing a leading cause of chronic liver disease. NAFLD can evolve into non-alcoholic steatohepatitis, with or without fibrosis, whose diagnosis requires a liver biopsy, a costly and invasive procedure. Non-invasive tests have recently been proposed to screen patients at risk of fibrosis. For instance, fibrosis-4 index (FIB-4) is an effective screening tool for the selection of patients at risk of fibrosis who have indication to liver biopsy. Although there is no established treatment for NAFLD, studies suggested a favorable influence of specific anti-diabetes drugs, such as glucagon-like peptide-1 receptor agonist (GLP-1 RA) and peroxisome proliferator-activated receptor γ (PPARγ) agonists. It is still debated, however, whether these drugs are effective once liver fibrosis has occurred.
Clinical case
A 64-year-old woman referring to our outpatient clinic for dyslipidemia and type 2 diabetes was treated with Vildagliptin 50 mg/bid. and Simvastatin 20 mg/die. She complained of mild right upper quadrant abdominal pain thus, in consideration of her clinical history, FIB-4 was calculated (2.39, n.v. <1.45); Metavir score at liver elastography was F3 (severe fibrosis); liver biopsy confirmed mild fibrosis. Diabetes treatment was shifted to dulaglutide 1.5 mg/week and pioglitazone 30 mg/die. After 12 months, Metavir score at elastography was F1 (fibrosis absent or mild). FIB-4 decreased to 1.63, thus liver biopsy was not performed. 6 months later, weight gain and fluid retention occurred. Empagliflozin 25 mg/die was added to treatment, reducing the symptoms.
Discussion
Recent studies proved the efficacy of dulaglutide in reducing liver fat content and preventing the progression of fibrosis. Pioglitazone promotes the uptake of free fatty acids and lipogenesis, reducing the saturation of subcutaneous adipose tissue, a key factor in the deposition of visceral fat. The reduction of visceral fat and the anti-inflammatory effects of these drugs may explain why they could induce a partial regression of the fibrosis, particularly in early stages. Preclinic studies have demonstrated that, activating the PPARγ pathway, pioglitazone directly inhibits IGF-1-induced collagen deposition in hepatic stellate cells. This might enable hepatic progenitor cells to differentiate into functional hepatocytes and replace the damaged liver tissue. Nevertheless, pioglitazone is rarely used due to its unfavorable effects on weight gain. In our patient, the addition of a Sodium/Glucose Cotransporter 2 inhibitor partially counterbalanced these side effects.

Bilateral charcot foot: case report

Imane el ghebir & Ait Abderrahmane Samir
Army Central Hospital, Diabetology, Algiers, Algeria

Introduction
Charcot foot is a rare and particular form of diabetic foot that presents a diagnostic and therapeutic challenge. It can lead to gross structural deformities of the foot and ankle, and subsequent skin ulceration and lower limb amputation from soft tissue or bony infection.
Case report
We report the case of Mr B.D, aged 55, type 2 diabetic for 29 years, poorly controlled despite intensified insulin treatment, at the stage of micro and macroangiopathic complications. He is hypertensive on triple therapy and has a history of multiple episodes of infection in both feet, resulting in amputation of the distal phalanx of the left big toe. He was admitted to our department for treatment of a left plantar neuropathic ulcer. Clinical examination revealed a plantar ulceration on the left foot opposite the 1st metatarsal head measuring 3 cm, painless, surrounded by significant hyperkeratosis and not infected, claw-like deformity of the 2nd toe. Both feet flat, oedematous, dry skin and hyperkeratosis of the heels, monofilament tactile sensitivity and achilles reflex abolished, neuropathic pain graded 5/10 according to DN4, permanent pain in both ankles. Normal IPS at 1.18 on the right and 1.12 on the left. This the lesion can be classified P1E2D2I1S2 according to the PEDIS classification on feet classified guard 3 according to podological risk. Investigation revealed fasting blood glucose of 1.24, HbA1c of 11% and a negative inflammatory panel. The standard X-ray of the left foot was without abnormality, while the MRI revealed extensive remodelling of the Chopart's joint space, suggestive of Charcot foot. Standard radiography of the right foot revealed major osteoarticular destruction of the ankle, suggestive of Charcot foot, confirmed by CT and MRI. Treatment consisted of progressive control of diabetes, strict off-loading of both feet by Aircast with preventive anticoagulation. Local care and oily dressings twice a week.
Discussion
Diabetic osteoarthropathy is a serious complication of diabetes whose early diagnosis is complex and often delayed. It manifests itself in the acute phase by localized inflammation of the foot or ankle, and in the absence of discharge. It leads to severe bone damage. Cases of bilateral Charcot's Foot are not frequent, from 5.9-39.3% of cases according to studies. Accurate diagnosis can lead to appropriate treatment and subsequent reduction in the risk of skin ulceration and lower limb amputation among an already high risk population.

The effect of physical activity on sleep quality in middle-aged diabetic patients

Sana Khamassi, Emna Bornaz, Haifa Abdesselem, Marouani Nouha, Kamilia Ounaissa & Chiraz Amrouche
National Institute of Nutrition, Outpatient Department and Functional Explorations, Tunis, Tunisia

Introduction
Sleep and physical activity (PA) are crucial lifestyle components for primary prevention. Governments worldwide have aimed to promote regular PA among diabetic patients to prevent complications and reduce mortality rates. Furthermore, literature data suggests that physical activity contributes to an enhancement in sleep quality[1]. This study aims to assess the level of PA and the sleep quality (SQ) in adults with type 2 diabetes and analyze the correlation between these two parameters.
Materials
One hundred adults with type 2 diabetes were enrolled in this study. Physical activity level was assessed using the Ricci and Gagnon questionnaire. Patients

were asked to complete Pittsburgh sleep quality index (PSQI) to assess SQ[2]. The total PSQI score was obtained by adding seven scores corresponding to seven components of SQ and a total score >5 indicates significant sleep disturbance and categorizes the subjects as poor sleepers.

Results

Mean age was 54.45±7.13 years with female predominance (72%). High blood pressure was reported in 40% of the study population and more than two thirds of patients (70%) had dyslipidemia. Mean diabetes duration was 12.67±7.35 years, 79% used insulin while 21% of patients used oral glucose-lowering drugs (OGLDs) only. Mean BMI was 29.49 ±4.97 kg/m^2. Half of our sample was obese (49%). Mean Ricci and Gagnon total score was 18.20±8.11 with extremes ranging from 9 to 38. More than half of our sample (57%) were inactive, 40% were active, and only 3% of patients were very active. The mean PSQI score was 7.89±3.69 and 69 % of our patients had poor sleep quality. The Ricci and Gagnon score was negatively correlated with the PSQI total score ($P=0.024$; $r=$ - 0.236). Regarding its relationship with sleep components our study revealed that the physical activity level was negatively correlated with self-reported sleep quality ($P=0.013$; $r=$-0.257), habitual sleep efficiency ($P=0.032$, $r=$-0.224) and daytime dysfunction ($P=0.003$; $r=$ - 0.303).

Conclusion

Our study suggests that physical activity could be an area of focus for interventions to improve sleep quality, which is often compromised in diabetic population.

Association of glycoregulation, microvascular complications and comorbidities in patients with diabetes mellitus in the republic of srpska/bosnia and herzegovina - cross-sectional study

Snjezana Popovic Pejicic[1,2], Anja Jankovic Pejicic[3], Nina Pejicic[1,2] & Ljiljana stanivuk[4]

[1]University of Banja Luka, Faculty of Medicine, Banja Luka, Bosnia and Herzegovina, Banja Luka, Bosnia and Herzegovina; [2]University Clinical Center of the Republic of Srpska, Banja Luka, Bosnia and Herzegovina, Banja Luka, Bosnia and Herzegovina; [3]Medical University of Vienna, Vienna, Austria; [4]Institute of Public Health of Republika Srpska, Banja Luka, Bosnia and Herzegovina

Introduction and objective

Unsatisfactory glycoregulation is the main cause of the development of diabetic microvascular complications. The gold standard for monitoring glycoregulation is glycated hemoglobin (HbA1c). The aim of the research is to determine the association between glycoregulation, microvascular complications and comorbidities in patients with diabetes in Republika Srpska (RS).

Methods

The study was conducted as a cross-sectional study, with the participation of 1088 patients with diabetes in RS. Anthropometric measurements, blood pressure measurement, serum albumin and creatinine, the ratio of albumin and creatinine in urine (ACR), total cholesterol (C), LDL-C, HDL-C, tryglicerides and HbA1c were performed in all patients. For screening of diabetic retinopathy, a nonmydriatic fundus camera with a field of 45 degrees was used, and for the diagnosis of neuroischemic and polyneuropathic changes in the foot was used neurological hammer, sound fork 128Hz and monofilament test with 10 g with mandatory neurological examination.

Results

The study included 1037 patients with diabetes, T1D4.6 % and T2D95.4 %, 576 women (55.5 %) and 461 (44.5%) of men, with an average age of 64.0 ±10.58. Unsatisfactory glycoregulation (HbA1c ≥ 6.5%) had 61.1% of patients ($\chi^2=$ 4.874, df=1, $P=0.027$). The duration of diabetes affected the deterioration of glycoregulation, statistically significantly more common in T2D ($\chi^2=62{,}070$, df=2, $P=0.000$). Patients with diabetes over 10 years (84.60% T1Di 76.10% T2D) had more frequent unsatisfactory glycoregulation (HBa1c≥ 6.5%) Based on the value of BMI, 50.1% of these patients were obese (≥30 kg/m^2), and based on waist circumference, abdominal obesity had 75.6% with a higher frequency in T2D compared to T1D (50.1:15.7%). Elevated blood pressure values (≥ 130/80 mmHg) were recorded in 88.61% i.e., 918 of these patients. Patients with unsatisfactory glycoregulation had significantly higher ACR values compared to satisfactory (79.50 mg/g: 39.00 mg/g) ($P<0.001$). Microalbuminuria was the most common microvascular complication (48.10%), polyneuropathy (42.5%) and retinopathy (25.0%). Polyneuropathy (T2D 43.0%; T1D31.4%) and microalbuminuria (T2D 49.10%; T1D 26.0%) were more common in patients with T2D ($\chi^2=10.217$, df =1, $P=0.001$), while retinopathy (T2D 24.6%; T1D31.4%) was more common in T1D.

Conclusion

Patients with diabetes in RS have a high percentage of unsatisfactory glycoregulation associated with microvascular complications and comorbidities, primarily obesity and hypertension. The results are similar to many studies in developing countries and indicate the need to implement additional measures to improve glycoregulation and reduce microvascular complications and comorbidities.

Amyotrophic lateral sclerosis (als): analysis from a nutritional perspective

Irene Zayas Aguilar, María González Pachecho, María del Mar Roca Rodríguez, María Alarcón Manoja & Francisco Javier Vilchez

Hospital Universitario Puerta del Mar, Endocrinology and Nutrition Department, Cádiz, Spain

Introduction

ALS is a neurodegenerative disease with a high prevalence of malnutrition. Nutritional diagnosis is important because of its prognostic implication.

Objective

To determine the clinical and morphofunctional characteristics in a series of patients with ALS.

Materials and methods

Cross-sectional descriptive study of patients seen at the multidisciplinary ALS clinic of the Hospital Puerta del Mar (Cádiz).

Results

17 patients, 58.8% women, mean age 68 years and weight 64.9 kg. The mean time of symptoms evolution was 39 months (64.7% spinal symptoms). Distribution according to disease stage: I 5.9%, II 35.3%, III 41.2% and IV 17.6%. The mean ALSFRS-R scale score 32 (moderate progression). 64.7% had dysphagia, with mean duration 6 months and 35.3% had nutritional risk or were classified as malnourished (The Subjective Global Assessment (SGA) B or C). Mean nutritional ultrasound parameters: (1) Anterior rectus quadriceps: area 3.17 cm^2, Y axis 1.07 cm, (2) Abdominal adipose tissue: total 1.73 cm and preperitoneal 0.55 cm, (3) Masseter: 1.12 cm. BIA: Phase angle 3.7º, Hydration 73.8%, Fat free mass 42.8%, Fat mass 23.1 kg, BCM 17.3 and ASMM 14.3 kg. Patients with SGA B or C had a higher weight percentage (11.1 vs 1.65%; P 0.032) and lower fat mass (16.7 vs 24.2 kg; P 0.039). There was a negative correlation between ALFRS-R score and preperitoneal fat ($r=$ - 0.837, $P<0.001$), and positive correlations between weight and fat mass ($r=$ 0.752, $P<0.001$), between lean mass and ASMM ($r=$ 0.966, $P<0.001$) and between lean mass and BCM ($r=0.776$, $P<0.001$).

Conclusions

In our cohort, malnutrition is highly prevalent. Overall, there is a marked decrease in phase angle, with a significant reduction in fat mass in malnourished patients. The prognostic value of these findings in the follow-up of the disease needs to be assessed.

Ultrasound parameters	**Median**
Area anterior rectus quadriceps	**3.17 cm^2**
Y axis anterior rectus quadriceps	**1.07 cm**
Abdominal adipose tissue: total	**1.73 cm**
Abdominal adipose tissue: total	**0.55 cm**
Masseter	**1.12 cm**
BIA Parameters	**Median**
Phase angle	**3.7º**
Hydration	**73.8%**
Fat free mass	**42.8%**
Fat mass	**23.1 kg**
BCM	**17.3**
ASMM	**14.3 kg**

Variables of diabetes distress and glycated hemoglobin in patients with type 2 diabetes mellitus

Volodymyr Pankiv
Ukrainian Scientific and Practical Center of Endocrine Surgery, Transplantation of Endocrine Organs and Tissues of MoH of Ukraine, Prevention and Treatment of Diabetes Mellitus and its Complications, Kyiv, Ukraine

Background
Among potential barriers for people with diabetes mellitus (DM) to reach glycemic goals is diabetes distress. Accumulating evidence suggests diabetes distress may be linked to individuals' emotion regulation capacities.
The aim of this study was to explicate the relationships between variables of glycated hemoglobin (HbA1c), diabetes distress, emotion regulation, and self-care variables through the analysis of cross-sectional data from individuals with type 2 DM.
Materials and methods
We used structural equation modeling to assess the cross-sectional relationships between variables of HbA1c, diabetes distress, emotion regulation, and self-care variables through the analysis of cross-sectional data from 95 individuals with Type 2 DM. After giving informed consent agreeing that their data would be used for research purposes without identifying them, study participants were evaluated by clinical psychologists with a structured clinical assessment and a series of other assessments relevant to DM.
Results
Study examined two potential explanatory models with one of the models showing a more comprehensive view of the data revealing a total effect of poor emotional regulation on HbA1c levels. Diabetes distress in adults is linked with heightened negative emotionality (Emotion Regulation-Experience) and reduced skill at emotional regulation (Emotion Regulation-Skill) in adults, both of which are related to elevated HbA1c levels and that these relationships are stronger than that with diabetes self-care.
Conclusions
This study suggests that, in people with DM, elevated HbA1c levels and diabetes distress are linked with poor emotion regulation. These data suggest that targeting difficulties in emotion regulation may hold promise for maximizing improvement in diabetes distress and HbA1c in individuals with DM.

Bridging the gap between short stature and metabolic alterations in children born small for gestational age: an exploratory study

Giulia Rodari[1,2], valeria citterio[2], Valentina Collini[2], Alessandro Risio[2], Eriselda Profka[1,2], Federico Giacchetti[1], Giovanna Mantovani[1,2] & Claudia Giavoli[1,2]
[1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Endocrinology Unit, Milan, [2]University of Milan, Department of Clinical Sciences and Community Health

Introduction
Children born small for gestational age (SGA) represent a heterogeneous population, displaying different phenotypes for both growth and metabolic status. Low birth length and/or weight increases the risks for not only growth impairment but also for metabolic derangements, the latter with an even amplified risk in children with rapid postnatal weight gain. Variability in metabolic parameters, catch-up growth as well as different GH treatment responses are still poorly understood.
Aims
We investigated a possible association between anthropometric/metabolic parameters in SGA children.
Methods
This cross-sectional observational study evaluated a series of 58 children aged between 4 and 15.7 years, with birth weight and/or length $<$ -2.0 SDS according to INeS Growth Charts. All patients with underlying chronic conditions, GH deficiency, other endocrinopathies and known genetic syndromes were excluded. Anthropometric (height-HT, Mid-parental height-MPH, weight, weight gain at 24 months, Body Mass Index-BMI, Tanner stage, body composition by Body Structure Analyzer BC-420MA TANITA) and metabolic (fasting glycemia and insulin, glycosylated hemoglobin-HbA1c) parameters were collected. Insulin resistance (HOMA-IR) and sensitivity (QUICKI) were calculated.
Results
Fifty-eight SGA patients (F 33/58, 57%), with a mean age of 9.5 $\pm$ 2.9 years were consecutively enrolled. In 22.4% of patients HT was below -2.0 SDS. Mean HT was 129.8 $\pm$ 17.7 cm, -0.88 $\pm$ 1.29 SDS according to WHO Growth Charts with a MPH distance (MPH SDS-HT SDS) of 0.70 $\pm$ 1.36 SDS. As far as glycemic profile was concerned, glycemia was in the normal range in all study patients apart from one with impaired fasting glucose (107 mg/dL), mean glycemia was 82.7 $\pm$ 7.9 mg/dl, mean HbA1c 35 $\pm$ 3 mmol/mol, with a median HOMA I of 1.45 (IQR 0.74-2.7) and QUICKI of 0.36 (IQR 0.32-0.39). At multiple regression, HbA1c was positively associated with HT SDS ($P = 0.005$), even after correction for MPH ($P = 0.01$). Moreover, weight gain at 24 months was positively associated with HT SDS ($P = 0.021$). No association was found between weight gain and metabolic parameters.
Conclusions
Our results suggest a possible relationship between postnatal height catch-up growth and metabolic impairment, as underlined by the association found between HT and HbA1c, even after correction for mid-parental height. This is only an explorative analysis; we would like to confirm our results on a larger scale in order to eventually bridge the gap between height gain and metabolic impairment in SGA children.

A rare cause of glucosuria and aminoaciduria in a patient with well-controlled diabetes mellitus

Saohoine Inthasot[1], Julien Vanderhulst[1], Sien Van Daele[2], Evelien Van Hoof[2], Cyrielle Kint[3], Laura Iconaru[4] & Jeroen de Filette[4]
[1]CHU Brugmann, Department of Internal Medicine, Université Libre de Bruxelles, Brussels, Belgium; [2]University Hospitals Leuven, Center for Human Genetics, Catholic University Leuven, Leuven, Belgium; [3]KU Leuven, Centre of Microbial and Plant Genetics, Leuven, Belgium; [4]CHU Brugmann, Department of Endocrinology, Université Libre de Bruxelles, Brussels, Belgium

Background
Familial renal glucosuria (FRG) is a rare renal tubular disorder characterized by increased urinary glucose excretion despite normoglycemia. The sodium-glucose cotransporter 2 (SGLT2) is expressed in the proximal renal tubule and is crucial for glucose reabsorption. *SLC5A2* is a member of the solute carrier family V transporter genes and encodes for this cotransporter. Mutations in *SLC5A2* are the primary cause of FRG.
Case presentation
We report the case of a 44-year-old male who was referred for unexplained glucosuria despite well-controlled diabetes mellitus (with fasting glycemia 138 mg/dl and HbA1c 6,5%) treated with metformin and gliclazide. He was diagnosed with diabetes mellitus at the age of 38. He complained of an unintentional 5-kg weight loss in one year (despite normal appetite) and nycturia. A 24-hour urinary collection revealed overt glucosuria (24,2 g/1,73 m^2/24 h) as well as generalized aminoaciduria (hydroxyproline, serine, glycine, alanine, valine, cystine, isoleucine and lysine) and increased uric acid excretion. Renal function was preserved and proteinuria was absent. Whole exome sequencing with analysis of the nephropathy gene panel was performed (with specific attention to the *SLC5A2* and *HFN1A* genes (MODY 3)) and revealed a novel heterozygous c.469-1G $>$ A variant in the *SLC5A2* gene. This mutation was classified as class 4 (likely pathogenic) according to the American College of Medical Genetics guidelines. In-silico analysis predicted a possible splice defect. No other pathogenic variants were detected. Familial genetic testing was recommended to the patient and his children.
Discussion
The *SLC5A2* gene encodes the kidney-specific low-affinity/high-capacity sodium-glucose cotransporter, SGLT2. Mutations in *SLC5A2* are associated with FRG, which is considered to be a benign disorder of proximal tubular glucose transport. FRG can be inherited in an autosomal recessive or autosomal dominant pattern. Individuals with bi-allelic pathogenic variants are considered to have a more severe phenotype than patients who only have a heterozygous variant. Generalized or selective aminoaciduria is a feature of FRG, although it has been suggested that aminoaciduria in this setting is a consequence of the impairment of glucose reabsorption rather than directly related to the *SLC5A2* mutation.
Conclusion
We describe a patient with renal glucosuria despite well-controlled diabetes mellitus, associated with a novel heterozygous c.469-1G $>$ A mutation in the *SLC5A2* gene. The pathogenesis of aminoaciduria and hyperuricosuria with aberrant renal glucose transport remains to be established.

Association of advanced glycation end products with diabetic retinopathy in type 1 and type 2 diabetes

Diana Simoniene[1], Lina Radzevičienė[1,2], Deimantė Paškevičienė[2] & Rasa Verkauskienė[1,2]
[1]Hospital of Lithuanian University of Health Sciences Kaunas Clinics, Endocrinology, Kaunas, Lithuania; [2]Institute of Endocrinology, Lithuanian University of Health Sciences Kaunas Clinics, Endocrinology, Kaunas, Lithuania

Some studies suggest that Advanced Glycation End products (AGEs) formation represent important and interconnected pathogenic mechanisms in diabetic retinopathy (DR).
The aim of this study was to investigate the association of AGEs products with DR in a cohort at Hospital of LHUS.
Methods
It was a cross-sectional study of a cohort of adults with type 1 or 2 type diabetes (T1D/T2D).
Results
78 patients with T1D and 81 with T2D were recruited. The overall incidence of any DR was 50.9 %. The prevalence of DR was significantly higher among patients with T1D compared to T2D group (70.5 vs 32.1 %, $P<0.001$). Patients with T1D had higher risk for DR in comparison to T2D (OR 5,059 [2,578-9,927], $P<0.001$). Univariate logistic regression revealed that higher risk for DR in T1D was related with diabetes duration > 11 years OR 60,563 [13,75-266,752], $P<0,001$, mean AGE Reader level > 1,8 OR 6,947[2,242-21,526], $P=0,003$, male gender OR 2,938[1,007-8,569] ($P=0,044$) and dyslipidaemia OR 3,231[1,103-9,464] ($P=0,029$). Higher risk for DR in T2D was related with diabetes duration > 13 years OR 4,604 [1,701-12,462], $P=0,002$, OR 6,947 [2,242-21,526], $P<0,001$ and albuminuria > 6.3 mg/24 hrs OR 10,431[2,681-40,586], $P=0,001$. In binary logistic regression analysis, the highest risk for DR was associated with dyslipidaemia OR 6 (0.99-36.26) $P=0.051$ and diabetes duration > 11 years OR 76 (13.63-423.73), $P<0.001$ in T1D. In T2D DR was associated with HbA1c > 7.5 % OR 7.42 (2.23-24.58), $P=0.001$ and diabetes duration > 13 years OR 4.35 (1.42-13.34), $P=0.01$.
Conclusions
Diabetic retinopathy prevalence in Lithuanian cohort was 50.9 %. Patients with T1D had a five times higher risk for DR in comparison to T2D. In univariate models, DR in T1D was significantly associated with mean AGE score, diabetes duration, male gender and dyslipidaemia, in T2D - with HbA1c level, increased albuminuria level and diabetes duration. In binary logistic regression analysis, diabetes duration remained the most significant predictor for DR in both types of diabetes. T1D patients with diabetes duration > 11 years and T2D patients with diabetes duration > 13 years, will have the highest rate risk of DR.

Hypoglycemia and beyond

Felicia Visconti, Marcella Libera Balbo, Daniela Rosso, Francesca Garino, Daniela Sansone & Salvatore Endrio Oleandri
ASL Città di Torino, S.C. Endocrinologia e Malattie Metaboliche, Torino, Italy

Introduction
Hirata Syndrome (SH) is a rare cause of autoimmune hypoglycemia, characterized by elevated circulating insulin levels without concomitant increase in C-peptide, anti-insulin antibodies positivity and pancreas alterations absence in patients never exposed to exogenous insulin. It is also known as insulin autoimmune syndrome (IAS) and is a relatively rare cause of spontaneous hypoglycemia. The syndrome was first described in 1970 by Yukimasa Hirata in Japan, the country where the highest number of cases was subsequently recorded.
Case report
77-year-old woman came to the emergency room for an episode of profuse sweating and aphasia. -for two months she had frequent lipothymic episodes for which she had undergone cardiological tests, the results of which were normal. Blood sugar levels were found to be 27 mg/dl on blood chemistry tests, whereby 10% glucose solution was administered, reaching glycemic values at the lower limits of normality, making it impossible to reduce or suspend therapy. Abdominal CT and echoendoscopy were negative for pancreatic lesions and hypoadrenalism was excluded (ACTH: 20 pg/ml, cortisolemia: 10.7 mg/dl). Fasting test was started: after 3 hours, the patient complained of sweating and tremor, with concomitant findings on blood tests: glycemia 29 mg/dl, insulinemia: 747 microU/ml, c-peptide: 4.9 mg/l, anti-insulin Ab: 11 U/ml (nv.: < 2.4). Autoimmune hypoglycemia was diagnosed, and patient started steroid therapy with prednisone 25 mg/day. The patient started flash glucose monitoring, showing an adequate response to steroid therapy, with progressive reduction of hypoglycemic episodes and normalization of glycemic levels. The patient was discharged, and at the endocrinological visit after one month steroid tapering was possible, according to the glycemic values.
Conclusion
Autoimmune forms of hypoglycemia are rare among Caucasians but should be taken into consideration in the setting of unsuppressed insulin levels, to avoid misdiagnosis of insulinoma. Treatment involves primarily the use of corticosteroid therapy or, in more severe cases, greater immunosuppressive drugs such as azathioprine. In extreme cases plasmapheresis can be necessary.

Diabetes mellitus after ocrelizumab treatment for primary progressive multiple sclerosis

Marco Grasso, Nino Cristiano Chilelli, Vera Frison & Alessio Filippi
Hospital of Cittadella, Diabetology Unit, Cittadella, Italy

Introduction
immune reconstitution therapies, which include cell-depleting monoclonal antibodies targeting CD20+ (ocrelizumab) or CD52+ (alemtuzumab) leukocytes, are approved for the treatment of multiple sclerosis. Autoimmune thyroid disease is the most common adverse effect of alemtuzumab, but some cases of autoimmune diabetes have been reported. To date, diabetes mellitus has not been reported after CD20-targeting monoclonal antibodies therapy.
Case presentation
A 41-year-old Caucasian man with primary progressive multiple sclerosis was started on ocrelizumab in July 2021, after the finding of active disease on MRI and progression of neurological symptoms. The patient had a family history of autoimmune thyroiditis. He was non-smoker, not overweight (BMI 24.5 kg/m^2), and treated with lamivudine for chronic hepatitis B and baclofen. There were two previous findings of impaired fasting glucose. In January 2022, before the second ocrelizumab administration, the urine test showed glycosuria (> 1000 mg/dl) and proteinuria, without ketonuria. In the last few weeks, the patient had reported polyuria and polydipsia, but no blurred vision or weight loss. HbA1c and blood glucose level confirmed the diagnosis of diabetes mellitus (87 mmol/mol and 442 mg/dl, respectively). The patient underwent further tests to clarify the etiology of hyperglycemia. GADA, IA-2A and ICA were found negative; C-peptide indicated a well-preserved beta-cell function (2.7 ng/ml). Renal and liver function were normal. Other autoantibodies related to endocrine diseases, such as TPO-Ab and ACA, were found negative. We started a strict glucose monitoring and basal-bolus insulin treatment (total daily dose 58 IU, 0.75 IU/Kg). Down-titration of insulin dosage had been progressive and relatively rapid: 43 IU after two weeks, 36 IU after the first month, 24 IU after six weeks. We added metformin 1000 mg and, after four months, insulin treatment has been permanently discontinued. The patient continued ocrelizumab treatment, but severe hyperglycemia has no longer occurred. In August 2023, the blood test showed a HbA1c level of 39 mmol/mol, indicative of an optimal glycemic control with only metformin.
Conclusions
this is the first case of diabetes mellitus reported after ocrelizumab administration. The timing of onset and course are similar to alemtuzumab-induced autoimmune diseases, usually defined as an 'immune reconstitution syndrome'; nevertheless, cell depletion induced by ocrelizumab shows some differences in duration and cell population affected. This case suggests the need for screening and follow-up of glycemic status in patients treated with this monoclonal antibody. Further investigation is required to elucidate the correlation between hyperglycemia and ocrelizumab.

A ketogenic diet as feasible treatment for post bariatric weight regain

Fiammetta Cipriani[1], Maria chiara Massari[1], Maria Letizia Spizzichini[1], Davide Masi[1], Ilaria Ernesti[2], Alfredo Genco[2], Silvia Migliaccio[1], Stefania Mariani[1], Lucio Gnessi[1], Carla Lubrano[1] & Mikiko Watanabe[1]
[1]Department of Experimental Medicine, Section of Medical Pathophysiology, Food Science and Endocrinology, Sapienza University of Rome, 00161 Rome, Italy; [2]Surgical Endoscopy Unit, Department of Surgical Sciences, Sapienza University of Rome, Rome, Italy

Introduction
Metabolic surgery is the most effective long-term treatment for obesity. However, studies reveal that up to 40% of post-bariatric subjects experience long-term weight regain (WR), particularly those who discontinue surgical and nutritional follow-ups. In contrast, the ketogenic diet emerges as a pivotal therapy for obesity, showing convincing evidence in weight loss and improvement of weight-related complications.
Purpose
This study aims to evaluate the safety and efficacy of a very-low calorie ketogenic diet (VLCKD) in the treatment of post-bariatric WR.
Materials and Methods
This prospective, single-center pilot study involved patients with previous metabolic surgery (RYGB or Sleeve gastrectomy) who had clinically significant WR after successful initial weight loss. Inclusion criteria included age between 18 and 65 years, a BMI ≥ 30 kg/m^2, while exclusion criteria included pregnancy/lactation, type 1 diabetes mellitus, renal and hepatic disease, alcoholism, and major psychiatric disorders. The primary outcome was weight loss, while secondary outcomes focused on safety, improvements in metabolic profile, and body composition. All participants followed an 8-week nutritional intervention with VLCKD, limiting their carbohydrate intake to less than 50 g/day and with adequate protein intake at 1.2-1.5 g/kg of ideal body weight. Dietary counseling was provided every 4 weeks by an experienced dietitian, and compliance was assessed by dietary recalls and beta hydroxybutyrate measurements. Patients underwent biochemical and body composition assessment by DXA scan at baseline and after dietary intervention.
Results
Fifteen patients were enrolled (10 females, 5 males) with a mean age of 49 ± 11 years and a mean BMI of 40.27 ± 6.59 kg/m^2. After 8 weeks, patients showed an average weight loss of 7.2%, a significant reduction in waist circumference ($P < 0.001$), hip circumference ($P = 0.007$) and improvement in body composition indices: reduction in fat mass ($P < 0.001$) and lean mass to fat mass ratio ($P = 0.03$). Favorable changes in glyco-metabolic balance were reported with a significant reduction in LDL cholesterol levels ($P = 0.03$). Safety parameters (renal function, uric acid, electrolytes) remained stable; the only adverse event reported was mild constipation.
Conclusions
This study emphasizes the efficacy of the VLCKD in the management of post-bariatric WR, demonstrating satisfactory weight loss and improved body composition without safety concerns. However, long-term weight loss maintenance remains uncertain without significant changes in lifestyle or pharmacotherapy. Further studies should explore the efficacy of dieting, including different weight loss scenarios and emphasizing maintenance strategies.

Reactive hypoglycaemia: A challenge in clinical practice

Usman Shah, Anna Hawkins, Raj Tanday, Azin Mohammadpoor, Nancy Enriquez & Khash Nikookam
Barking, Havering and Redbridge Hospitals University NHS Trust, United Kingdom

This is a case of a 38-year-old lady with a past medical history of Ehlers Danlos Syndrome, functional neurological syndrome and unremarkable cardiac investigations for palpitations. She was referred by her general practitioner (GP) with episodic shaking, excessive sweating, recurrent hypo-and hyperglycaemia recorded by her own capillary blood glucose (CBG) meter, ranging from 1.9mmol/l to 19mmol/l. The episodes would mostly occur 1 to 3 times per week, usually in the afternoon and last for approximately 15 minutes. She denied loss of consciousness and the episodes would leave her feeling either weak or fine. All her medications (Duloxetine, bisoprolol and oral contraceptive pill) were stopped prior to her endocrine appointment. She was admitted following recurrent hypoglycaemia and with presenting symptoms suggestive of urinary tract infection. She had various investigations including a normal IGF-1, coeliac screen, a short synacthen test (SST) with 0, 30 and 60mins serum cortisol response of 452, 658 and 820 respectively, normal 24 hr urine metanephrine and a 72 hour fast which did not reveal any spontaneous hypoglycaemia. Subsequent prolonged oral glucose tolerance test (OGTT) was indicative of Type2 Diabetes Mellitus with a CBG at 0 mins of 6.3 and at 120 mins of 12.1mmol/l. She experienced symptoms of headache, tiredness and sweating at 240 mins with a CBG of 3.5mmol/l. The patient has continued to experience hypoglycaemic episodes in daily life. She has therefore been advised to have smaller meal portions but more frequent intake which she reports have reduced her hypoglycaemia episodes.
Conclusion
Reactive hypoglycaemia could be a cause of recurrent hypoglycaemia in individuals with or without diabetes mellitus. Reactive hypoglycaemia can be a debilitating condition with a significant impact on one's general wellbeing and daily activities. Diagnosing and understanding of reactive hypoglycaemia would potentially change one's life for the better.

Depression in elderly diabetics: prevalence and impact on glycemic control

Maryam Cheikhrouhou, Kamilia Ounaissa, Chaima Sdiri, Haifa Abdesslem, Sana Khamessi, Emna Bornaz & Chiraz Amrouche
national nutrition institute, Department of Nutritional Diseases D, Tunisia

Introduction
Depression is a frequent pathology in elderly subjects, due to lifestyle changes, age and the high frequency of comorbidities. Our study aimed to assess the prevalence of depression in a group of elderly diabetics and to investigate its impact on diabetes control.
Methods
This was a cross-sectional study, conducted in a group of 200 type 2 diabetic patients, aged 70 years or more. We screened for depression using the 15-point geriatric depression scale (GDS15). The diagnosis of depression was made if the score was < 5. Depression was considered mild to moderate if the score was between 5 and 9 and severe if the score was ≥ 10.
Results
The meanage was of 74.7 ± 4.2 years, ranging from 70 to 90 years. A female predominance wasn oted with a sex ratio M/F = 0.62. The mean duration of diabetes was 16.5 ± 9.26 years. The mean GDS15 score was 4.35 ± 2.8. Depression was diagnosed in 45.5% of patients. It was severe in 7.5% of cases and it was more frequent in the 75-80 yearsage group. It was more frequent in women then in men (60.2% vs 22.1%, $P < 0.001$). Patients with a GDS15 score below 5 had a better glycemic control than those with GDS15 scores more then 5 (51.4% vs 34.1%, $P = 0.014$). Likewise, we found a statistically significant relationship between depression on one hand and the occurrence of hypoglycemia ($P < 0.001$), the presence of diabetic retinopathy ($P = 0.04$) and diabetic neuropathy ($P = 0.004$) on the other hand.
Conclusion
Systematic screening and appropriate management of depression are essential in elderly diabetic patients in order to improve patients' quality of life.

EP273

The association between heat exposure and hospitalization for diabetic ketoacidosis, hyperosmolar hyperglycemic state, and hypoglycemia. a scoping review

Emmanuel Sandoval Garcia[1] & Stephani Rubi Hellwege[2]
[1]Royal Infirmary of Edinburgh, United Kingdom; [2]University Hospital of Zürich, Zürich, Switzerland

Introduction
Global mean surface air temperatures have risen by about 1 °C in the past century and are projected to increase by another 1–6 °C by 2100 depending on greenhouse gas emissions. As a result of the increase in mean temperatures, heatwaves have become more severe, frequent, and prevalent. Heat exposure in ambient temperature is associated with all-cause diabetes mortality and all-cause hospitalisation in people with diabetes. However, there is a paucity about the current evidence of the association between heat exposure and hospitalisation for hyperglycaemic emergencies, such as diabetic ketoacidosis (DKA), hyperosmolar hyperglycaemic state (HHS), and hypoglycaemia. This scoping review aims to map existing literature and provide a summary of diabetic ketoacidosis (DKA), hyperosmolar hyperglycemic state (HHS), and hypoglycaemia and heatwaves in people with diabetes. This includes risk factors, interventions and identification of research gaps in the literature.
Methods
Electronic databases (MEDLINE, EMBASE, and, Global Health) were systematically and independently searched following the Joanna Briggs Institute (JBI)

guidelines. Two independent researchers assessed the literature and conducted the review according to the Preferred Reporting Items for Systematic Reviews and Meta-Analysis guidelines for Scoping Reviews (PRISMA-ScR). Covidence was used for for title/abstract screening, full-text screening, data extraction, and quality assessment.
Results
Of the 4406 articles screened, 75 articles met inclusion criteria and 12 were included for this scoping review. The majority of studies were cross-sectional concentrated in the Americas, Asia and Australia. The findings indicated that heat exposure was associated with an increased risk of hospitalisations for DKA, HHS but not hypoglycaemia. There was a lack of information regarding other environmental conditions such as humidity, air pollution and extreme weather events which may interact with these outcomes.
Conclusions
People with diabetes face heightened susceptibility to health threats linked to climate change, such as increased heat exposure. This research has the potential to inform proactive measures against the elevated risk of hyperglycaemic emergencies. These findings offer an opportunity for developing public health initiatives aimed at managing heatwaves in the contemporary context of global warming. Implementing policies that acknowledge the interplay between climate change and diabetes outcomes could improve the overall health of the diabetic population. Clearly, further studies are necessary for investigating potential solutions to tackle this crisis

Endocrine disorders in adult patients with inherited metabolic diseases: their diagnosis and long-term management

Adrian Heald[1], John Bassett[1], John Warner-Levy[1], Nuria Puente-Ruiz[2], Peter Clayton[3] & Karolina Stepien[2]
[1]Salford Royal Hospital, Salford, Department of Endocrinology and Diabetes, Salford, United Kingdom; [2]Northern Care Alliance NHS Foundation Trust, Adult Inherited Metabolic Disorders, Salford, United Kingdom; [3]Royal Manchester Children's Hospital, Manchester University NHS Foundation Trust, Manchester, UK, Manchester, United Kingdom

Background
Inherited metabolic disorders (IMDs) are a group of heterogenous genetic disorders resulting in substrate accumulation, energy deficiency or complex molecular defects due to the failure of specific molecules to act as enzymes, cofactors, transporters, or receptors in specific metabolic pathways. The pathophysiological changes seen in IMDs sometimes impact on the endocrine system. We here describe our experience at one UK centre where patients are seen jointly by an endocrinologist and an IMD specialist.
Methods
The study has two parts: 1) a review of the types of IMDs and the endocrine problem, to understand the molecular mechanisms in the metabolic pathways that might have led to the hormonal dysfunction; 2) service development for joint working between the endocrinology and metabolic specialities.
Results
61.0% of the attendees are women and 67.5% of patients have a solitary endocrine disorder with (sub)infertility problems being the most frequent reason for attendance. 28.2% had 2 endocrine conditions and 4.435% had at least 3 endocrine complications. The most prevalent IMDs related to endocrine complications included Classical Galactosemia (15.2%), X-linked Adrenoleukodystrophy (10.9%), Mucopolysaccharidosis type I Hurler (8.7%) who underwent Haemopoietic Cell Transplantation in childhood, and mitochondrial disorders. The mechanisms of endocrinopathy were directly related to the metabolic pathway of an IMD in most patients. Learning disability was a feature of several IMDs; in our cohort, 26.0% had mild/moderate type of learning disability.
Conclusion
Endocrine disorders are long-term complications of IMDs. Thus awareness among endocrinologists of the potential for an IMD to be the underlying cause of an endocrine presentation is important. Signs and symptoms of common hormonal problems may be wrongly attributed to the underlying IMD, if not diagnosed promptly. Hormonal dysfunction may be the first manifestation of previously unknown IMDs in adults in both men and women and further investigations may lead to a diagnosis of an attenuated form of an IMD in adulthood. Advice on hormonal replacement therapy choice should consider its effects on metabolism and efficacy.

Plasma SHBG levels as an early predictor of response to bariatric surgery

Pablo Gabriel-Medina[1], Roser Ferrer[1,1,2,2], Francisco Rodriguez-Frias[1], Marta Comas[3], Ramon Vilallonga[4], Andreea Ciudin[3] & David Selva[5]
[1]Vall d'Hebron University Hospital, Clinical Biochemistry Department, Barcelona, Spain; [2], Clinical Biochemistry Department, Barcelona; [3], Vall d'Hebron University Hospital, Endocrinology and Nutrition Department, Barcelona, Spain; [4]Center of Excellence for the EAC-BC and Vall d'Hebron University Hospital, Endocrine, Metabolic and Bariatric Unit, Barcelona, Spain; [5]Vall d'Hebron Research Institute, Diabetes and Metabolism, Barcelona, Spain

Background
Obesity is a growing global health problem and currently bariatric surgery (BS) is the best solution in terms of sustained total weight loss (TWL). However, a significant number of patients present weight regain (WR) in time. There is a lack of biomarkers predicting the response to BS and WR during the follow-up. Plasma SHBG levels, which are low in obesity, increase one month after BS but there is no data of plasma SHBG levels at long term. We performed the present study aimed at exploring the SHBG role in predicting TWL and WR after BS.
Methods
Prospective study including 62 patients with obesity undergoing BS. Anthropometric and biochemical variables, including SHBG were analyzed at baseline, 1, 6, 12, and 24 months; TWL $\geq$25% was considered as good BS response.
Results
Weight loss nadir was achieved at 12 months post-BS where maximum SHBG increase was reached. $\geq$25% TWL patients presented significantly higher SHBG increases at 1st and 6th month follow-up respect to baseline (100% and 150% respectively, $P=0.025$), than $<$25% TWL patients (40% and 50% respectively, $P=0.03$). Also, these presented 6.6% WR after 24 months. The 1st month SHBG increase predicted BS response at 24 months (OR=2.71; 95%CI=[1.11-6.60]; $P=0.028$) and TWL in the 12th month ($r=0.330$, $P=0.012$) and the WR in the 24th month after BS ($r=-0.301$, $P=0.028$).
Conclusion
Our results showed for the first time that increase in plasma SHBG levels within the first month after BS is a good predictor of TWL and WR response after two years.

The effects of different weight-loss interventions on Bile acid and FGF-19 metabolism and correlation with metabolic improvement

Preeshila Behary[1,2], Kleopatra Alexiadou[1], Tracey Mare[3], Julian Walters[4], David Taylor[3], Royce Vincent[3] & Tricia Tan[1,2]
[1]Imperial College London, Section of Endocrinology and Investigative Medicine, London, United Kingdom; [2]Imperial College Healthcare NHS Trust, Department of Endocrinology, London, United Kingdom; [3]King's College Hospital NHS Foundation Trust, Department of Clinical Biochemistry (Synnovis), London, United Kingdom; [4]Imperial College Healthcare NHS Trust, Department of Gastroenterology, London, United Kingdom

Background
Bariatric surgery, dietary restriction and gut hormones treatment for obesity, lead to distinctive changes in weight-loss maintenance and glycaemia. We previously showed that Roux-en-Y Gastric Bypass (RYGB) and Very-Low-Calorie-Diet (VLCD) were superior in weight-loss, compared to a tripeptide hormone infusion of G lucagon-like Peptide-1, O xyntomodulin and P eptide-YY over a month (**GOP**, infused at doses to replicate their peak post-prandial concentrations as seen at 1 month after RYGB). However, better glycaemic improvement with superior glucose variability attenuation were observed with GOP (1). Bile acids (BA) are important mediators of energy and glucose metabolism. The aims of this study are to investigate the acute and long-term changes in BA metabolism post-RYGB, relative to other weight-loss interventions and to correlate with metabolic improvement.
Methods
Obese participants with type 2 diabetes/pre-diabetes underwent RYGB or a VLCD or were randomised to GOP infusion. Fasted and post-prandial BA and FGF-19 were measured following a mixed meal test, at baseline and 1-month after all 3 interventions, and additionally at 2-3 years post-surgery. Fifteen plasma BA fractions were measured using a liquid chromatography-tandem mass spectrometry. A mixed-effects analysis with Bonferroni correction was applied for within-group comparison.

(Abstract EP278)

	Weight loss (%)		Fructosamine (μmol/l)			Fasting BA (μM/l)		
	1-month	2-3 years	Baseline	1-month	2-3 years	Baseline	1-month	2-3 years
RYGB ($n=20$)	8.8±0.6*	26.7±2.5*	248.3±8.0	216.4±4.8*	241.1±5.1	3.9±0.4	3.2±0.5	4.4±0.8
GOP ($n=14$)	3.7±0.4*		304.1±17.2	261.7±12.7*		3.1±0.3	2.2±0.1*	
VLCD ($n=20$)	7.6±0.4*		254.9±8.5	225.1±7.3*		2.8±0.3	3.0±0.6	

Mean ±SE, *$P<0.05$ compared to baseline

Results
Study subjects were well matched for baseline characteristics. Changes in weight, fructosamine and fasting BAs are described below:
At 1-month, fasting and post-prandial BA remained statistically unchanged after RYGB and VLCD, but there was a significant reduction in total and other BA parameters with GOP. Post-prandial FGF-19 concentrations decreased with GOP, but no significant change was noted from baseline after RYGB and VLCD at 1-month. However, at 2-3 years post-RYGB, there were significant increases in post-prandial total BAs and the 12 hydroxylated:12 non-hydroxylated BA ratio, as well as an increase in post-prandial FGF-19 concentrations were observed.
Conclusion
Different weight-loss interventions have distinctive effects on the BA/FGF-19 axis. Despite its lowering effect on several BA fractions and FGF-19 concentrations, significant weight loss and improvement in glycaemia were still observed following a tripeptide gut hormone infusion. Total post-prandial BAs and FGF-19 were only increased at 2-3 years post-RYGB, suggesting a potential role in the long-term rather than short-term efficacy of RYGB.

Prediction of post-COVID syndrome development in type 2 diabetes: retrospective analysis based on national survey in Ukraine
Anton Matviichuk[1], Vitalii Gurianov[1], Viktoriia Yerokhovych[1], Oleksandr Livkutnyk[2], Tetyana Falalyeyeva[3,4], Iuliia Komisarenko[1], Oksana Sulaieva[4] & Nazarii Kobyliak[4,5]
[1]Bogomolets National Medical University, Kyiv, Ukraine; [2]Kyiv City Clinical Endocrinology Center, Kyiv, Ukraine; [3]Taras Shevchenko National University of Kyiv, Kyiv, Ukraine; [4]Medical Laboratory CSD, Scientific, Kyiv, Ukraine; [5]Bogomolets National Medical University, Endocrinology, Ukraine

Background
Post-COVID-19 condition (long COVID-19, post-acute COVID-19, long-term effects of COVID-19) is an emerging health problem in people recovering from COVID-19 infection within the past 4-6 months. Patients with type 2 diabetes (T2D) are in the risk group for a more severe course of COVID-19 and the development of its complications.
Aim
to define the prevalence and prediction of post-COVID-syndrome development in patients with T2D according to retrospective analysis based on national survey in Ukraine.
Method
The retrospective analysis include data from 403 patients who suffered from COVID-19 infection in different regions on Ukraine. Among these patients, 168 (41.7%) developed post-COVID syndrome and 235 (58.3%) reported it absence. Patients were asked to fill out specially developed questionnaires for the purpose of retrospective assessment of the main parameters. The questionnaires included the following information: anthropometric indicators, year of diagnosis ofT2D, existing T2D complications history of COVID-19, COVID-19 severity and treatment, post-COVID phenotype and symptoms, duration of post-COVID syndrome, hypoglycemic therapy, levels of HbA1C, lipids and basic biochemical indicators. The stepwise multivariate logistic regression and PNN (Probabilistic Neural Network) models were used to select independent risk factors. The ROC curve analysis was used to assess the accuracy of models.
Results
As a result of the selection, 8 independent factor associated with the risk of post-COVID development in T2D patients were selected: treatment of COVID-19 with steroids (OR 1.73, 95% CI 1.06 – 2.84; $P=0.029$), remdesmevir (all patient presented), mechanical ventilation (OR 36.9, 95% CI 4.2 – 322; $P=0.001$), myocardial infarction (OR 2.68, 95% CI 1.3 – 5.5; $P=0.007$) and stroke (OR 4.18, 95% CI 1.79 – 9.75; $P=0.001$) in anamnesis, T2D duration (OR 0.94, 95% CI 0.9 – 0.97; $P=0.001$), commbination of anti-diabetic drugs with insulin (OR 2.98, 95% CI 1.35 – 6.58; $P=0.007$) and used of insulin analogues (OR 2.94, 95% CI 1.34 – 6.48; $P=0.007$). It should be noted that the indicators. In ROC analysis 8-factorial model constructed with PNN AUROC 0.831; 95% CI 0.791–0.866) significantly better predict post-COVID syndrome development as compared multiple regression model (AUROC 0.759; 95% CI 0.714–0.800; $P=0.004$)
Conclusion
Treatment of COVID-19 with steroids, remdesmevir, mechanical ventilation, myocardial infarction and stroke in anamnesis, T2D duration, commbination of anti-diabetic drugs with insulin and use of insulin analogues are the main predictors of post-COVID development. The prediction of post-COVID with PNN are clearly accurate as compared to step-wise logistic regression model.

Fluasterone (16-α-fluoro-5-androsten-17-one) is a structural analogue of dehydroepiandrosterone (DHEA) that retains DHEA clinical properties without its androgenic effects. In animal models, fluasterone exhibits DHEA-like effects, including anti-inflammatory, anti-proliferative, and anti-diabetic properties but is consistently more potent than DHEA. An orphan-drug designation for fluasterone has been granted by the FDA for treatment of Cushing's syndrome (CS), including hyperglycemia, nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatosis (NAS). Oral DHEA was shown to produce remission of hyperglycemia in mice. Oral fluasterone was shown to be superior to control in reduction of plasma glucose levels and while DHEA is highly androgenic, producing 25-fold increase in plasma testosterone levels and a dose-related increase in seminal vesicle weights, these findings were not present in mice treated with fluasterone. The mechanism of the anti-glucocorticoid effect of fluasterone has not been established. Fluasterone prevents thymic involution induced by treatment with pharmacological doses of dexamethasone in mice, which indicates marked anti-glucocorticoid action independent of any changes in endogenous glucocorticoid levels. In mice, fluasterone, when injected subcutaneously at 5 mg/kg, decreased plasma corticosterone levels, and this was correlated with lowering of fasting plasma glucose. As the dose of fluasterone was increased, corticosterone and fasting plasma glucose levels both rebounded due to increased corticotropin. In mice that develop NAFLD, 8-wk treatment with fluasterone lowered inflammation and NAS fibrosis. In humans, a total of 105 adults have received one or more oral or buccal doses of fluasterone during seven phase-1 and phase-2 trials. Because oral fluasterone underwent extensive first-pass metabolism, oral dosing was discontinued. Nevertheless, oral studies showed efficacy in patients having either rheumatoid arthritis or hypertriglyceridemia. Buccal fluasterone was then investigated in a phase 1/2 study of 24 adults with metabolic syndrome who received an 8-wk, once-daily buccal tablet of fluasterone or placebo. The triglyceride levels in the 80 mg fluasterone group

declined from baseline by 34% at week 2, 4, 6, and 8 and by 35% at week 8. In the placebo group, at the corresponding time points the triglyceride levels increased by 6% and 7%, respectively. The decline in triglyceride level from baseline in the 80 mg buccal fluasterone group was significantly greater than that in the placebo group with no adverse events reported. Thus, we propose a double-blind, placebo-controlled, crossover pilot study of the efficacy and safety of buccal Fluasterone in the control of hyperglycemia in adults with CS.

Enigma of hypogonadism in men with type 2 diabetes: central or peripheral origins?

Anis Grassa[1], Manel Jemel[1], Salma Salhi[1], Marwa Chiboub[1], Brahim Khalfa[2], Rahma Mahjoub[2], Emna Talbi[2], Hager Kandara[1] & Ines Kammoun[1]
[1]National Institute of Nutrition and Food Technologies, Zouheir Kallel, Endocrinology, Tunisia; [2]National Institute of Nutrition and Food Technologies, Zouheir Kallel, Biochemistry, Tunis, Tunisia

Introduction
Male hypogonadism (HG), characterized by a decrease in testosterone levels, becomes more prevalent with age, significantly impacting the quality of life. A noteworthy association with type 2 diabetes (T2D) has increasingly captured medical interest. The critical question persists: is the HG observed in T2D patients of central or peripheral origin? This study delves into this inquiry to enhance our understanding and inform better management.
Methods
We recruited 68 adult male patients with type with T2D and HG from outpatient clinics at the National Institute of Nutrition and Food Technology. Testosteronemia, Sex Hormone-Binding Globulin and albumin, for calculating Free Testosterone (FT) and Bioavailable Testosterone (BT) using the Vermeulen formula[1]. The diagnostic criterion for HG included specific thresholds: Total Testosterone (TT) below 231 ng/dl, FT below 6.5 ng/dl or BT below 150 ng/dl. Hypogonadism was Hypergonadotropic (HGHyper) if LH $>$ 8.6 mIU/ml, and hypogonadotrophic (HGHypo) if LH values $\leq$ 8.6 mIU/ml. For HGHypo cases, magnetic resonance imaging (MRI) was performed in case of clinical and/or biological signs, indicating pituitary hypersecretion or insufficiency, or if TT was below 150 ng/dl.
Results
The median age of the studied population was 59 years with an interquartile range of [56–64]. The highest prevalence of HG was observed in patients aged 60 to 65, reaching 49%. The prevalence of HG did not show statistical significance ($P=0.270$) in the age groups. The central origin of HG was identified in 75% of cases ($n=51$). There was no significant correlation between patients' age and the nature of HG (58.4 $\pm$ 5.6 vs 59.9 $\pm$ 6.4; $P=0.366$). Four patients required an MRI-HH justified by TT $<$150 ng/dl. The etiological investigation didn't reveal anomalies in all cases.
Conclusion
The study demonstrates a predominance of the central origin of hypogonadism in patients with type 2 diabetes, irrespective of their age. Emphasis is placed on the importance of thorough hormonal exploration for this population. Further investigations are necessary to elucidate underlying mechanisms and guide the development of more personalized therapeutic strategies.

Evaluation of nurses 'knowledge on diabetic foot wounds management

Dhoha Ben Salah, Kouloud Boujelben, Mohamed Khairi Arous, Mouna Elleuch, Faten Haj Kacem Akid, Fatma Mnif, Nadia Charfi, Mouna Mnif, Mohamed Abid & Nabila Rekik Majdoub
Hedi Chaker Hospital, Endocrinology, Sfax, Tunisia

Introduction
Diabetic foot wounds (DFW) are one of the most challenging complications of diabetes. DFW is one of the leading causes of foot ulceration and amputation in patients with diabetes mellitus. Then, a multidisciplinary approach is of a great importance in the prevention and management of DFW. Healthcare personnel, particularly nurses, have an important role in this process. The objective of our study was to evaluate nurses 'knowledge on diabetic foot wounds management.
Patients and methods
We conducted a cross sectional study between September and November 2021. Knowledge were assessed by referring to a questionnaire based on International Working Group on the Diabetic Foot (IWGDF) recommendations, designed to evaluate the knowledge levels of 50 nurses, working in various departments of diabetology, regarding DFW management.
Results
The average age was 30,9 years (25-58 years). There were 45 females and only 5 males. Twenty four percent of nurses reported that patients with diabetes mellitus should be referred to podiatric physicians when they developed hyperkeratosis. Sixty six percent of our population reported that hyperkeratosis may be removed by a 20 minute bathfoot. Thirty eight percent of nurses knew principal characteristics of neurological wounds. Thirty four percent of asked population were able to identify ischemic wounds. Thirty percent of nurses recognized that a wound is considered chronic when the healing process exceeds 4 to 6 weeks. Thirty four percent of respondents were familiar with chronic wound cleaning with saline physiological serum. Fourty four of nurses knew that the removal of fibrinous tissue requires mechanical debridement. Only 8% of patients knew the infected wounds classification according to Texas University systems.
Conclusion
Levels of foot care knowledge and approach are various among studies. Our study highlights the importance of foot care in patients with diabetes mellitus and the need of regular training courses for nurses.

EP290

Association between emerging lipid indicators and diabetic degenerative complications

Youssef Gharbi, Bchir Najla, Bel Hadj Sliman Chayma, Annam Benchhida, Dorra Dorraelguiche, Zouaoui Chadia & Haroun Ouertani
Military Hospital of Tunis, Endocrinology, Tunis, Tunisia

Introduction
Screening and preventing the onset of degenerative complications of type 2 diabetes is the cornerstone of patients follow up. Recently, new emerging indicators have been suggested to be more sensitive for the early detection of the onset of micro and macroangiopathies. These indicators emerge from the involvement of metabolic syndrome, dyslipidemia and glycemic imbalance in endothelial dysfunction. Among these indicators, we cite the atherogenic index (TC-(HDL-C))/HDL-C), the atherogenic plasma index (LDL-C/HDL-C) and the HbA1C/HDLc ratio. The objective of our study was to evaluate the association between these indicators correlated with atherosclerosis and degenerative complications of diabetes.
Methods
It was a cross-sectional study that included 100 type 2 diabetic patients followed at the Tunis Military Hospital for a period of 3 months. An assay of the various biological parameters dating back for less than six months as well as an evaluation of micro and macroangiopathies were carried out.
Results
In our population, patients had an average HbA1C of 10.51% $\pm$ 2.44% and 88% of patients had dyslipidemia. Regarding the impact of diabetes, the distribution of degenerative complications was 50% for diabetic retinopathy, 61% for diabetic neuropathy, 43% for diabetic nephropathy, 7% for stroke, 32% for coronary heart disease and 9% for peripheral arterial disease. Diabetic nephropathy was significantly associated with the atherogenic plasma index ($P=0.041$) and the HbA1C/HDLc ratio ($P=0.003$). As for microalbumiuria, it was associated with the atherogenic index ($P=0.024$) and atherogenic plasma index ($P=0.007$). However, no association between these different indicators and the other degenerative complications of diabetes has been found.
Conclusions
Positive associations suggest that the atherogenic index, the atherogenic plasma index and the HbA1C/HDLc ratio may be good indicators of the occurrence of diabetic nephropathy in the Tunisian population. However, larger multicenter studies are needed to determine their exact place as an indicator of the occurrence of degenerative complications of diabetes.

Defining male hypogonadism in type 2 diabetes: a fresh approach and diagnostic insights

Anis Grassa[1], Manel Jemel[1], salma salhi[1], Brahim Khalfa[1], Meriem Adel[1], Asma Krir[2], Ahlem Benhmid[2], Hager Kandara[1] & Ines Kammoun[1]
[1]National Institute of Nutrition and Food Technologies, Zouheir Kallel, Tunis, Tunisia; [2]Pasteur Institute of Tunis, Tunis, Tunisia

Introduction
The association between male hypogonadism (HG) and type 2 diabetes (T2D) has become a growing focus in medical research. However, a major challenge stems from the lack of consensus in defining HG, leading to variations in diagnostic thresholds among different medical societies. This study addresses this challenge by proposing a new perspective on the classification and thresholds of HG.
Methods
The research focused on a group of 250 adult male individuals with T2D. A comprehensive assessment of gonadal hormones was conducted to calculate Free Testosterone (FT) and Bioavailable Testosterone (BT) using the Vermeulen formula, available at https://www.issam.ch/freetesto.htm[1], and adhering to the suggested cut-off values[2]. Diagnostic criteria for male HG included specific thresholds, such as Total Testosterone (TT) below 231 ng/dl or TT$\geq$ 231 ng/dl with FT below 6.5 ng/dl, and/or BT below 150 ng/dl. Additionally, participants responded to an Arabic-validated ADAM questionnaire [3]
Results
The median age of our population was 58 years, with an interquartile range (IQR) of [52.7–62]. The prevalence of HG was 27.2% ($n=68$). In our study, a significant correlation was observed between responses to the ADAM questionnaire and the diagnosis of HG ($P<10^{-3}$). The most notable differences in clinical signs between the HG and non-HG groups were the decrease in muscle strength and endurance, present in 86.6% vs 46.1% ($P<10^{-3}$), followed by erectile dysfunction, present in 82.1% vs 52.2% ($P<10^{-3}$), and a decrease in libido, present in 65.7% vs 37.8% ($P<10^{-3}$). Biologically, the differences between the HG and non-HG groups for mean levels of TT, FT, and BT were 301 vs 491.5 ng/dl ($P<10^{-3}$), 5.6 vs 9.8 ng/dl ($P<10^{-3}$), and 124.6 vs 213.9 ng/dl ($P<10^{-3}$), respectively. A TT level $>$ 350 ng/dl was noted in 173 (69.2%), among whom 17 were diagnosed as having HG (6.8%).
Conclusion
In conclusion, this study offers a new perspective on addressing the definition of male hypogonadism within a T2D population and emphasizes the importance of standardizing diagnostic criteria for HG to enhance sensitivity and clinical management within this population.

arGLP-1: our experience in a tertiary hospital in southern spain

Víctor Siles-Guerrero[1], Patricia Vílchez-Fernández[2], Piedad Santiago-Fernández[1] & Martín López-de-la Torre Casares[1]
[1]Hospital Universitario Virgen de las Nieves, Servicio de Endocrinología y Nutrición, Granada, Spain; [2]Hospital Universitario Virgen de las Nieves, Servicio de Cirugía General, Granada, Spain

Objectives
The development of drugs to aid weight loss as an adjunct to dietary and lifestyle recommendations prior to surgical treatment of obesity may help in the management of these patients. To compare the percentage of weight loss among patients who received dietary recommendations (Group 1) and lifestyle recommendations vs those who added arGLP1 semaglutide 1 mg sc (Group 2) or liraglutide 3 mg sc (Group 3) to these recommendations, analysing other variables such as the presence of diabetes mellitus.
Methods
Patients undergoing bariatric surgery from 01/01/2022 to 01/09/2023 were reviewed using normality, t-Student, ANOVA and non-parametric tests with the Jamovi v2.3.28 software.
Results
Included were 67 females and 31 males with a mean age 49.2 $\pm$ 8.97 SD years with a baseline weight 128 $\pm$ 20.1 kg, who followed treatment for 29.2 $\pm$ months: (1) diet: 48 patients 28.33 $\pm$ 22.9 SD months, (2) diet with semaglutide 1 mg sc: 21 patients 22.14 $\pm$ 18.23 SD months and (3) diet with liraglutide 3 mg sc: 19 patients 11.42 $\pm$ 14.15 SD months. At the end of follow-up they lost: - 5.98% $\pm$7.82 SD kg. In the percentage of weight loss there were no differences between sexes, whether or not they used aGLP1, but the loss was greater in those treated pharmacologically ($P<0.001$), being -10.2 $\pm$ 7.89 SD with diet and drugs and -3.09 $\pm$ 6.37 SD Kg with diet alone. 83% achieved losses greater than 5% and 48% greater than 10% with pharmacological treatment. There was no difference when comparing Liraglutide sc vs Semaglutide sc in weight loss. In the 26 DM2 patients treated with arGLP-1, weight loss was lower (-8.8% $\pm$ 6.42 kg) than in non-DM2 patients (-10.6% $\pm$ 7.29 kg) ($P<0.05$).
Conclusions
Adding arGLP-1 to dietary and lifestyle changes treatment improves the percentage of weight loss achieved before bariatric surgery, reaching the usual recommended 10% weight loss, being more effective in non-DM, without differences between sexes or arGLP-1 used.

Diabetes and psychiatric disorders: optimizing dual care

Manal Bennani, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
Ibn Rochd University Hospital - Clinical Neuroscience and Mental Health Laboratory Faculty of Medicine and Pharmacy - Hassan II University-, Department of Endocrinology, Nutrition and Metabolic Diseases, Casablanca, Morocco

Introduction
A mental disorder is characterized by a significant clinical impairment in an individual's cognitive state, emotional regulation, or behavior. It typically accompanies a sense of distress or functional impairments in crucial areas of life. The coexistence of diabetes and mental illness is not uncommon. However, due to the necessity of a collaborative approach between healthcare providers and patients to optimize treatment and considering the chronic nature of both conditions, it is essential to explore specific aspects.
Objective
Our study aims to assess factors influencing the management of diabetic patients with psychiatric disorders to enhance their adherence to treatment and follow-up.
Materials and Methods
This is a retrospective descriptive study conducted at the Endocrinology and Diabetology Department of CHU IBN ROCHD in Casablanca. It focuses on diabetic patients with psychiatric disorders requiring specialized hospital care in either the psychiatry or endocrinology department from January 2021 to December 2023; data were collected using Excel.
Results
In our study, 112 patients were included, comprising 68 men and 44 women. The overall average age of diabetic patients with psychiatric disorders was 40 years (ranging from 15 to 61 years). Two distinct peaks were observed: one during adolescence, where depression predominated, and another around 54 years, with a clear prevalence of psychoses. The prevalence of type 1 diabetes was higher in adolescence, with the basal-bolus regimen being essential, necessitating educational, medicinal, and psychotherapeutic support to prevent multiple hospitalizations due to complications such as ketoacidosis or hypoglycemia. Underlying depressions were often identified during stays in the endocrinology department in 22% of cases. For patients with type 2 diabetes or those with a debated diabetes type, representing 50% and 28% of the sample, respectively, and facing challenges in the applicability of educational strategies during psychoses or situations of hetero-aggression, oral antidiabetics were preferred if HbA1c values and diabetes duration allowed. Otherwise, premixed or basal-plus regimens were considered.
Conclusion
Managing diabetic patients with mental disorders remains a challenge for both healthcare professionals and caregivers. Thus, collaboration between endocrinologists, psychiatrists, and psychotherapists is crucial to mitigate the complications associated with these conditions.

Management of bell palsy in diabetic patients

Meherzi Samia[1], Omri Rihab[2] & Iansari Salma[2]
[1]Universitu of Sousse, Faculty of Medecine of Sousse, ENT Department, Tunisia; [2]University of Sousse, Faculty of Medecine of Sousse, ENT Department, Tunisia

Objective
Our study aims to review the therapeutic management guideline of diabetic patients who presented with Bell's palsy.

Materials and Methods
A retrospective study which consisted of 35 diabetic patients with idiopathic peripheral facial paralysis (PFP) over a period of 3 years (from January 2020 to December 2022). All patients underwent a complete ENT examination, a neurological examination, and a minimal assessment including a complete blood count, blood glucose measurement, and an audiometry (tonal audiometry + impedance audiometry).
Results
Our series identified 10 female and 25 male, with an average age of 47 years (26–65 years). Others than diabetes, risk factors for PFP were found within 29 patients, involving hypertension, hematological disorders, and pregnancy. Twenty-four cases were classified as type 2 diabetes, 22 of them were treated with Oral antidiabetic medications. All patients presented with an unilateral facial asymmetry, with an average delay of consultation of 3 days. In the initial physical examination, 20 patients presented with mild-to-moderate facial palsies (grades I-III), while moderate-to-severe palsies (grades IV–VI) were observed in fifteen of the patients. Twelve patients underwent a cerebral computed tomography, completed in one case of a magnetic resonance imaging, showing normal results. Stapedial reflex was absent in 19 cases. Eleven patients were treated on an outpatient basis while twenty-four patients required hospitalization, including 4 children. Corticosteroid therapy based on prednisolone or methylprednisolone was initiated in all patients with an average duration of 7 days. Antiviral treatment, always in combination with corticosteroid therapy, was prescribed for 21 patients with an average consultation delay of 3 days. All patients received vasodilators and vitamin therapy. Facial rehabilitation was initiated in all cases with an average delay of 7 days (3–10 days). After 1 year of follow-up, 19 patients recovered normal facial tone
Conclusion
Bell's palsy is the most common form of facial paralysis therefore it remains a diagnosis of exclusion. The therapeutic management in diabetics relies on an early combination of corticosteroids and antivirals. The prognosis is often favorable, with the potential for aesthetic and functional sequelae.

Hypogonadism and and chronic complications in type 2 diabetic males

Anis Grassa[1], Manel Jemel[1], Salma Salhi[1], Brahim Khalfa[1], Rahma Mahjoub[1], Emna Talbi[1], Asma Krir[2], Radhouane Gharbi[1] & Ines Kammoun[1]
[1]National Institute of Nutrition and Food Technologies, Zouheir Kallel; [2]Pasteur Institute of Tunis

Introduction
Type 2 Diabetes (T2D) is a widespread metabolic disorder associated with chronic complications. Few studies have explored the relation between **chronic** complications in type 2 diabetic males presenting an hypogonadism (HG). Understanding how T2D, its complications, and HG are connected is crucial for overall health. This study aims to explore these links in simpler terms.
Methods
This is a descriptive cross-sectional study that included 250 adult men with T2D. Participants underwent a clinical examination and metabolic and hormonal assessments. The diagnosis of HG was established based on the Vermeulen criteria, involving the measurement of total testosterone and the calculation of free testosterone.
Results
The prevalence of impaired glucose was 27.2% ($n=68$). The average duration of diabetes was 12.5 ± 7.4 years [Range: 1-31]. Patients with a diabetes duration exceeding 10 years accounted for more than half of the cases (62.2%). In total, 52% of the patients exhibited chronic complications of diabetes. Microangiopathic complications were present in one hundred and nine patients, accounting for 44.1% of the total. In 37.6% of cases, retinopathy was observed, while nephropathy affected 25.6% ($n=64$) and neuropathy impacted 18% of the total. One-fourth of the patients had macroangiopathic complications, accounting for 25.8%. Among these complications, 50 patients (20%) exhibited coronary involvement. A history of stroke or transient ischemic attack (TIA) was found in 2.4% of the patients. Lower limb arteritis was observed in 9.7% of the cases. Sixty-eight patients were diagnosed with HG, representing 27.2%. When comparing the HG and non-HG groups, there was no correlation between the prevalence of impaired glucose and microangiopathic complications ($P=0.071$). Regarding retinopathy (42.4% vs 39.9%; $P=0.402$), nephropathy (27.3% vs 25.7%; $P=0.452$), and neuropathy (18.2% vs 19.2%; $P=0.516$), no significant differences were observed. Similarly, for macroangiopathy, coronary insufficiency and lower limb arteriopathy were nearly identical in the two groups, HG and non-HG, respectively: 19.7% vs 20.8%; $P=0.511$ and 9.1% vs 10.2%; $P=0.514$. Regarding stroke/TIA, they were more frequent in patients with hypogonadism, 4.5% vs 1.7%, but this correlation was not statistically significant ($P=0.199$).
Conclusion
The study reveals no significant correlation between HG and key parameters, including diabetes duration, micro and macroangiopathic complications. The lack of association prompts further investigation into the complex relationships between HG and diabetic complications.

The role of a behavioral approach in the treatment of obesity

Anna Brodovskaia
Normed Medical Center, Yerevan, Armenia

Approximately 2.6 billion people worldwide (38% of the planet's population) are already overweight or obese. In 12 years, according to analysts' forecasts, every second person on the planet will have an excess of fat. Unfortunately, adhering to diets only contributes to weight gain. Under calorie restriction, physiological adaptation mechanisms are activated in the body, which increase hunger and reduce basal metabolism. In such conditions, weight loss is possible only in the case of sustainable food restriction, which inevitably leads to breakdowns and relapses. The only method that will help reduce weight in the long term is changing eating habits and working on food behavior.
Aim
To evaluate the effect of behavioral interventions in the treatment of overweight/obesity in adults.
Methods
The study was conducted in obese/overweight adults in an outpatient setting and with remote monitoring. The behavior modification included goal-setting, motivational counseling, self-monitoring and self-motivation, reward system, problem-solving, and social support. The observation period consisted of weekly sessions for the first three months and then monthly supporting meetings. Evaluation of the results of observation was carried out after 9 months.
Results
A total of 17 patients at the age from 23 to 45 years old were examined. The average body mass index was 31.3 ± 3.14 kg/m^2. Average weight loss was 8.2%; average rate of weight loss - 2.7 kg/month. Patients had good adherence to recommendations and continued to maintain/lose weight after the active intervention period.
Conclusion
Long-term weight loss is possible when abandoning restrictions and under conditions of adequate activity. There is a need for a more holistic approach that includes behavioral treatments to promote adherence to treatment and maintain lifestyle modifications.

Ocular infections: distinctive aspects in diabetic patients

Manal Bennani, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
Ibn Rochd University Hospital - Clinical Neuroscience and Mental Health Laboratory Faculty of Medicine and Pharmacy - Hassan II University-, Department of Endocrinology, Nutrition and Metabolic Diseases, Casablanca, Morocco

Introduction
Ocular infections are a serious threat to the visual prognosis of diabetic patients. Often exacerbated by glycemic imbalance and pre-existing eye conditions, their progression remains unpredictable due to the limited therapeutic options available. Factors contributing to this unpredictability include the restricted diffusion of antibiotics within the eye, the toxicity associated with prolonged use of certain fortified eye drops, and the emergence of antibiotic-resistant strains.
Objective
The aim of our study is to assess predisposing factors for specific types of ocular infections and their prevalence among diabetic patients, with the ultimate goal of enhancing preventive measures.

Materials and Methods
This study is an observational statistical analysis conducted at the Endocrinology and Diabetology Department of CHU IBN ROCHD in Casablanca, using the SPSS software. It focuses on diabetic patients who presented with severe ocular infections requiring specialized ophthalmological care from January 2021 to December 2023.
Results
In our study, 92 patients were included, comprising 38 men and 54 women, all of whom had ocular infections. The average age was 61 years (ranging from 27 to 81 years), with 93% having type 2 diabetes and an average diabetes duration of 12 years. The identified pathologies included endophthalmitis (42%), corneal abscesses (31%), and retro-orbital cellulitis (15%). Initial treatment involved local and intravenous antibiotics, and 12 patients eventually underwent evisceration. A1c levels were below 7% in 27% of cases, between 7% and 8% in another 27%, and above 8% in the remaining patients. The majority of diabetic patients were initially on insulin therapy (93%).
Conclusion
The severity of ocular infections in diabetic individuals is heightened by age, diabetes duration, and underlying glycemic imbalance. The risk of progressing to loss of ocular function underscores the need for strict glycemic control and close monitoring to mitigate these avoidable complications.

Secondary failure of oral therapy in patients with type 2 diabetes mellitus - possibilities of overcoming

Aleksandra Markovic[1,2], Mirjana Bojic[1], Tamara Dojcinovic[1,2], Ivona Risovic[1,2], Milena Brkic[2], Valentina Soldat Stankovic[1,2] & Djuro Macut[3,4]
[1]University Clinical Centre of the Republic of Srpska, Internal Medicine, Banja Luka, Bosnia and Herzegovina; [2]University of Banja Luka, Faculty of Medicine, Banja Luka, Bosnia and Herzegovina; [3]University Clinical Centre of Serbia, Belgrade, Serbia; [4]University of Belgrade, Faculty of Medicine, Belgrade, Serbia

Introduction
Secondary failure (SF) of oral therapy in patients with type 2 diabetes is a common clinical phenomenon, which often puts the practitioner in a dilemma as to which therapeutic regimen to choose for continuing therapy. The dilemma primarily applies to patients in whom there is no clear clinical and biochemical evidence of significant insulin deficiency. This is precisely why there has been an increased interest in the use of short-term intermittent insulin therapy. The aim of the study was to examine the acute and residual effects of short-term mono insulin therapy on glycoregulation and insulin secretory function.
Methods
The prospective study took place in two phases and included 69 patients with type 2 DM and SF oral therapy. The first phase represents the introduction of insulin therapy (monoinsulin or combined) for three months, and the second phase represents the assessment of the residual effects of insulin therapy on glycoregulation and insulin secretory function (postinsulin period). During the second phase of the study, which lasted for 3 months, the patients again used the oral therapy they used until the diagnosis of SF. Glycoregulation and insulin secretory function were evaluated at the beginning and at the end of both phases.
Results
After three months of insulin therapy, there was a significant improvement in all observed parameters: morning glycemia (6.1 vs 9.5; $P<0.001$), postprandial glycemia (6.9 vs 11.6; $P<0.001$), glycemia from all-day profile (7.3 vs 10.3; $P<0.001$), while in the post-insulin period there was a certain deterioration of these parameters. Also, after three months of insulin therapy, the values of basal C-peptide increased (1.23 vs 1.67; $P<0.001$), while the level of basal insulinemia was reduced (9.17 vs 11.46; $P<0.001$). In the post-insulin period, there were no significant changes in C-peptide and insulin values compared to the period immediately after insulin therapy.
Conclusion
Short-term monoinsulin therapy represents a rational alternative to permanent insulin therapy in properly selected patients who do not have clear clinical and biochemical parameters of significant insulin deficiency. It can cause a state of re-sensitivity to oral therapy and delay permanent insulin treatment.

Background and Objective
Fixed-dose combination (FDC) of dapagliflozin + metformin + sulfonylurea with complementary mechanisms can provide effective glycaemic control, preserve beta-cell function, improved compliance without risk of weight gain, and reno-protective action in type 2 diabetes mellitus (T2DM) patients. This subgroup analysis assessed efficacy and safety of triple-drug FDC vs (vs) two-drug combination in T2DM Indian patients aged <45 years and 45-65 years.
Method
This is a subgroup analysis of phase 3, open-label, four-arm, active-controlled study (CTRI/2022/06/043249) in T2DM patients (glycated haemoglobin [HbA1c] 8%-11%) taking metformin 1000 mg 2000 mg/day and glimepiride 2 mg/day at screening. Patients received FDC of dapagliflozin + glimepiride + metformin IR tablet twice-daily (BID) (5 mg + 1 mg + 500 mg [test-1]/5 mg + 1 mg + 1000 mg [test-2]) OR co administration of glimepiride tablet + metformin IR BID (1 mg + 1 tablet of 500 mg [comparator-1]/1 mg + 2 tablets of 500 mg [comparator-2]) for 16 weeks. Post Week 16, up titrated dose of glimepiride (2 mg) in respective treatments was provided to patients with HbA1c ≥7% in each arm. This subgroup analysis evaluated glycaemic and safety parameters from Baseline till Week 28 in two age subgroups; subgroup 1 (S1:age <45 years) and subgroup 2 (S2:age 45-65 years).
Results
At baseline, 223 patients aged <45 years (S1) and 310 patients aged 45-65 years (S2). Adjusted mean change (SE) in HbA1c in S1 was statistically significant in test-1 vs comparator-1 [2.48% (0.14%) vs 1.64% (0.14%), $P<0.0001$) and in test-2 vs comparator-2 [-2.31% (0.13%) vs -1.65% (0.13%), $P=0.0004$) at Week 16. Adjusted mean change (SE) in HbA1c in S2 was statistically significant in test-1 vs comparator-1 (2.1% (0.12%) vs -1.63% (0.12%), $P=0.0043$)] and in test-2 vs comparator-2 [-2.18% (0.12%) vs -1.75% (0.12%), $P=0.0116$] at Week 16. In S1, proportion of patients achieving HbA1c <7% were significantly higher in test-1 vs comparator-1 (74.5% vs 46.9%, $P=0.0047$) and test-2 vs comparator-2 (85.5% vs 58.1%, $P=0.0011$) at Week 16. In S2, proportion of patients achieving HbA1c <7% were significantly higher in test-1 vs comparator-1 (70.1% vs 46.8%, $P=0.0032$) and test-2 vs comparator-2 (73.7% vs 47.1%, $P=0.0011$) at Week 16. Significant reduction in HbA1c, fasting and post prandial blood glucose was observed from Baseline to Weeks 12 and 16 in each arm in both subgroups. No patient reported hypoglycaemia or required rescue medication. Both treatments were well tolerated.
Conclusion
Triple FDCs of dapagliflozin + glimepiride + metformin IR tablets showed statistically significant reduction in HbA1c from Baseline to Week 16 as

compared to dual combinations in T2DM patients of both age groups (<45 years and 45-65 years) and is a treatment option for all age groups.

Patient with type 1 diabetes mellitus with poor glycemic control with adrenocorticotropic hormone (ACTH)-secreting pituitary macroadenoma

Paloma González Lázaro[1], Maria Zhao Montero Benítez[1], Pedro Jimenez Torrecilla[1], Juan A. Mascuñana Calle[1], Cristina Contreras Pascual[2] & Ines. R Gomez García[1]
[1]Hospital General La Mancha Centro, Alcázar de San Juan, Spain; [2]Hospital Santa Barbara, Soria, Spain

Introduction
Diabetes mellitus is the most common chronic disease in children, with type 1 diabetes accounting for 80% of diabetic patients under the age of 19 years. Though hyperglycemia in pediatric patients with diabetes mellitus commonly occurs due to poor adherence to insulin therapy, other etiologies should be considered when hyperglycemia is refractory and additional systemic signs and symptoms are present. We discuss a case of a female patient presenting with signs and symptoms of elevated cortisol levels several years after being diagnosed with T1DM.
Case Presentation
We present the case of a 19-year-old woman diagnosed with type 1 diabetes mellitus and celiac disease at 3 years and 9 months. Come to our consultation after follow-up in Pediatric Endocrinology for follow-up of type 1 DM. Screening for Cushing's syndrome is requested due to reports of increased insulin needs, weight gain, rounder face and menstrual alterations since 2020. On examination, attention is drawn to facial plethora, a full moon face, vinous red striae on the abdomen and accumulation of retrocervical and supraclavicular fat. A functionality study was performed (Suppression with 1 mg of Dexamethasone, urinary free cortisol, salivary cortisol, cortisol rhythm, strong suppression with Dexamethasone and CRH test) suggestive of ACTH-dependent syndrome. A subsequent brain MRI showed pituitary gland with an increase in size of 9.9×8.6 mm in the sagittal plane suggestive of pituitary adenoma. Normal appearing pituitary stalk and optic chiasm. Medical treatment with ketoconazole was initiated with improvement in glycemic control and normalization of urinary free cortisol until complete transsphenoidal resection of the adenoma was performed. Following resection her long-acting insulin requirement decreased by 50%. At his three-month postoperative follow-up, the patient's striae and facial edema had improved significantly and her weight decreased by 9 kg.
Conclusions
We described the case of a 19-year-old Spanish female, with poorly controlled T1DM and Cushingoid features, who was found to have a functioning pituitary macroadenoma. An ACTH-secreting pituitary adenoma is an extremely rare phenomenon in such young patients, but it should be considered in patients presenting with refractory hyperglycemia and other signs and symptoms of Cushing disease.

Gender affirming hormonal care induces a gender-concordant gut metagenome transition in transgender individuals

Matthias Auer[1], Timur Liwinski[2], Johanna Schröder[3], Ina Pieknik[4], Christian Casar[5], Günter Stalla[6], Undine Lang[2], Alina von Klitzing[4], Corinna Bang[7], Peer Briken[4], Christoph Schramm[8] & Johannes Fuss[8]
[1]Klinikum der Universität München, Medizinische Klinik and Poliklinik IV, Munich, Germany; [2]University of Basel, Clinic for Adult Psychiatry, Basel, Switzerland; [3]Medical School Hamburg, Institute for Clinical Psychology and Psychotherapy, Hamburg, Germany; [4]University Medical Center Hamburg-Eppendorf, Institute for Sex Research, Sexual Medicine and Forensic Psychiatry, Hamburg, Germany; [5]University Medical Centre Hamburg-Eppendorf (UKE), I. Department of Medicine, Hamburg, Germany; [6]Medicover Neuroendocrinology, Munich, Germany; [7]Christian-Albrechts-University Kiel, Institute of Clinical Molecular Biology, Kiel, Germany; [8]University Medical Centre Hamburg-Eppendorf, Hamburg Centre for Translational Immunology (HCTI), Hamburg, Germany

Aim
There is no data on gender-specific microbial alterations during the gender-affirming transition of trans people, along with inconsistent investigations regarding the specific impact of sex steroids on gut microbiota taxonomy and function.
Method
Our study included 36 transgender participants (17 trans women and 19 trans men). We collected stool samples before and three months post-GAHT initiation, employing shotgun metagenomic sequencing to evaluate the microbiota's response.
Results
Taxonomically, alpha and beta diversity did not differ between trans men and trans women before transition. Moreover, transition was not associated with changes in overall alpha or beta diversity. Nevertheless, four species, namely *Parabacteroides goldsteinii* (FDR = 0.0264), *Coprococcus sp. ART55/1* (FDR = 3×10^{-4}), *Coprococcus eutactus* (FDR = 0.0289), and *Escherichia coli* (FDR = 0.0019), exhibited significant abundance changes in response to hormonal treatment aligning with the participants' affirmed gender. Our analysis revealed a statistically significant effect of gender and transition on the overall functional metagenome ($R^2 = 4.1\%$, $P = 0.0115$). Single pathway analysis demonstrated alignment of the transition-related changes with the affirmed gender, particularly in fatty acid-related metabolism, which was more pronounced in the high testosterone state.
Conclusion
The study highlights distinct microbial profiles in men and women's gut microbiomes. GAHT tends to masculinize the microbiome in trans men and feminize it in trans women. These changes could influence various health outcomes, emphasizing the importance of considering the gut microbiome in transgender health care.

EP422

Variation in metabolic control in children with DM1 after a summer camp

Javier García Sánchez[1], María Cristina Palma Conesa[2], María Teresa Zarco Martín[4], Raquel María López Ortiz[1], Enrique Redondo[1] & Pablo José López-Ibarra Lozano[1]
[1]San Cecilio Clinical University Hospital, Endocrinology and Nutrition, Granada; [2]San Cecilio Clinical University Hospital, Pediatrics, Granada

Introduction and objectives of the study
Every year the Diabetes Association of Granada (AGRADI), organizes a summer camp for children with Diabetes Mellitus type 1 with the aim of combining leisure activities and facilitating learning and developing autonomy in their pathology. The presence of health professionals is essential to ensure the monitoring and safety of children and a good diabetological education. The aim of this study is to evaluate the clinical characteristics and compare different parameters of the diabetic control of the participants before and during the activity.
Material and methods
Retrospective descriptive observational study that analyzes the participants in two camps for children with DM1 in the years 2022 and 2023. Clinical, glucometric and pharmacological variables were measured. The analysis was performed with SPSS 25.0.
Results
Sixty-five subjects aged 7 to 16 years were included, being 33 males and 32 females. The time of evolution of DM was 5 ± 2.8 years with a mean HbA1c of $7.07 \pm 0.6\%$. Of these, 31 were continuous insulin pump infusion (CIIP) users and 34 used multiple doses of insulin (MDI). With respect to insulin dose, a significant reduction in total insulin dose was found overall and in both groups. The reduction occurred in slow insulin doses in users with MDI (21.6 Units (U) vs 14.9 U) and bolus in the case of CIIP (30.7 U vs 25.8 U), both significant. A significant increase in the sensitivity factor was also observed in global terms and in the ISCI group. Regarding glucometry, there was an improvement in mean glucose with an increase in time in range with no significant difference in time below range, during the camp, compared to previous weeks. In addition, there was no significant difference in the use of glucose sensors and the number of glucose sensor readings compared to the pre-camp discharge.
Conclusions
In conclusion, an improvement in metabolic control was observed during the summer camp. Time in range improved without a significant increase in the number of hypoglycemia. The insulin dose was reduced without requiring a greater number of controls during the camp. Diabetic education, therefore, is key to correct metabolic control.

Semaglutide therapy in people with type 2 diabetes and obesity: efficacy on glycated hemoglobin and weight loss

Michela Del Prete[1], Olga Eugenia Disoteo[1], Renato Cozzi[2], Gianleone Di Sacco[1], Federico Vignati[1], Lidia Gavazzi[1] & Fabrizio Muratori[1]
[1]Sant'Anna Hospital – ASST Lariana, Division of Endocrinology, Diabetology and Clinical Nutrition, Como, Italy; [2]Niguarda Hospital, Division of Endocrinology, Milan, Italy

Introduction
The long acting GLP-1 analogue, Semaglutide (S), is indicated for the treatment of adults with type 2 diabetes mellitus (T2DM). Since November 2021, S has also been approved by the European Medicines Agency (EMA) at a dose of 2.4 mg for the treatment of obesity. Here, we report the efficacy of S, either alone or in combination with other antidiabetic drugs, in patients with T2DM and obesity on glycated hemoglobin (HBA1C) and weight loss.
Patients and Methods
We retrospectively evaluated 129 patients (75 F and 54 M; mean age 61.2 ± 9.8 years) with T2DM and obesity treated with S for glycemic control and for weight loss. At the first visit, mean weight was 101.8 ± 24.6 kg and mean body mass index (BMI) was 36.7 ± 8.7 kg/m^2. At baseline mean HBA1C was 7.7 ± 1.5%. S was administered as monotherapy or in combination with metformin. S was administered once-weekly subcutaneously at starting dose of 0.25 mg and with monthly increases up to 1.0 mg. The aim of this study was to evaluate the efficacy of S on HBA1C and according to the weight loss reduction more than (>) 5% or > 10% in this setting of patients.
Results
After 6-month follow up, 115/129 patients had a mean weight of 95.2 ± 24.3 kg and mean BMI of 34.3 ± 9.4 kg/m^2, with a mean percentage weight reduction of -9.5 ± 6.5% and mean BMI reduction of -3.7 ± 3.1 kg/m^2. After 6-month of therapy HBA1C was 6.4 ± 0.9%, with a mean reduction of -1.8 ± 1.5%. In 55.4% of patients that lost > 5% of weight, mean HBA1C reduction was -1.6 ± 1.2%, while in 44.6% patients that lost > 10% of weight from baseline, there was a mean HBA1C reduction of -2.1 ± 1.7%. After 12-month follow up, 47/129 patients had a mean weight of 88.9 ± 17.9 kg and mean BMI of 31.9 ± 5.6 kg/m^2 with a mean percentage weight loss of -9.2 ± 7.6% and mean BMI reduction of -3.3 ± 2.8 kg/m^2. After 12-month follow up mean HBA1C was 6.4 ± 0.9%, with a mean reduction of -1.6 ± 1.6%. In 42.6% of patients with a weight loss > 5%, there was a mean HBA1C reduction of -1.4 ± 1.6%. In 57.4% of patients with a weight loss > 10%, mean HBA1C reduction was -1.7 ± 1.5% from baseline. S was well tolerated and no patient experienced serious adverse events.
Conclusions
Our results confirm the efficacy and safety in glycometabolic control of S therapy in patients with T2DM and obesity. In our study S provide significant weight loss and reduction in HBA1C, probably further reduced also due to the significant weight loss.

Assessment of the Exsel Test to detect excessive salt consumption in type 2 diabetic patients

Rym Ben Othmen[1], Emna Talbi[2], Nesrine Dhieb[1], Ramla Mizouri[1], Brahim Khalfa 2[2], Skandar Msolly1[1], Rahma Mahjoub2[2], Olfa Berriche1[1] & Henda Jamoussi1[1]
[1]1National Institute of Nutrition and Technology, Department A, Tunis, Tunisia; [2]Zouhair Kallel Institute of Nutrition and food technology, Clinical Biology Laboratory, tunis, Tunisia

Introduction
Despite the fact that excessive salt consumption is a risk factor in the development of a number of diseases. There is no doubt that dietary intake of sodium chloride remains well above recommended levels. The aim of our study was to evaluate the effectiveness of the Exsel Test in detecting excessive salt consumption in type 2 diabetic patients.
Methods
This was a cross-sectional study of 106 type 2 diabetic patients hospitalised in department A of the National Institute of Nutrition and Food Technology in Tunis. Each patient benefited from a physical examination, a biological check-up and an Exsel Test.
Results
The mean age was 55.46 ± 7.51 years. The majority of patients were women (57). The mean BMI was 29.68 ± 5.92 kg/m.2 We noted a significant difference ($P = 0.001$) in BMI between patients with a positive Exsel Test and those with a negative test. In our study, the Exsel test was associated with the frequency of consumption of salted cheese ($P = 0.001$), tinned food ($P = 0.005$), dried fruit ($P = 0.01$), variants ($P = 0.005$) and sauces ($P = 0.03$). The mean 24 h natriuresis was reported as 106.45 ± 63.82 mmol/24 h and the mean salt intake predicted by natriuresis as 6.22 ± 3.73 g/. The kappa test for comparing the relationship between the exsel test and predicted salt intake was 0.9 and the chi-square was 0.7. The sensitivity of the self-questionnaire was 25%, specificity 74%, PPV 4% and NPV 96%. The area under the curve was equal to 0.577, which is a very low value for a threshold of positivity for the Exsel Test self-questionnaire.
Conclusions
We suggest improving the Exsel test to adapt it to people's culinary habits.

SGLT-2 inhibitors-induced erythrocytosis: a case series

David Verissimo, Beatriz R Pereira, Joana Vinhais, Catarina Ivo, Ana Cláudia Martins, Joao Silva, Dolores Passos, Luis Lopes, J Jácome Castro & Mafalda Marcelino
Armed Forces Hospital, Department of Endocrinology, Lisboa, Portugal

Introduction
Sodium-glucose co-transporter 2 inhibitors (SGLT2i) have emerged as a promising class of medications, demonstrating a significant reduction in the risk of cardiovascular events. An associated consequence of SGLT2i is an increase in hematocrit levels, with cardiovascular outcome trials revealing frequent hematocrit mean elevations varying from + 2.3% to 3.5%. This rise in hematocrit introduces a potential dilemma when evaluating the risk-benefit profile of SGLT2i in patients with high cardiovascular risk. While effectively reducing the relative risk of major cardiovascular events, the associated secondary polycythemia raises concerns about an elevated risk of thrombotic events. Notably, existing guidelines and recommendations do not address this specific concern, emphasizing the need for further exploration and guidance in managing hematological alterations associated with SGLT2i therapy.
Case series
To address this issue, we present a case series involving five male patients, with a median age of 53 years [41-61], diagnosed with type 2 diabetes for 6 years [1-12], all prescribed a daily dose of the SGLT2 inhibitor dapagliflozin. Only one patient was a former smoker. Baseline blood tests revealed normal hemogram values, including hemoglobin at 16.2 g/l [15.5-16.9], hematocrit at 47.2% [44.7-49.8], and erythrocytes at 5.33×10^{12}/l [5.28-5.33]. Following a mean treatment duration of 3 ± 1 months, a substantial increase was observed in both hemoglobin (17.8 g/dl [17.3-18.3], $P = 0.043$) and hematocrit (51.2% [49.5-53.4], $P = 0.043$), reaching peak values of 18.4 g/dl and 54.2%, respectively. However, there was no significant change in erythrocyte count ($P = 0.109$). All patients underwent normal blood smear assessments, and their erythropoietin levels, electrolytes, kidney, and liver functions remained within the normal range. The absence of the JAK2 v617f mutation in all five patients ruled out Polycythemia Vera and other myeloproliferative disorders. In two cases, dapagliflozin was suspended, resulting in decreased hemoglobin levels (15.9 and 16.4 g/l) and reduced hematocrit (44% and 46.5%) after three and four months, without the need for phlebotomy. Conversely, for the remaining three patients, the cardiovascular benefits of dapagliflozin were deemed superior, and consequently, treatment continued in conjunction with periodic phlebotomies. In conclusion, these case reports demonstrate that SGLT2i-induced erythrocytosis accompanies the cardiovascular benefits of these drugs. Clinicians should maintain close monitoring of patients' hemogram and carefully weigh the risk-benefit profile in an individualized approach, considering potential interventions such as drug suspension or therapeutic phlebotomy.

The effect of SGLT-2 inhibitor switching from TZD with triple combination treatment in type 2 diabetes

Yonghyun Kim & Donghyun Shin
Jesaeng Hospital, Endocrinology and Metabolism, Seongnam-si, Korea, Republic of South Korea

Before launching of SGL-2 inhibitor, triple combination of TZD with metformin and DPP-4 inhibitor was best option for delaying progression of diabetes by improving insulin resistance and secretory dysfunction. But due to side effects of TZD such as weight gain and edema, SGL-2 inhibitor can be

another option instead of TZD. So we tried to know the effect of SGLT2 inhibitor switching from TZD with triple combination therapy in type 2 diabetes. In 80 patients treated with triple combination of metformin, DPP4 inhibitor and 15 mg of pioglitazone –the usual dose in this country, pioglitazone was switched to 10 mg of dapaglifozin or empagloflozin. The 6 months after HbA1c was compared with mean HbA1c of 3 months and just before switching. Weight change was compared and other clinical characteristics were assessed. The mean age was 59.6±11.4, duration of diabetes was 9.3±4.3 year and BMI was 28.3±3.6. The HOMA-IR was 3.59±3.5 and fasting c-peptide was 2.42±1.16. The mean of HbA1c 3 month and just before switching was 6.90±0.58%. HbA1 was increased in 44%, decreased in 39% and mean elevation and reduction was 0.49 and 0.64, each in 52 patients with dapaglifozin group. HbA1 was increased in 46%, decreased in 46% and mean elevation and reduction was 0.33 and 0.48, each in 28 patients with empagloflozin group. HOMA-IR was improved by 3.79 in 62% and aggravated by 1.90 in 38%. Body weight was reduced in 100% by 4.92±2.38 kg. So, triple combination of SGLT-2 inhibitor with metformin and DPP-4 inhibitor was similar effec in glucose control, but efficient in weight control compared to TZD as expected.

Clinical and laboratory factors associated with response to therapy with sodium-glucose cotransporter 2 inhibitors in patients with type 2 diabetes mellitus

Sophia Pitsiava[1], Vasilis Tsimihodimos[2], Kalliopi Kotsa[3] & Theocharis Koufakis[4]
[1]Thessaloniki, School of Medicine, Aristotle University of Thessaloniki, Greece; [2]Ioannina, Department of Internal Medicine, Faculty of Medicine, University of Ioannina, Greece; [3]Thessaloniki, Division of Endocrinology and Metabolism and Diabetes Centre, First Department of Internal Medicine, Medical School, Aristotle University of Thessaloniki, AHEPA University Hospital, Greece; [4]Thessaloniki, Second Propedeutic Department of Internal Medicine, Hippokration General Hospital, Aristotle University of Thessaloniki, Greece

Background
Response to therapy with glucose-lowering agents, in terms of glycemic control and weight loss, presents significant interindividual variability. This study investigated the association between clinical and laboratory parameters and response to therapy with sodium-glucose cotransporter 2 inhibitors (SGLT2i) in patients with type 2 diabetes mellitus (T2DM).
Methods
We retrospectively analyzed the medical records of people with T2DM in whom SGLT2i was started, without the concomitant initiation of any other pharmaceutical agent. Clinical and laboratory parameters were recorded before, at 3 and 6 months after starting treatment. We defined a good response in terms of glycemic control, as meeting one of the following criteria, at 3 or 6 months: i. Glycated hemoglobin (HbA1c) $<7\%$ ii. Reduction in HbA1c $\geq 1\%$ compared to baseline iii. Maintaining HbA1c $<7\%$ that a patient had before starting SGLT2i. A good response in terms of weight loss was defined as losing $\geq 3\%$ of the baseline weight at 3 or 6 months.
Results
We included 50 individuals (64% men) with a mean age of 65.8 ± 8.5 years. 86% and 64% of the participants were classified into good response categories for glycemic control and weight loss, respectively. Good responders in terms of glycemia had lower high-density lipoprotein cholesterol levels at baseline compared to bad responders (43.3 vs 57.4 mg/dl, $P=0.044$). Both the good and bad responders in terms of weight loss experienced a significant reduction in HbA1c levels between baseline and 3 months (-0.6%, $P=0.002$ and -0.8%, $P=0.003$, respectively). Only good responders in terms of glycemic control and weight loss experienced a significant improvement in the estimated glomerular filtration rate values at 3 months compared to baseline ($+2.9$ ml/min/1.73 m^2, $P=0.015$ and $+3.68$ ml/min/1.73 m^2, $P=0.006$, respectively). In logistic regression analysis, a higher baseline weight was associated with a better response to therapy in terms of weight loss ($P=0.04$).
Conclusions
Specific clinical and laboratory parameters are associated with response to SGLT2i treatment. Responses in terms of glycemic control and weight loss appear to be two distinct outcomes, despite the common underlying mechanism. These findings can contribute to a more personalized approach to T2DM care.

The influence of individual learning at the Diabetes School on the achievement of glycemic control goals in patients with type 1 diabetes

Volha Shyshko[1,2] & Uladzislau Marozik[1]
[1]Minsk City Clinical Endocrinology Center, Minsk, Belarus; [2], Belarusian State Medical University, Department of Endocrinology, Minsk, Belarus

Introduction
Despite the emergence of all new means of control and treatment of type 1 diabetes (T1DM), the achievement of target indicators of glycemia remains a serious problem, which leads to the development of chronic complications. Therapeutic training of the basics of life with diabetes allows patients with T1DM to improve glycemic control.
Target
Evaluate the influence of individual learning at the Diabetes School on HbA1c.
Methods
For the study were selected 103 patients in the Minsk City Clinical Endocrinological Center. The selection criterion was the nonattendance of the target HbA1c. The average HbA1c was 9.26% (± 1.51%). Men amounted to 33.98% ($n=35$), women 66.02% ($n=68$). Average age 36.9±11 years. Diabetes experience 17.2±9.7 years. All patients in the past were trained under the standard program of the Diabetes School.
Results
Each patient underwent individual counseling with a teacher of the Diabetes school. The first control of HbA1c showed a decrease in its average level to 8.87±1.47% ($P=0.025$). The difference with the starting indicator HbA1c is 0.39%. Only 94 patients participated in the second control of the HbA1c. The average level of HbA1c was 9.02±1.48 % ($P=0.037$), which is 0.25 % less than HbA1c before consultation, but already higher than after 1 control of HbA1c. Only 46 people have reached a persistent decrease in HbA1c after 1 and 2 control. The average level of HbA1c was 8.62±1.43 % ($P=0.016$).
Conclusions
Individual consultations at the Diabetes School improve glycemic control One consultation is not enough to achieve the goals of HbA1C in the long term It is necessary to develop individual learning standards for its implementation in everyday practice.

Effect of Diabetes education through social media in young patients with type 1 diabetes

Bharat Saboo[1], Aniket Inamdar[2], Vipul Chavda[3] & Dhruvi Hasnani[3]
[1]Prayas Diabetes Center, Indore, India; [2]Samarpan clinic, Omerga, India; [3]Rudraksha Institute of Medical Sciences, Ahmedabad, India

New modalities of patient education have come up, young people are more attracted towards social media WhatsApp is very common messaging and networking tool. This study compared the effects of WhatsApp-based patient education and routine care on the disease knowledge and glycemic control of adolescents and young adults with T1D in a low-resource setting. A two-month three diabetes clinics in India. The intervention group received six WhatsApp sessions of patient education, while the control group followed their usual care. Diabetes knowledge, acute events, and glycemic control were assessed before and after the intervention. The study enrolled 42 patients, 22 in the intervention group and 20 in the control group. The median age was 19 (16-21) years for both groups. The intervention group showed a significant increase in diabetes knowledge from 12/20 to 17/20 ($P< 0.01$) after two months, while the control group showed a no change from 12/20 to 12/20 ($P=0.33$). The intervention group also had a lower mean proportion of acute complications, from 24% to 18% ($P=0.52$), while the control group had a higher proportion, from 8% to 36% ($P=0.01$). There was no difference in glycosylated hemoglobin level between the groups. The study concluded that patient education via WhatsApp improved diabetes knowledge and reduced acute events, but did not affect glycemic control, after two months.

Obesity-related comorbidities as potential factors influencing features of premature ageing in severely obese patients

Alicja Dudek[1,2], Barbara Zapała[3], Karol Ciszek[1], Ilona Kawa[1], Wojciech Zgliczyński[2] & Piotr Major[1]

[1]Jagiellonian University Medical College, 2nd Department of General Surgery, Krakow, Poland; [2]Department of Endocrinology CMKP, Warsaw, Poland; [3]Jagiellonian University, Department of Pharmaceutical Microbiology, Krakow, Poland

Background
Obesity poses a considerable threat to health, increasing the likelihood of accompanying conditions such as type 2 diabetes, hypertension, dyslipidemia, and cancer. Ageing results in the accumulation of damaging factors leading to the development of chronic diseases. Inflammation levels, telomere length, level of neurocognitive function, metabolic age serve as acknowledged indicators of biological aging. The prevalence of premature ageing in obesity has been evidenced. The precise factors driving this premature aging in obese individuals remain uncertain.
Objectives
The aim of the study was to assess the impact of comorbidity on premature ageing in obesity.
Methods
In this prospective cohort study the interleukin-6 (IL-6), C-reactive protein (CRP), telomere length (TL), speed of attention in Colour Trailed Test and metabolic age were evaluated in patients with severe obesity (SG, BMI $\geq$ 40 kg/m^2 or $\geq$35 kg/m^2 with obesity comorbidities, $n=100$) and the healthy volunteers (CG, BMI 18.5 - 24.9 kg/m^2, $n=30$). SG was divided into two subgroups: subjects with comorbidities ($n=78$) and subjects without comorbidities ($n=21$). The regression model tested the effect of dyslipidaemia, hypertension, diabetes and pre-diabetes on markers of ageing.
Results
Our results demonstrated that both SG subgroups presented higher levels of IL-6 (4.75 vs 3,96 vs 1.13 pg/ml), CRP (22.45 vs 17.8 vs 0.43 pg/ml); shorter TL (4002 vs 3809 vs 5353 bp) than never-obese subjects ($P<0.05$). However, there were no differences between patients with obesity and comorbidities and without comorbidities. The effect of BMI on increased inflammation has been demonstrated. The effect of the presence of hypertension on cognitive decline was observed.
Conclusions
Our study showed that obesity regardless of comorbidity causes premature ageing. An interesting point is the association of hypertenstion with cognitive function decline.

Introduction
Bariatric surgery (BS) is an effective strategy for the remission of non-alcoholic steatohepatitis (NASH) in morbidly obese (MO) patients, producing an improvement in comorbidities and better glycaemic control in patients with DM2. Liver biopsy remains the definitive test to classify a patient with NASH/NASH, however, the use of non-invasive techniques such as fibroscan would avoid the limitations and risks that biopsy can cause in this type of patient. Therefore, in this study we determined the improvement of NASH by fibroscan in patients with OM undergoing BC and classified according to diabetes (DM2).
Material and Methods
We included 38 patients with OM classified according to the presence of DM2, who underwent BC and were followed up 1 year after BC. Fibroscan was performed before surgery and one year after BC. Anthropometric and biochemical variables and liver fibrosis scores were measured.
Results
Of the 38 patients included, 22 (non-DM2), and 16 (DM2), only 7 patients remained DM2 at 1 year after BC, which meant a remission of 56.3%. BMI before and 1 year after BC were similar in the two cohorts studied. Fibroscan was also similar in both groups before surgery, reflecting a significant improvement, especially in non-diabetics, but also in diabetics after surgery.
Conclusions
According to this study, liver improvement is equal in both groups of patients after one year. It shows that elastography is a valid technique to assess NASH remission in OM patients undergoing bariatric surgery. Therefore, it is important to use fibroscan to evaluate those patients with NAFLD with liver fibrosis and to prioritise their surgical intervention over those without obesity-associated comorbidities.

Correlation between depression and type 2 diabetes mellitus in durres community

Ira Xhemollari[1], Edlira Elezi Bucpapaj[2] & Agron Ylli[3]
[1]Municipial Hospital, Endocrinology, Kavaje, Albania; [2]Municipial Hospital, Endocrinology, Lac, Albania; [3]Mother Teresa University Hospital Center, Endocrine and Metabolic Diseases Unit, Tirane, Albania

Background
Worldwide, depression is the second-leading cause of disability and diabetic patients have more chances to develop depression compared to non-diabetic people. The aim of our study is to estimate the prevalence of depression among type 2 diabetes patients and to investigate the sociodemographic and clinical factors associated with the presence of depression among these patients in Regional Hospital of Durres, Albania.
Methods
Through a cross-sectional study were prospectively analyzed 111 consecutive patients with diabetes mellitus admitted to the regional hospital of Durres between January and February 2022. For each patient was assessed the sociodemographic and clinical characteristics and screening of depression was performed through questionnaire according to the patient health questionnaire Beck's depression Inventory (BDI). SPSS 16.0 was used for data analysis.
Results
The prevalence of depression was 73.9 % among the diabetic patients and the female patients had a higher percentage of depression compare to men. Multivariate logistic regression analysis showed that gender female (OR=3.4), unemployment (OR=9), poor economic level (OR 4.7), the duration of diabetes mellitus over 3 years (OR=4) and marital status (OR=6) are the independent factors that influence the onset of depression.
Conclusion
Many factors as being female, unemployment, poor economic level, marital status, duration of diabetes above three years, are the independent factors that influencing the onset of depression. It is a need to develop an integrated care program to manage depression in diabetic patients. Early recognition of predictive factors associated with anxiety and depression in diabetic people is necessary to promote adherence with the treatment and compliance to diabetes control.

Applicability of intermittent intersticial glucose monitoring in patients admitted to the intensive care unit of the hospital universitario san cecilio in granada

Raúl Rodríguez Juárez[1], María Del Carmen Andreo-Lopez[1], Elena Martínez Silla[1], Javier García Sánchez[1], Laura Cánovas Noguera[1], Juan Luis Delgado Montoya[1], Maria Teresa Cruces Moreno[2] & Pablo José López-Ibarra Lozano[1]
[1]Granada, UCG Endocrinología y Nutrición, Granada, Spain; [2]Granada, UCG Cuidados Intensivos, Granada, Spain

Objective
Optimal glycemic management in critically ill patients with diabetes or stress hyperglycemia has prognostic value. For adjustment, the most used measurement in the Intensive Care Unit (ICU) is the capillary glucose. In this study, we compare interstitial glucose (IG) and capillary glucose (CG) concentrations to assess the applicability of sensor placement in patients requiring vasoactive agents.

Materials and Methods
Prospective longitudinal observational study with 6 diabetic patients or stress hyperglycemia admitted to the ICU. Demographic (sex, age), clinical (DM, high blood pressure, obesity), hemodynamic (need for vasoactives) and metabolic (A1c-type glycosylated hemoglobin (HbA1c) determined by laboratory analysis, presence of angiopathic complications, CG and IGM measurements (in mg/dl)) variables were collected. The statistical analysis was performed with the IBM SPSS v.25 programme (Statistical significance $P<0.05$).
Results
67% were males with a mean age of 65.5 ± 21.5 years. 100% have high blood pressure and 50% obese. 67% were type 2 diabetic with a mean HbA1c 6.5 ± 1.6% and 75% had angiopathic complications. The mean CG was 205 ± 66.9 and the mean IG was 152.2 ± 53.4. 67% required vasoactive agents. There was a positive correlation between capillary and interstitial measurements both in patients with and without vasoactive agents ($r=0.8$ and $r=0.7$, respectively, $P=0.0$).
Conclusions
There's a positive and strong correlation between capillary and interstitial measurements, with or without vasoactive agents. This suggests that, regardless of the patient's hemodynamic situation, IG could be useful as a glycemic measurement instrument in critically ill patients, thus improving their comfort.

Ohridski', Faculty of Mathemathics and Informathics, Faculty of Mathemathics and Informathics, Sofia, Bulgaria; [7]Sofia University 'St. Kl. Ohridski', Faculty of Mathemathics and Informathics, Sofia, Bulgaria; [8]Bulgarian Academy of Sciences, Institute of Biology and Immunology of Reproduction "Acad. Kiril Bratanov, Sofia, Bulgaria

Interferon gamma-induced protein 10, a proinflammatory chemokine, has a significant effect in inflammatory diseases. Interferon-inducible protein of 10 kD (IP-10/CXCL10), is a member of the C-X-C chemokine superfamily. It is a potent chemoattractant for activated T lymphocytes and is reported to be involved in various disease states, including atheroma plaque formation, inhibition of tumor angiogenesis and maintenance of podocyte function. However, the involvement of IP-10 in DMT2, especially in its vascular and renal complications, is not thoroughly studied. A study domain with promising potential of the IP-10 influence is its relation with patients with DMT2 with macrovascular complications in the context of disbalanced lipid profile LDL, HDL, Total cholesterol, triglycerides, BMI >30 kg/m^2, poor Glycaemic control.
Materials. Methods
To elucidate the etiopathological role of IP-10 in DMT2, we measured the concentrations of IP-10/in plasma samples from 130 patients with various degrees of macrovascular complications, and with high level of BMI and poor Glycaemic control and dyslipidemia. We focus our research on measuring of the IP-10/CXCL10 as an inflammatory marker in DM2T and its relation to the above-mentioned complications. IP-10/CXCL10 is related to patients with dyslipidaemia. Patients with higher BMI are potentially associated with increased levels of IP-10/CXCL10. To examine the dependencies between the studied blood test parameters and IP-10/CXCL10 we set up a study including following data: IP-10/CXCL10 plasma levels of 56 men and 74 women with DMT2 were measured by ELISA and compared with dose in 115 healthy control subjects. Some significant differences (t-test) between averages were obtained for all blood test parameters measured for patients with DMT2 related to IP-10CXCL10.
Results
The IP-10/CXCL10 levels were higher in diabetics than in healthy controls (251 pg/ml vs 209 pg/ml $p = 0.043$). IP-10/CXCL10 were significantly increased in hyperlipidemic men and women as compared to those with normal lipidemic profile, respectively within the group of DMT2 patients. The distribution of the number of the controlled patients in both DMT2 subgroups is not well-balanced, where very often is observed different directions of the levels of such parameters like HbA1c and BMI as compared to lipid panel. All the lab tests are significantly differentiated as related to the introduced groups of DMT2 patients and healthy controls as well as within the groups of DMT2 patients having different referent levels of the blood tests and IP-10. IP-10/CXCL10 is related to patients with high levels of LDL, HDL, Total cholesterol and triglycerides.

The role of COVID-19 in the development of diabetic nephropathy

Dilafruz Khudaybergenova[1], Dilorom Najmutdinova[1] & Khilola Mirakhmedova[2]
[1]Tashkent medical academy, Endocrinology, Tashkent; [2]Tashkent medical academy, The propaedeutics of internal disease, Tashkent

Introduction
COVID-19 is the disease caused by a new coronavirus, now called severe acute respiratory syndrome coronavirus. Long COVID is a wide range of new, returning, or ongoing health problems that people experience after being infected with the virus that causes COVID-19. Diabetic nephropathy(DN) is a frequent comorbidity in patients with COVID-19.
Aim
The aim of the present work was to study the relationship between chronic kidney disease (CKD) and SARS-CoV-2 infection and early detection of CKD.
Methods
A cohort of patients were studied with confirmed COVID-19 infection examined at the Department of infectious disease, Zangiata Infectious Diseases Hospital, Tashkent region. Bloodwithdrawalwas carried outwhen the recruited adolescents tested negative for the SARS-CoV-2 ('post-infected COVID-19'), 90 to 95 days after the last molecular test.
Results
120 adult patients were examined: 80 patients with type 2 diabetes complicated by CKD (main group) who had suffered COVID-19, and 30 patients with type 2 diabetes complicated by CKD who had not suffered COVID-19 (control group). Patients in the main (COVID-19 in combination with T2DM) and control groups (T2DM) did not differ, as expected, in gender (7 men (33.3%) in each group; $P=1.00$), age (64.3 ± 8.50 and 62.3 ± 5.96 years; $P=0.333$), HbA1c level (9.8 ± 2.09 and 9.6 ± 1.82%; $P=0.670$), as well as body mass index (30.7 ± 5.15 and 29.2 ± 5.83 kg/m^2; $P=0.131$). Both groups had the same number of patients with diabetes experience of more than 5 years (16 people each, or 76.2%; $P=1.00$). The study and control groups did not differ in the frequency of detection of such diabetes complications as nephropathy (10 (47.6%) and 11 (52.4%); $P=0.762$), retinopathy (7 (33.3%) and 11 (52.4%); $P=0.213$) and polyneuropathy (16 (76.2%) and 11 (52.4%); $P=0.110$). Analysis of tissue growth factor (TGF-β1) indicators in patients with covid 19 and diabetic nephropathy showed that TGF-β1 in this group was 1.9 times higher than normal (54.7 ± 6.1 ng/ml), compared with the control group it was 0.65 times higher ($P< 0.05$). Scientific studies have determined the levels of sensitivity and specificity of TGF-β1 as diagnostic markers in the early detection of CKD.
Conclusions
The results of our study are in accordance with those of the literature regarding in early diagnosis and prevention is the use in clinical practice of highly diagnostic laboratory research methods to identify CKD of various etiologies among the population.

Dazzeling evolution with unusual metastases of a medullary thyroid carcinoma: about a case

amira bouchenna, Benabdelatif Katia & Bensaleh meriem
central hospital of army, endocrinology, algiers, Algeria

Introduction
At the time of diagnosis of medullary thyroid carcinoma (MTC) 10 to 15% of patients have distant metastases, 25% of them develop them over a longer or shorter period of time. The usual metastases concern cervical lymphadenopathy, bone, lung and liver. There are also unusual secondary localisations. We report a case.
Observation
A 56-year-old patient who consulted a year after apparition of cervical lymphadenopathy, whose fine needle aspiration returned in favor of a MTC with serum thyrocalcitonin (TCT) level at 2000 pg/l. The extension assessment was negative, the patient was operated on and the anatomopathological study confirmed the diagnosis of MTC classified as PT3N1bM0. The genetic study of the RET mutation could not be carried out. 6 weeks after surgery the TCT level returns to 1500 pg/l. At 3 months after surgery, the patient presented with inguinal lymphadenopathy, the fine needle aspiration of which revealed a carcinomatous process with a TCT level in the liquid washing was 2342 pg/l. the serum TCT level returned to 3789 pg/l, and the extension assessment found a right adrenal metastasis of 14mm (the diagnosis of pheochromocytoma was ruled out), multiple right femoral and vertebral bone metastases with spinal cord compression of L1,

the latter's surgery is rejected, so he benefits from decompression radiotherapy. The patient is put on vandetanib

Discussion

The rapid evolution in our patient with the appearance of multiple metastases, two of which are unusual in 2 months, raises fears of a codon 918 mutation of the RET proto-oncogene. Few studies specify the proportion of rare localizations of MTC; one study of 19 patients reported 10% adrenal and digestive metastases, while another of 35 patients found no cases. In our reading we found only two described cases of metastatic inguinal lymphadenopathy.

Conclusion

Metastases from unusual locations do not seem so rare, they must be sought in the event of a doubling of TST values and be treated in patients whose survival is sometimes very prolonged.

Relationship of the mediterranean diet with vitamin d status in patients with obesity

Javier García Sánchez[1], Maria Hayon Ponce[2], María Teresa Zarco Martín[1], Socorro Leyva Martínez[1], Maria Luisa Fernández Soto[1] & Verónica Ávila Rubio[1]

[1]San Cecilio Clinical University Hospital, Endocrinology and Nutrition, Spain; [2]Virgen de las Nieves University Hospital, Endocrinology and Nutrition, Spain

Introduction

Obesity is a known risk factor for hypovitaminosis D and although several studies point out that higher adherence to the Mediterranean Diet (Diet-Med) is associated with higher dietary vitamin D intake, there are very limited data on the influence of Diet-Med on serum 25-Hydroxy Vitamin D (25OHD) levels. Our aim was to evaluate the relationship between adherence to Diet-Med and vitamin D status in obese patients.

Material and Methods

Retrospective observational study of a sample of 125 candidates for bariatric surgery evaluated during 2018-2022 at the UNCyD of the Hospital San Cecilio of Granada. Sociodemographic, anthropometric data and serum 25OHD levels were analyzed. Adherence to Diet-Med was assessed using the PREDIMED-score (<7 points = low adherence).

Results

Prevalence of good adherence to Diet-Med: 54.4%. 68.8% women. Mean age 45.3 ± 12.4 years. Mean weight 126 ± 24 kg and mean BMI 45 ± 6.8 kg/m^2. The group with good adherence to Diet-Med presented higher age (47.6 ± 10.6 vs 42.6 ± 12.8, $P = 0.03$) and higher number of patients with vitamin D sufficiency (25OHD ≥ 20 ng/ml: 46.3% vs 28.1%, $P = 0.037$). Furthermore, a statistically significant positive relationship was observed between good adherence to Diet-Med and vitamin D sufficiency ($r = 0.187$, $P = 0.038$) with an odds ratio of 2.207 (95% CI: 1.0141-4.677, $P = 0.039$).

Conclusion

The association between adherence to Diet-Med and vitamin D status in obese subjects is demonstrated.

Clinical characteristics of people with type 1 diabetes at the axarquia hospital

Luis Ignacio Navas Vela, Viyey Kishore Doulatram Gamgaram, Javier Gómez Pino, María José Vallejo Herrera & Monica Tomé García

Hospital Regional Universitario, Endocrinology and Nutrition

Introduction

For the past three years, patients with type 1 diabetes have been treated with basal-bolus therapy at the Axarquia Hospital by doctors from the Clinical Management Unit of Endocrinology and Nutrition at the Malaga Regional University Hospital. Treating patients in their own health area avoids travel and could have an impact on better follow-up, metabolic control, and the incidence of complications. The aim of this study is to describe the socio-demographic and clinical characteristics of the patients seen in this clinic.

Material and Methods

Cross-sectional descriptive observational study of patients with type 1 diabetes mellitus followed up at the Diabetes Clinic of the Axarquia Hospital. Data were obtained from their electronic medical records. The analysis was carried out using the JAMOVI programme.

Results

Data were collected from 335 people with type 1 DM. The mean age was 42.9 ± 14.8 years (16-82). Forty percent were women. The mean BMI was 26.6 ± 5.27 (15.1-51.1). 22.9% were smokers and 25.7% were ex-smokers. 25.8% had hypertension and 45.5% were on lipid-lowering therapy. 9.8% had diabetic nephropathy, 32.4% had diabetic retinopathy and 12.9% had diabetic neuropathy. The mean glycated haemoglobin was 7.70 ± 1.15. Regarding the glucose activity profile recorded by the intermittent glucose monitoring systems, sensor usage was $89.6 \pm 10.3\%$, mean glucose 174 ± 38.9 mg/dl, glucose variability $37.6 \pm 7.65\%$, mean interstitial glucose (MIG) $7.49 \pm 0.94\%$, time in range (70-180 mg/dl) $56.6 \pm 18.5\%$, time above range (181-250 mg/dl) $23.9 \pm 8.78\%$, time in very high range (>250 mg/dl) $15.8 \pm 15.4\%$, time below range (55-69 mg/dl) $3.24 \pm 3.21\%$ and time far below range (<54 mg/dl) $0.6 \pm 1.52\%$. Regarding basal insulin use, 48.2% used degludec, 49.3% used glargine U100 and the remaining 2.5% used a first-generation basal insulin analogue. For rapid insulin, 70.7% used Fiasp and the remaining 29.3% used rapid insulin analogues.

Conclusions

The Diabetes Unit of the Axarquia Hospital treats patients with complex characteristics and a high percentage of microvascular complications. It would be interesting to follow the long-term evolution of these patients and to analyse the impact of the care provided in the regional hospital on the achievement of glycaemic targets.

Impact of the world diabetes day in greece

Dimitra Ragia, Sofia Dionysopoulou, Eleni Kouroglou, Konstantinos Belis, Stella Proikaki & Ioannis Ilias

Hippokration General Hospital, Department of Endocrinology, Athens, Greece

Introduction/Aim

In this study, we aimed to evaluate the long-term impact of the diabetes awareness day in Greece (in 2016-2023), which is organized every year in November, by examining the relevant local internet searches.

Materials/Methods

We collected monthly data with Google Trends, exclusively from Greece, on relevant [online] search volumes (RSVs), with keywords "diabetes" (study group; in medical/scientific and lay terms, in Greek and in English) and "breast cancer" (control group - in Greek). The data were collected and analyzed in three periods: 2016-2019 (period A), 2020-2021 (COVID-19 period, period B), 2022-2023 (period C; Google Trends implemented a major change in the algorithms to calculate RSVs on January 1, 2022). RSVs for diabetes and breast cancer were compared by month (Kruskal-Wallis test). In addition, RSVs for diabetes were compared with those for breast cancer and were also assessed for longitudinal trends using the Sign test and Spearman's correlation analysis, respectively (statistical significance was set at $P < 0.05$).

Results

In period A, searches for diabetes-related terms outnumbered those for breast cancer, but with no differentiation in months with corresponding days of awareness for the diseases. Searches for "[blood] sugar" and "breast cancer" increased with time. In period B, searches for diabetes terms outnumbered those for breast cancer (except for "[blood] sugar"). Months with disease awareness days had more searches compared to other months. Searches for "diabetes" showed a downward trend. In period C, searches for diabetes terms outnumbered those for breast cancer. The months with diabetes awareness days showed more searches compared to other months and showed an increasing phase. Overall, of the diabetes terms, searches for "[blood] sugar" stood out for their predominance over the other terms combined with their increasing trend.

Discussion/Conclusions

Diabetes was more popular in online searches than breast cancer and interest in it online, with the exception of the Covid-19 period, had an increasing trend in Greece. Based on these results, the effectiveness of the diabetes day is judged positively, in spite of critics of such actions. The trend of the lay search term "[blood] sugar" could be attributed to the doubling of the percentage of people over 65 years of age in the country accessing the Internet in the last decade. In addition, it is important to note that the study's reliance on internet searches and the potential influence of other factors on search trends may introduce limitations.

The main risk factors in type 2 diabetes for cognitive dysfunction, depression, and psychosocial problems

Maarja Randväli[1], Toomas Toomsoo[2] & Jekterina Šteinmiller[1]
[1]Tallinn Health Care College, Nursing, Tallinn, Estonia; [2]Tallinn University, Natural Science and Health, Tallinn, Estonia

The aim of this study is to analyze the risk factors that lead to cognitive impairment, depression, and psychosocial problems in type 2 diabetes and discern what aspects they have in common. Type 2 diabetes is associated with a higher risk of cognitive impairment, including dementia, which in turn increases the risk of hospitalization, falls, and premature mortality. In this study, we conducted a systematic review to achieve this goal, including searches on electronic databases such as PubMed, Medline, Web of Science, EBSCO Discovery, EBSCO host, Scopus, and ScienceDirect, from 2016 onwards. Additionally, we carried out manual searches in leading journals in the field. After evaluating and analyzing the articles, 60 remained, focusing on the following four main themes: disorders due to biological, psychological, social, and pharmacological causes that lead to neuropsychological complications. Based on the results, consistently analogous risk factors contributing to the onset of cognitive impairments, depression, and psychosocial predicaments encompass comorbid ailments, dysglycemia, gender, heightened levels of apprehension and anxiety, educational attainment, socio-economic standing, and pharmaceutical interventions. Furthermore, in the realm of type 2 diabetes, factors such as disease duration, adiposity, specifically overweight and obesity, and advancing age were also identified as significant contributors to cognitive impairments and depression. Concomitantly, the absence of a robust support system and social network emerged as a shared risk factor, predisposing individuals to psychosocial challenges and depressive states. These findings emphasize that the risk factors for cognitive impairments, depression, and psychosocial issues for type 2 diabetes are similar, highlighting the importance of psychosocial support, education, and patient-centered treatment to optimize outcomes and quality of life.

Determination of diabetes care profile and diabetes management in individuals with type 2 diabetes: turkey survey

Saadet Can Cicek[1], Muhammed Emin Demirkol[2], Emine Kir Biçer[3] & Derya Kocadag[4]
[1]Bolu Abant izzet Baysal University, Department of Nursing, Bolu, Turkey; [2]Abant izzet Baysal Üniversitesi, Department of Internal Medicine, Turkey; [3]Mustafa Kemal Üniversitesi Tayfur Sökmen Kampüsü, Turkey; [4]Bolu Provincial Health Directorate, Turkey

Objective
This study aimed to determine the diabetes care profile and diabetes management in individuals with type 2 diabetes.
Methods
The population of the cross-sectional study consisted of individuals with Type 2 diabetes who received treatment in the internal medicine services of Public Hospitals in a province, and 377 individuals who met the inclusion criteria constituted the sample. Data was obtained using the Information Form, the Summary of Diabetes Self Care Activities Questionnaire (SDSCA) and the Diabetes Care Profile Scale.
Results
The mean age of the participants was 60.7 ± 9.7 years, 65.3% were female, the duration of diabetes was 10.71 ± 7.0 years, the HbA1c level was 7.2 ± 1.4, the most common type of diabetes treatment was nutrition and oral antidiabetic medication, and 7.2% developed diabetes-related complications. Among the subscales of the diabetes care profile scale, control problems (4.87 ± 1.14), which is one of the factors that impede diabetes control, and long-term results (4.41 ± 1.07), which is one of the factors that improve diabetes control, received the highest scores. Control problems was higher in women who were illiterate, living with their parents, using nutrition + oral antidiabetic medication + insulin and did not receive training on diabetes ($P < 0.05$). The long-term care benefits sub-scale was higher in smokers, those who take nutrition + oral antidiabetic medication + insulin therapy, and those with a family history of diabetes. An inverse correlation was found between diabetes self-care activities and the factors that impede diabetes management difficult except for medical barriers while a positive correlation was found between diabetes self-care activities and the factors promoting diabetes management except for long-term care benefits and blood glucose monitoring ($P < 0.05$).
Conclusion
It was seen that factors impeding and promoting diabetes management differed in terms of sociodemographic and diabetes-related characteristics of individuals with diabetes, and a significant relationship was determined between diabetes care profile and diabetes self-care activities.

Evaluation of knowledge and practices of individuals with diabetes towards diabetes technologies

Emine Kir Biçer[1] & ilker Tutur[2]
[1]Mustafa Kemal Üniversitesi Tayfur Sökmen Kampüsü, Demartment of Internel Medical Nursing, Turkey; [2]Kırıkhan Devlet Hastanesi, Turkey

Objective
This study was conducted to evaluate the knowledge and practices of individuals with diabetes towards diabetes technologies
Method
A total of 514 people consisted of the sample of the descriptive and cross-sectional study. Data were collected through a questionnaire developed by the researchers, and the Unified Theory of Technology Acceptance and Use Scale-2 was applied using an online Google survey distributed through social media.
Results
The study's participants, with a mean age of 29.9 ± 12.2 years, displayed a diverse demographic profile, with 68.3% being female, 38.9% holding a bachelor's degree or higher, and 59.3% being single. The mean duration of diabetes among participants was 10.4 ± 6.6 years, primarily managed with insulin (82.7%). Among insulin users, 67.7% favored insulin pens, 19.3% opted for insulin pumps, and 13.0% used insulin injectors. Participants checked blood glucose levels an average of 7.9 ± 8.0 times per day and injected insulin 3.6 ± 0.7 times daily. Regarding technology usage, 94.9% of participants reported using mobile phones, 91.4% owned smartphones, and 77.8% used computers. Notably, 72.6% were aware of Continuous Glucose Monitoring Systems (CGM), 78.4% knew about insulin pump therapy, 77.8% were familiar with insulin pens, and 34.0% recognized mobile applications related to diabetes. In terms of technology adoption, 39.9% used CGM, 51.8% utilized glucometers, 20.2% employed insulin pumps, 1.8% accessed telehealth services, and 16.3% utilized mobile technology. Participants expressed interest in receiving information about CGM (21.4%), insulin pumps (41.8%), hypoglycemia warning wristbands (45.1%), and insulin ports (37.7%). Overall, 80% of individuals reported that diabetes-related devices significantly influenced their lives, with 82.3% finding them effective. Internet usage in relation to diabetes included participation in social networks (58.9%), seeking information (58.4%), and gaining social support (20.4%). Participants most frequently searched for information on nutrition (67.1%) and insulin treatment (53.5%). The frequency of use of mobile services by individuals with diabetes was found to be every day at the highest rate (66.3%). The mean score of the Unified Theory of Acceptance and Use of Technology Scale-2 was 132.2 ± 47.8 (min = 27-max = 188).
Conclusion
The study revealed predominant use of insulin pens and a high reliance on mobile technology among individuals with diabetes. While interest in advanced technologies exists, the adoption of telehealth services remains low. The study suggests a moderate level of technology acceptance and use among the participants.

Correlation between kalemia and biochemical parameters in patients with diabetic ketoacidosis

Ines Mezghani[1], Omaima Hammami[1], Rim Marrakchi[1], Faten Hajkacem[2], Mariem Boudaya[1], Kamel Jammoussi[1], Nabila Rekik[2], Mohamed Abid[2] & Mouna Turki[1]
[1]Hedi-Chaker University Hospital, Biochemistry Departement, sfax, Tunisia; [2]Hedi-Chaker University Hospital, Endocrinology Departement, sfax, Tunisia

Introduction
Ketoacidosis is a frequent and life-threatening complication of diabetes. Our aim was to study the Correlation between kalemia and biochemical parameters in patients with diabetic ketoacidosis.

Methods
This is a retrospective descriptive study concerning all patients hospitalized in the Endocrinology Department for Diabetic Ketoacidosis (DKA) between August 2021 to December 2022. Acidosis markers were measured using an ABL 80 FLEX blood gas analyser, and the biochemical parameters using the DXI 700 AU (Beckman Coulter) analyser. IBM SPSS was used for statistical analyses.
Results
Out of 30 patients, 19 (63,3%) patients had type 1 diabetes and 11(36.7%) had type 2 diabetes. The mean age of patients was 26.7 ± 10.4 years (type 1 diabetes 22 ± 6.5 years; type 2 diabetes 34.9 ± 11 years). The sex-ratio (H/F) was 0.66. There was significant difference in the initial laboratory evaluation between type 1 and type 2 diabetes patients only for the pH and serum bicarbonate ($P=0.010$ and $P=0.024$, respectively). Among patients, 26.66% had hypokalaemia (potassium concentration (k^+C) <3.3 mmol/l), 16.66% had k^+C between 3.3 and 3.5 mmol/l. In 26.66% of cases the k^+C was between 3.5 and 4 mmol/l and 16.66% of patients had k^+C between 4 and 4.5 mmol/l. In 10% of patients the k^+C was between 4.5 and 5 mmol/l. Only one patient was presented with hyperkalemia. The mean age of the group who presented hypokalemia was 27.12 years ± 8.62 and 50% of them were Type 1 diabetes. None of the patients had neuromuscular or electrical signs of dyskalemia. Potassium levels were correlated with serum glucose($r=0.523$), glycated hemoglobin ($r=0.468$), pH ($r=0.597$), serum bicarbonate($r=-0.380$), PCO2($r=0.309$), PO2($r=0.257$) and creatinine($r=0.293$).
Conclusion
Hypokalemia was observed in 26.66% of patients with DKA. Further research is needed to better determine the risks and benefits of administering insulin before obtaining serum potassium values.

Post-absorptive and post-prandial glucose and fat metabolism in post-menopausal women with breast cancer after chemotherapy compared to healthy controls

Kristian Buch-Larsen[1], Simone Marstrand[1], Djordje Marina[1], Linn Gilberg[2], Michael Andersson[1], Gerrit Hall[1] & Peter Schwarz[1]
[1]Rigshospitalet, København, Denmark; [2]Copenhagen University, København, Denmark

Background
Breast cancer survivors are a growing population due to improved treatment. It is known that postmenopausal women treated for breast cancer may experience weight gain and increased insulin resistance, but detailed knowledge on how chemotherapy impact metabolic and endocrine mechanisms remain unknown.
Objective
We performed a thorough, preliminary study to elucidate the differing mechanisms of post-prandial absorption and metabolism in postmenopausal early breast cancer (EBC) patients treated with adjuvant chemotherapy compared to healthy controls. We hypothesize that chemotherapy has a negative impact on metabolism in EBC patients.
Methods
We examined four postmenopausal women shortly after treatment with chemotherapy for EBC and four age-matched healthy women who served as controls using isotopic tracers during a mixed meal-test. Blood was sampled during the 240 min meal-test to examine post-prandial absorption and endogenous synthesis of lipid and carbohydrate metabolites.
Results
We found that insulin concentrations were numerically higher before the meal-test in the EBC patients compared to controls (76.3 pmol/l vs 37.0 pmol/l; $P=0.06$). Glucose kinetics was increased post-prandial (most pronounced at 30 minutes, 9.46 mmol/l vs 7.33 mmol/l; $P=0.51$), with no difference between the groups regarding liver glucose output. Fatty acid kinetics showed a numeric increase in oleic acid rate of appearance in BC patients, but only during the first hour after the mixed meal. There was no significant difference in VLDL-TAG synthesis between the two groups.
Conclusions
This preliminary study is unique in using advanced tracer methods to investigate *in vivo* metabolism of EBC patients after chemotherapy although no statistical differences in glucose and fatty acid kinetics was seen compared to controls. However, during the first two post-prandial hours, oral glucose and oleic acid appearance in the systematic circulation was elevated in the EBC patients. This could be due to changes in gastrointestinal uptake and further studies with altered set-up could provide valuable insights.

Differences in sleep quality of patients with type 2 diabetes experiencing low perceived psychological stress and high perceived psychological stress

Lina Radzeviciene & Lina Lasaite
Lithuanian University of Health Sciences, Institute of Endocrinology, Kaunas, Lithuania

Aim
to assess sleep quality in patients with type 2 diabetes (T2D) experiencing low perceived psychological stress and high perceived psychological stress.
Methods
Perceived stress level and sleep quality were assessed in 154 patients with T2D (58 men, 96 women, age 58.7 ± 11.8 years), using Perceived Stress Scale (a higher score denotes a higher level of perceived stress) and Pittsburgh Sleep Quality Index (a higher score denotes worse sleep quality).
Results
Patients with T2D with high stress level had worse subjective sleep quality ($P=0.027$), higher use of sleeping medication ($P=0.023$), daytime dysfunction ($P<0.001$) than those with low stress level. No significant differences were found in sleep latency, sleep duration, habitual sleep efficiency and sleep disturbances as well as in T2D duration, body mass index and glycated haemoglobin (HbA1c) level between patients experiencing low and high perceived stress. Perceived stress level in patients with T2D correlated with subjective sleep quality ($r=0.260$, $P=0.002$), sleep duration ($r=0.228$, $P=0.005$), use of sleep medication ($r=0.245$, $P=0.004$), daytime dysfunction ($r=0.326$, $P<0.001$).
In conclusion, patients with type 2 diabetes experiencing high perceived psychological stress level have worse subjective sleep quality, higher use of sleeping medication, daytime dysfunction than patients experiencing low perceived stress level. Perceived stress level in patients with type 2 diabetes is related to subjective sleep quality, sleep duration, use of sleep medication, daytime dysfunction.

Type 2 diabetes and cancer: phenotyping of patients followed in a tertiary diabetic centre

Edoardo Luigi Maria Mollero[1], Carola Ciamparini[1], Davide Vimercati[1], Leonardo Bighetti[1], Giulia Marsan[1], Lorenza Scotti[2], Paolo Marzullo[1], Marina Caputo[1,3], Gianluca Aimaretti[1] & Flavia Prodam[1,3]
[1]SCDU Endocrinologia, University of Eastern Piedmont, Department of Translational Medicine, Novara, Italy; [2]University of Eastern Piedmont, Department of Translational Medicine, Novara, Italy; [3]University of Eastern Piedmont, Department of Health Sciences, Novara, Italy

Background
Data on the relationship between type 2 diabetes (T2D) and cancer consistently suggests the involvement of metabolic mechanisms such as inflammation, obesity, and glucose alteration. These mechanisms, including the activation of factors like IGF-1 or m-TOR, may influence the development of cancer.
Aim
Our study had two main objectives. Firstly, we aimed to investigate the relationship between specific identifiable factors associated with T2D and the timing of cancer onset. Secondly, we sought to examine the relationship among cancer recurrence, second primary cancers, and the presence of either of them, while considering the same variables.
Methods
We selected 1089 patients affected by both T2D and cancer, carried out from the Smart Digital Clinic electronic medical record system using relevant key words related to the field of cancer. The variables of interest were measured at baseline and during the last visit of follow-up. For statistical purposes, only the variables at baseline were compared to the time of cancer onset. Subsequently, all variables were stratified by sex. Various types of cancers were classified based on the organ system they affected.
Results
Almost all the variables considered had not a statistically significant relationship with the time of cancer onset. Smoking resulted the only factor that can influence it ($P=0.0024$). Furthermore, when considering cancer recurrence, second primary cancer, or either of them, none of the variables showed a relationship with them. The same variables were stratified by sex at baseline and at the last visit of follow-up. Females were found to be more overweight ($P=0.0314$) and in need of higher doses of insulin ($P=0.0181$) compared to males. This is because they had worse glucose control, with higher levels of HbA1c ($P=0.0004$) and fasting blood glucose ($P=0.0348$) compared to males both at baseline and at the last visit. On the

contrary, males had a higher rate of smoking and alcohol consumption compared to females (both $P<0.0001$). Lastly, among the variables considered and the three events (cancer recurrence, second primary cancer and either of them), the only variable found to be sex-related was the LDL-cholesterol compared to cancer recurrence, which was slightly higher in female than males ($P=0.0356$).
Conclusion
We observed that, apart from smoking, all the variables considered identifiable factors with T2D had not an influence on the time of cancer onset, as well as on cancer recurrence, second primary cancer or either of them.

Necrotizing otitis externa in diabetic patients: clinical features and out come

Meherzi Samia[1], Lansari Salma[2] & Omri Rihab[3]
[1]University of Sousse, Faculty of Medecine of Sousse, ENT Departement, Tunisia; [2]University of Sousse, Faculty of Medecine of Sousse, Ent Department, Tunisia; [3]University of Sousse, Faculty of Medecine of Sousse, Ent Department, Tunisia

Objective
Describe clinical features and therapeutic modalities of diabetic patients hospitalized for necrotizing otitis externa in our department.
Materials and methods
Retrospective study about 19 diabetic patients treated for necrotizing otitis externa in our department over a period of 7 years (2016 - 2022). All patients had a bacteriological and mycological otorrhea sampling, computed tomography and laboratory test.
Results
The average age of our patients was 60 years old (22-91 years old) with female predominance. Severe otalgia resistant to standard treatments was observed in all cases. Two patients suffered from facial palsy. All patients received pre-hospital antibiotic therapy for an average duration of 7 days (5 – 21 days). The average time for germ isolation was 4 months (3 days – 3 months). The bacteriological study of the initial samples was positive in 12 cases. The most common germ was Pseudomonas Aeruginosa (9 cases). 4 patients had an aspergillary infection (fungal transformation in 3 cases). Aspergillus serology was positive in two patients who still had negative samples. Treatment was based on parenteral antibiotic therapy combining a Fluoroquinolone (Ofloxacin) with a Third Generation Cephalosporin (Ceftazidim) or a Carbapenem in the majority of cases, with an average duration of 45 days. The fungal forms received antifungal treatment (Itraconazole) for an average duration of 3 months (66 days– 5 months). The evolution was favorable in all cases. No recurrence was noted with an average follow-up of 15 months.
Conclusion
Necrotizing otitis externa represents a diagnostic and therapeutic challenge for any ENT practitioner. Fungal forms are clearly on the rise. The multiplicity of bacteriological and mycological samples improves the rate of positive results and establishes the appropriate treatment.

Coronary arteries atherosclerosis in patients with type 2 diabetes and coronary heart disease

Elena Brutskaya-Stempkovskaya[1], Alexandr Aleshkevich[1], Oleg Kozak[2], Iryna Subota[2], Karina Liahkova[1], Lizaveta Tsitova[1] & Yuliya Dydyshka[1]
[1]Belarusian State Medical University, Minsk, Belarus; [2]Minsk Scientific and Practical Center for Surgery, Transplantology and Hematology, Minsk, Belarus

Type 2 diabetes (T2D) is an independent risk factor for coronary heart disease (CHD). CHD in patients with T2D develops at an earlier age and is characterized by severe damage to the distal coronary arteries.
Materials and Methods
A cross-sectional controlled study of 50 hospitalized cardiac patients with chronic CHD was conducted to assess the effect of T2D on the condition of the coronary arteries using coronary angiography. The main group: patients with CHD and T2D, age-68.5$\pm$9.63 years (women-44.12%, men-55.88%). The comparison group: patients with CHD without T2D, age–69.5$\pm$13.14 years (women–43.75%, men–56.25%).
Results
Patients of both groups were comparable in gender, age ($P>0.05$), laboratory data: cholesterol, TG, HDL, VLDL, AST, ALT, creatinine, total protein ($P>0.05$) in blood serum. The blood glucose level in patients of the main group was significantly higher compared to the comparison group (6.8 (5.5-8.5) vs 5.5 (5.2-6.0) mmol/l, $P=0.01$). HbA1c=7.7$\pm$1.73% in patients of the main group, the experience of T2D according to the anamnesis was 8.2$\pm$3.14 years. The HbA1c level in patients of the main group was 7.7$\pm$1.73, which indicates insufficient control of T2D. According the coronary angiography results, hemodynamically significant stenosis involving coronary arteries peripheral parts were identified in 43.7% of patients in the comparison group: in the left coronary artery, right coronary artery, anterior interventricular branch, circumflex branch, diagonal branch, obtuse edge branch. In 79.4% of patients in the main group the number of hemodynamically significant stenosis involving peripheral parts was identified in the left coronary artery, circumflex branch, diagonal branch, and obtuse margin branch, and right coronary artery, anterior and posterior interventricular branches. The results indicate a significant increasing of hemodynamically significant stenosis involving the peripheral parts of the coronary arteries in patients with CHD and T2D ($\chi2 = 6.4$, $P=0.012$). The higher prevalence and depth of the pathological process was recorded in patients with CHD and T2D.
Conclusions
The results of the study show an increasing prevalence of the coronary atherosclerosis confirmed by coronary angiography in patients with coronary heart disease and type 2 diabetes compared with patients with coronary heart disease without type 2 diabetes by 35.7%. More severe coronary atherosclerosis was identified in patients with coronary heart disease and type 2 diabetes, included hemodynamically significant stenosis involving predominantly peripheral parts of the coronary arteries, caused by the development of atherosclerotic plaques and arterial tortuosity, which is likely due to diabetic angiopathy against the background of chronic hyperglycemia.

Incidence of new onset type 1 diabetes in children during the covid-19 global pandemic

Nataliia Kurmacheva[1], Michail Svinarev[2], Olga Gumeniuk[1] & Yuriy Chernenkov[1]
[1]Saratov State Medical University, Hospital Paediatrics, Saratov, Russian Federation; [2]Saratov State Medical University, Paediatrics, Saratov, Russian Federation

The COVID-19 pandemic has an impact on the incidence of type 1 diabetes. It is important to synthesize estimates of changes in incidence rates.
Aim
To compare the incidence rates of type 1 diabetes mellitus (T1DM) in children of Saratov region during and before the COVID-19 pandemic.
Patients and methods
This is a retrospective multicenter study involving new onset T1DM paediatric patients (0-17 y.o.) in Saratov region, during periods 1994-2023 years.
Results
Incidence of T1DM in children of Saratov from 1994 to 2019 it increased by 3 times (8 cases in 1994 and 24 cases in 2019 per 100,000 paediatric person). The type 1 diabetes incidence rate increased during the COVID-19 pandemic vs before the pandemic among children and adolescents (32 cases in 2020 and 28 cases in 2021 per 100,000 paediatric person). The incidence of new onset DM1 among children in the Saratov region remains high (26 cases in 2022 and 29 cases in 2023 per 100,000 paediatric person).
Conclusions
New onset T1DM increased during the pandemic. Further studies are required to evaluate the mechanism leading to this rise to guide intervention measures. It is important to further study the prevalence and features of the course of T1DM in children who have been ill COVID-19, compared with those who have not had coronavirus infection and vaccinated children.

Micronutrients intake and cellular protection in type 2 diabetics

Hana Ben jemâa, Berriche Olfa, Rym Ben Othman, Ramla Mizouri, Ben Amor Nadia, Amel Gamoudi, Emna Talbi & Jamoussi Henda
National Institute of Nutrition, A

Introduction
Micronutrients play a crucial role in cellular protection against external aggressions, particularly combating oxidative stress and aging. The aim of our study was to

determine the association between micronutrient intake and cellular protection in diabetic patients.
Methods
A descriptive study was performed on 115 type 2 diabetics. Each patient underwent a dietary survey to assess micronutrient intake. We used the Functional Food Questionnaire (FFQ) related to cellular protection and validated by the European Institute of Dietetics and Micronutrition (IEDM) to classify the patient's dietary habits into favorable, less favorable, and unfavorable categories based on the obtained score.
Results
The median age of patients was 57.93 ± 7.48 years. The majority of included patients were female (67.8%) with a sex ratio (female/male) of 2.1. For vitamins, a deficiency in vitamin D intake was the most observed among our patients (51.4%). Regarding minerals, a magnesium intake deficiency was the most frequent and encountered in 52.2% of patients. Favorable, less favorable, and unfavorable dietary habits were observed in 22.6%; 38.3%; and 39.1% of the patients, respectively, using the FFQ. In our study, we found positive and significant associations between the FFQ score relative to cellular protection and intake of vitamin A ($P=0.033$), vitamin C ($P<0.001$), and manganese ($P=0.031$). In multivariate analysis favorable habits were associated with vitamin C intake ($P=0.002$).
Conclusion
A well-balanced diet rich in antioxidants, especially in vitamin C, vitamin A, and manganese, enables the body to combat oxidative stress. A deficiency in micronutrient intake may clinically manifest through various functional signs such as skin disorders and infectious issues, potentially altering the quality of life of patients.

Charcot foot in diabetes: review of 35 cases

Hani Meriem[1], Imane el ghebir[1,2], Rehaimia Amina[1] & Ait Abderrahmane Samir[1]
[1]Algiers Province, Algeria; [2]

Background and aims
Charcot neuroarthropathy (CN) is a devastating and destructive disease of the bone structure and joints. Despite the fact that its description was published almost 130 years ago, its pathophysiology, risk factors, diagnosis, and treatment remain areas that need to be described. This study aims to describe patient characteristics and comorbidities as well as the clinical and morphological characteristics of these neuroarthropathies.
Material and methods
This is a retrospective and prospective study of 35 patients with neuro-arthropathy among patients hospitalized in our department between 2002 and 2022. Data for sex, age, diabetes type, duration, complications and treatement as well as the anatomical classification, stage of CN, diabetic foot ulcer, Hba1c were collected.
Results
35 patients aged 56 years on average, were included. Patients are mostly type 2 diabetics (79%), aged 56 on average, male (66%) and overweight (average BMI 27.57 kg/m^2). Diabetes is of long evolution (17 years on average) with poor glycemic control (average Hba1c at 9.39%), insulin-requiring (83%) and presents multiple micro and macrovascular complications (diabetic neuropathy 100%, diabetic retinopathy 83%). The majority of neuroarthropathies are chronic (79%), with acute cases (21%) being rarely diagnosed in time. An ulcer is revealing in nearly half of the cases (51%). Midfoot involvement is classically the most frequent: Type 2 (31%), Type 3 (17%). We observed a large number of simultaneous attacks on several areas. The radiological stages were as follows: Stage 0 (3%), Stage 1 (14%), Stage 2 (14%), Stage 3 (69%). MRI is performed in 41% of cases: grade 1 (4%), grade 3 (10%), grade 4 (17%), grade 5 (10%).
Conclusion
Charcot's foot constitutes a diagnostic and therapeutic challenge. Indeed, an early diagnosis makes it possible to avoid the installation of sometimes severe and disabling deformations.

Can micronutrients intake really impact brain health ?

Berriche Olfa, Hana Ben jemâa, Rym Ben Othman, Amel Gamoudi, Emna Talbi & Jamoussi Henda
National institute of nutrition, A

Introduction
Micronutrients are involved in numerous physiological processes at the cellular level. They play an essential role in the synthesis of neurotransmitters, crucial for the brain's optimal functioning. The aim of our study was to determine the association between micronutrient intake and brain function in type 2 diabetic patients using a validated questionnaire.
Methods
A descriptive analysis was conducted on 115 type 2 diabetics. Each patient underwent a dietary assessment to evaluate their micronutrient's intake. The Dopamine Norepinephrine Serotonin questionnaire (DNS) is used to assess the impact of diet on brain function. The DNS is validated by the European Institute of Dietetics and Micronutrition (IEDM) and it classify individuals into 4 groups: low score, moderate score, high score, and very high score based on the functional disorders presented by the patients.
Results
The median age of patients was 57,93 ± 7,48 years. The majority of included patients were obese (53.4%). For the DNS score related to dopamine, moderate, high, and very high scores were noted in 30.4%, 19%, and 18.8% of patients, respectively. Regarding norepinephrine, a high score was most observed among patients (36.5%). Low, moderate, and very high scores were noted in 25.2%, 35.7% and 2.6% of patients, respectively. As for serotonin, patients predominantly had a low score (44.3%). Moderate, high, and very high scores were noted in 36.5%, 15.7% and 3.5% of patients, respectively. Negative and significant associations were found between dopamine score and intake of vitamin B9 ($P=0.002$), magnesium ($P=0.003$), and copper ($P=0.007$). Negative and significant associations were found between Noradrenaline score and intake of vitamin C ($P=0.046$), vitamin B6 ($P<0.001$), magnesium ($P=0.024$), and zinc ($P=0.009$). Negative and significant associations were found between Serotonin score and intake of vitamin B12 ($P=0.001$), magnesium ($P=0.027$), and zinc ($P=0.047$).
Conclusion
As cofactors in neurotransmitter synthesis, Micronutrients influence not only the brain but the entire body functioning. In fact, nourishing the cellular city with a balanced diet help patients particularly type 2 diabetics having optimal brain functioning and long-term prosperity.

Benefits of Moringa oleifera on metabolic parameters in type 2 diabetics

Khouloud Boujelbene, Maryam Cheikhrouhou, Fatma Mnif, Dhouha Ben Salah, Mouna Elleuch, Mouna Mnif, Nadia Charfi, Faten Hadj Kacem, Mohamed Abid & Nabila Rekik
Hedi Chaker Sfax, Endocrinology Department, Tunisia

Introduction
Moringa is a common tropical tree in Africa that has become a subject of interest for scientists due to its interesting composition and nutritional qualities. The objective of this study was to evaluate the effects of Moringa oleifera powder on metabolic parameters in diabetic patients in the short term.
Method
We conducted a randomized controlled study with ten type 2 diabetic patients treated with oral antidiabetic medications. Each patient received 5 g of Moringa powder per day for 15 days, followed by 8 g per day for the next 15 days. Glycemic and lipid profiles were assessed before the protocol, on day 15, and on day 30.
Results
There was a female predominance (80%) in the study. Hypertension was found in 80% of patients, and obesity was present in 20% of patients. Before the protocol, the average fasting blood glucose was 8.61 ± 3.51 mmol/l, and the average HbA1C was 7.93 ± 3.67%. After 30 days of Moringa powder consumption, a decrease of 18.73% in fasting blood glucose was observed. Regarding HbA1C, no significant change was noted after 30 days. Analysis of the lipid profile showed a decrease of 13.05% in total cholesterol and a decrease of 19.62% in triglyceride levels after 30 days of Moringa powder consumption.
Conclusion
While further research is needed to confirm these observations, these results suggest that Moringa oleifera could be considered as a potential dietary supplement to improve metabolic parameters in individuals with type 2 diabetes.

Diabetics Retinopathy Knowledge and Awareness Assessment among Tunisian patients with Type 2 Diabetes

Mouna Elleuch, Hamdi Frikha, Dhoha Ben Salah, Khouloud Boujelben, Faten Haj Kacem Akid, Fatma Mnif, Nadia Charfi, Mouna Mnif, Mohamed Abid & Nabila Rekik Majdoub
Hedi Chaker University Hospital, Department of Endocrinology, Sfax, Tunisia

Introduction
Diabetic retinopathy (DR) is the most common cause of acquired blindness. Patient information about its course and prognosis is key to insure therapeutic adherence and reduce the risk of blindness. The aim of this study is to assess Tunisian patients' level of knowledge about DR and to correlate it with DR severity.
Methods
We conducted a cross-sectional descriptive and analytical study of diabetic patients with DR followed at outpatient unit of the endocrinology department of Hedi Chaker University of Sfax, Tunisia. Patients' knowledge about DR was assessed using a open-end survey in Arabic language.
Results
We enrolled 41 T2DM patients in the study. Mean age was 49 years. Patients were predominantly male. Funduscopic examination showed that 76% of patients had pre-proliferative DR while 24% had proliferative DR. We found that 51% of patients were unaware of the risk of DR. The majority of patients (69%) were unable to specify the types of ocular damage related to diabetes. Preventive measures were poorly understood and executed: In fact 84% of patients could not enumerate any effective method to delay the onset of DR and 78% have never undergone a specialized ophthalmological assessment of retina throughout the course of the disease. We found that a lesser survey global score was associated with more severe DR phenotype (OR = 3.2; $P = 0.04$).
Conclusion
DR is emerging as an important cause of visual impairment. Proactive participation of patient is key to insure better management outcomes. Our results showed poor global level of knowledge among Tunisian patients, in contrast with results by Almalki *et al*. (2018). Adequate therapeutic education about DR has been linked to better outcomes in a study by Assem *et al*. (2020). These results should prompt practitioners to develop therapeutic education programs regarding DR.

Knowledge of diabetes mellitus during Ramadan fasting among Tunisian patients with diabetes mellitus

Khouloud Boujelben, Dhoha Ben Salah, Feriel Touzi, Elleuch Mouna, Mouna Mnif, Fatma Mnif, Faten Hadj Kacem, Charfi Nadia, Abid Mohamed & Rekik Nabila
Hedi Chaker Hospital, endocrinology department, Sfax, Tunisia

Introduction
For individuals adhering to the Islamic faith, the observance of Ramadan fasting introduces a multitude of challenges, particularly regarding patients' non-adherence to mitigating increased risks of glycemic imbalance and associated complications. This study aimed to assess the depth of knowledge among Tunisian Muslim patients diagnosed with diabetes mellitus (DM) regarding their self-management practices while fasting during the holy month of Ramadan.
Patients and Methods
A cross-sectional and descriptive study was conducted, involving 70 patients diagnosed with diabetes mellitus, at the Endocrinology Department of Hedi Chaker Hospital in Sfax, Tunisia. The study was conducted from March 15 to the end of April 2021, targeting adult individuals with diabetes mellitus who observed fasting for at least 15 days per month. Data were collected through a questionnaire in French, comprising 76 questions, translated into Arabic, and aligned with the Tunisian consensus on the management of diabetes during Ramadan.
Results
Seventy patients were enrolled, with an average age of 55 years and a female predominance, resulting in a sex ratio (M/F) of 0.3. Eighty-six percent of patients were diagnosed with type 2 diabetes, and 41% were prescribed oral antidiabetics, predominantly metformin, used as a monotherapy in 62% of cases. The mean HbA1c was recorded at 10%. Diabetic risk stratification revealed that 22.8% of patients were classified as high risk. More than half (56%) of patients demonstrated awareness that hypoglycemia poses a significant risk, especially for younger individuals. Nineteen (27%) patients could accurately identify high-risk treatment scenarios. Sixty-four percent of respondents were aware that the pre-dawn meal (suhoor) should be consumed as late as possible. Relating to clinical practices, fifty-five (79%) patients underwent a pre-Ramadan consultation. The medical practitioner advised against fasting in 36 patients. Moreover, thirty patients (43%) were equipped with a glycemic monitoring device. Hypoglycemic events were reported in 25 (36%) patients. However, forty-seven (67%) individuals did not alter their prescribed medication regimen. A notable 33% of patients skipped the pre-dawn meal. Additionally, 53 patients (76%) refrained from engaging in regular physical activity.
Conclusions
This study underscores the importance of providing clear and practical guidance on dietary choices, glycemic control, physical exercise, and potential therapeutic adjustments for individuals with diabetes observing fasting during Ramadan.

Diabetic retinopathy: Is neuropathy part of its etiopathogenesis?

Youssef Gharbi, Bchir Najla, Salma Salhi, Annam Benchhida, Dorra Dorraelguiche, Zouaoui Chadia & Haroun Ouertani
Military Hospital of Tunis, Endocrinology, Tunis, Tunisia

Introduction
Diabetic retinopathy (DR) is the leading cause of blindness before the age of 50. The etiopathogenesis of DR is still controversial. Even if the microvascular damage is undeniable, the place and importance of the nerve damage must be defined. Our objective was to evaluate the association between DR and diabetic neuropathy (DN) in type 2 diabetics.
Methods
It was a cross-sectional, comparative study that included 100 type 2 diabetic patients divided equally into two groups according to the presence or absence of DR, matched according to age, gender and duration of diabetes. We detected neuropathic damage using the DN4 score. We also evaluated the deep tendon reflexes and looked for signs of autonomic neuropathy such as gastroparesis, intractable constipation, and erectile dysfunction.
Results
The average age of our population was 62.01 ± 9.37 years and the sex ratio (Men/Women) was 1.08. DR had a mean duration of progression of 3.84 ± 2.63 years. 39% of the total population had diabetic neuropathy distributed as follows: 71% peripheral neuropathy, 11% autonomic neuropathy, 18% peripheral and autonomic neuropathy. DN was 4.57 times more present in the group with DR than in the group without DR (64% vs 14%) and DR was significantly associated with DN ($P < 0.001$). Multivariate analysis confirmed this association ($P < 0.001$, OR = 9.6).
Conclusion
Our study showed a strong association between DN and DR. These results support the involvement of ophthalmic nerve damage to a greater extent than our prerequisites, giving rise to a promising field of investigation (with extensive ophthalmic and neurological imaging).

Association of type 1 diabetes and autoimmune diseases

Fatima Zahra Zerrouki[1], Fatimzahra Bentebbaa[1], Magouri Oumaima[1], Siham Rouf[2] & Hanane Latrech[2]
[1]Department of Endocrinology-Diabetology and Nutrition CHU Mohammed-VI Oujda, Oujda, Morocco; [2]Department of Endocrinology-Diabetology and Nutrition CHU Mohammed-VI Oujda, Laboratory of Epidemiology, Clinical Research and Public Health, Faculty of Medicine and Pharmacy Oujda, Mohammed Premier University Oujda, Morocco, Oujda, Morocco

Introduction
Type 1 diabetes (T1DM) is an autoimmune disease that accounts for over 90% of diabetes in children and adolescents. It may be associated to other autoimmune diseases, especially thyoiditis, celiac and Addison's diseases. These associations may represent a challenge for management of this disease for the child and his family. The aim of this study is to describe the different aspects of this association.
Patients and Methods
This is a retrospective descriptive study including 428 type 1 diabetic patients hospitalized at the Endocrinology Diabetology and Nutrition Department of the university hospital Mohammed VI of Oujda, between 2016 and 2023. All our

patients had a complete clinical examination and a biological workup including the autoimmune workup.
Results
The mean age of our patients was 20±10.7 years, ranging from 2 to 78 years, women was predominant (sex ratio 0.8), the mean duration of diabetes was 12±8 years, and the mean glycated hemoglobin was 10.3%. Of all patients, 59 had autoimmune disease (14% of cases), with a higher incidence in women (70% of cases). 8 of these patients had familial autoimmune disease (13% of cases) Autoimmune thyoiditis was present in 63% of cases. 21 patients had hypothyroidism (36% of cases) including 12 patients with positive anti-TPO antibodies, and 16 cases of hyperthyroidism (27% of cases), including 11 with Graves' disease. Celiac disease was revealed by positive anti-transglutaminase antibodies in 16 patients (27% of cases). Addison's disease was present in 2 patients (3.3% of cases) same percentage for ovarian insufficiency and psoriasis.
Conclusion
Our results confirm the frequent association of type 1 diabetes with autoimmune diseases, mainly dysthyroidism, as well as celiac disease, this result confirm the importance of screening according to recommendations to ensure optimal and comprehensive management.

Anxiodepressive disorders in Type 1 Diabetics
Deus Niyongabo, Nassim Essabah Haraj, Siham El aziz & Asma Chadli
Ibn Rochd University Hospital of Casablanca, Endocrinology, Diabetology, Nutrition and Metabolic Diseases Department, Casablanca

Introduction
Individuals with type 1 diabetes have an increased risk of depression, which can worsen their health condition and elevate the risk of complications. This study aims to estimate the prevalence of anxiety and depression in these patients and evaluate their impact on disease management.
Patients and Methods
A retrospective study over six years (2018-2023), including 168 hospitalized type 1 diabetic patients, assessed for their mental state using the Hamilton and Beck scores. Statistical analysis was performed using Epi-Info 7.2 software.
Results
The mean age of the patients was 26 years, with a sex ratio of 1.3 males to 1 female. The prevalence of toxic habits was 39.2%. The average diabetes duration was 8.5 years, and glycemic imbalance was observed in 88.6% of patients. Degenerative complications (retinopathy, nephropathy, neuropathy) were present in a quarter to a third of patients. Acute complications (ketosis, acidosis, frequent hypoglycemia) were very common, affecting 89.8%, 32.1%, and 82.1% of patients, respectively. Depression and anxiety were present in 20.2% and 61.3% of patients, respectively, with co-occurrence observed in 18.4%. Diabetes and anxiodepressive disorder follow-up were irregular in 78.3% of cases. Treatment mainly included supportive psychotherapy, as well as anxiolytics and antipsychotics as needed.
Conclusion
Detecting anxiodepressive disorders in the management of type 1 diabetic patients is of paramount importance. Appropriate psychological intervention could promote better glycemic control and more effective disease management.

Metabolic syndrome in type 1 diabetes: About 638 cases
Imane Hasbi[1], Nassim Essabah Haraj[2], Siham El Aziz[3] & Asma Chadli[2]
[4]Ibn Rochd University Hospital, Endocrinology and Metabolic Diseases, casablanca, Morocco; [2]Ibn Rochd University Hospital, Endocrinology and Metabolic Diseases, Casablanca, Morocco; [3]Endocrinology and Metabolic Diseases, Endocrinology and Metabolic Diseases, Casablanca, Morocco

Introduction
The increasing association between metabolic syndrome and type 1 diabetes, along with its impact on micro and macrovascular complications, is becoming more evident. The aim of our study was to assess the prevalence of different components of metabolic syndrome in type 1 diabetic patients and identify any possible correlation with various complications related to type 1 diabetes
Materials and Methods
This is a descriptive retrospective study involving 638 patients with type 1 diabetes, hospitalized at the endocrinology department of Ibn Rochd University Hospital in Casablanca. All patients underwent a clinical examination, including anthropometric measurements for calculating body mass index (BMI) and waist circumference (WC). A metabolic assessment was also conducted. Metabolic syndrome was defined according to the criteria of the International Diabetes Federation (IDF). The statistical analysis was performed using the SPSS software, version 25.
Results
The mean age was 25.7 years with a gender ratio (M/F) of 1.1, the mean duration of diabetes was 9.5±2 years. Metabolic syndrome (MS) was identified in 15.8% of patients. Analysis of patients with MS revealed an average age of 31.3 years, ranging from 15 to 60 years, an average BMI of 27.4/m2, and an average WC of 91 cm. Most participants exhibited evident glycemic imbalance, reflected by an average HbA1c level of 12.2%. Arterial hypertension was observed in 61.4% of cases. The mean levels of total cholesterol, HDL cholesterol, and triglycerides were 1.78 g/l, 0.44 g/l (with hypo-HDLemia in 68.5% of cases), and 1.48 g/l (with hypertriglyceridemia in 33.7% of cases), respectively. Participants with MS were older (31.3 vs 24.9 years, $P=0.01$) and predominantly female (75.2% vs 41.3%, $P=0.001$), had longer diabetes duration (15.3 vs 8.6 years, $P=0.001$), and a higher prevalence of microangiopathy (66.3% vs 23.9%, $P=0.001$), although no significant difference was observed for macroangiopathy. Therapeutically, patients with MS had a higher average insulin dose ($P=0.001$), and the use of an insulin sensitizer was necessary in 18.8% of cases
Discussion and Conclusion
The prevalence of metabolic syndrome in type 1 diabetes is increasing. Its presence indicates an increased risk of micro and macrovascular complications. This subgroup of type 1 diabetes requires optimal glycemic control and a reduction in other risk factors.

Necrotizing fasciitis of the upper extremity complicated by ulnar vein thrombophlebitis revealing diabetes: A case report
Ilham Midhat, Hanane Boualam, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Centre Hospitalo-Universitaire Mohammed VI Marrakech, Marrakech, Morocco

Introduction
Necrotizingfasciitis is a severe infection of deep subcutaneous tissue and hypodermal fascia with secondary skin necrosis.
Observation
Patient M.A., aged 67, with no particular pathological history, presented with an 11-day history of a boil on the left forearm, treated with traditional herbs. The evolution was marked by the development of an inflammatory placard on the forearm with extensive necrotic lesions. Ultrasound revealed extensive infiltration of the soft tissue, organized into micro and macro logettes. Biological findings included a predominantly neutrophilic hyperleukocytosis, CRP 406 mg/l, and bacteriological sampling of the pus isolated multi-sensitive Pseudomonas aeruginosa. With the onset of edema and insomniac pain, the investigation was completed by a venous echodoppler of the left upper limb, which revealed thrombophlebitis of the ulnar vein. The patient underwent necrosectomy. Treatment consisted of curative anticoagulation, intensified insulin therapy and strict glycemic control. Triple intravenous probabilistic antibiotic therapy was instituted, then adapted to the antibiogram. The evolution was favorable, with a good clinico-biological improvement and good directed healing.
Discussion and conclusion
Necrotizing fasciitis of the upper limbs remains a relatively rare infection. It can occur at any age, although advanced age is considered a risk factor. Necrotizing fasciitis is a major medical and surgical emergency, and the rapidity of its evolution makes it essential to establish the diagnosis as soon as possible, in order to reduce the risk of mortality and disabling functional sequelae. Clinically, differentiating a necrotizing infection from a common soft-tissue infection is difficult when cutaneous necrosis does not dominate the clinical presentation. The germs responsible are varied (frequently streptococci, multi-microbial flora in over half of cases). It requires early, intensive management based on three pillars (early surgical excision, broad-spectrum antibiotic therapy and resuscitation) in parallel with strict glycemic control. The prognosis is clouded by the severity of lesions and delays in treatment. Prevention must be encouraged through effective patient education, with targets to be set consistently.

Epidemiology of type 2 diabetes and prediabetes in the adult population of the Republic of Moldova

Lorina Vudu[1], Aristia Seremet[1], Vlada Furdui[2], Stela Bacinschi-Gheorghita[1], Diana Munteanu[1], Carolina Piterschi[1] & Stela Vudu[1]
[1]Nicolae Testemitanu State University of Medicine and Pharmacy, Endocrinology, Chisinau, Moldova; [2]Nicolae Testemitanu State University of Medicine and Pharmacy

Background and Aim
Diabetes mellitus (DM) represents a substantial burden on health care systems, being the 8th leading cause of death and disability in the world in 2019, associated with long-term microvascular (neuropathy, retinopathy, and nephropathy) and macrovascular (ischemic heart disease, stroke, peripheral vascular disease) complications. DM comorbidities lead to a substantial decrease in quality of life, as well as important socio-economic consequences. In 2022, the health system in the Republic of Moldova (RM) had records of 131,550 people with DM. Data on the prevalence and incidence of DM and prediabetes are limited due to the lack of studies in this direction. The aim of the study was to assess the prevalence of diabetes, prediabetes and obesity in the adult population of RM.
Methods
This is the first cross-sectional, epidemiological study that analyzes the prevalence of DM, prediabetes, and dyslipidemia in the population of RM. The diagnosis of DM was established based on the diagnostic criteria of the American Diabetes Association: HbA1c $\geq$ 6.5%, fasting glucose (FG) $\geq$ 7 mmol/l, blood glucose 2h after the oral glucose tolerance test (OGTT) $\geq$ 11.1 mmol/l or the presence of diabetes history - reported by the patient. The diagnostic criteria for prediabetes were: HbA1c value between 5.7 and 6.4 %, FG – 5.6 – 6.9 mmol/l, blood glucose 2 hours after OGTT 7.8 – 11 mmol/l. Statistical analysis used Spearman's correlation test, chi-square, and Wilcoxon tests.
Results
A total of 1039 persons were enrolled (66.4% women and 33.6% men, with an average age of 49 $\pm$ 13 years). 10,8 % of the investigated persons were with diabetes mellitus, 1.9 % of whom had unknown DM. 51 % of persons with DM were men; 71 % of whom – with a BMI $\geq$ 25 kg/m^2; 93 % - with abdominal obesity. 69 % of women with DM were with BMI $\geq$ 25 kg/m^2 and 94 % - with abdominal obesity. Prediabetes was diagnosed in 29.6% of the investigated persons, with a prevalence of 48 % in men vs 52 % in women. Advanced age, obesity, and dyslipidemia were the diabetes influencing factors.
Conclusion
The study showed an increased prevalence of carbohydrate metabolism disorders, including prediabetes, as well as a high prevalence of abdominal obesity. Persons with unknown diabetes mellitus have been identified.

Assessment of oxidative stress levels in gestational diabetes mellitus (GDM) patients: a cross-sectional study

Justyna Hryniewicka[1], Angelika Buczyńska[2], Katarzyna Siewko[1], Popławska-Kita Anna[1], Agnieszka Adamska[1], Adam Krętowski[1] & Małgorzata Szelachowska[1]
[1]Medical University of Bialystok, Department of Endocrinology, Diabetology and Internal Medicine, Bialystok, Poland; [2]Medical University of Bialystok, Clinical Research Centre, Bialystok, Poland

Background
Gestational Diabetes Mellitus (GDM) is a common pregnancy-related metabolic disorder associated with increased maternal and fetal complications. Oxidative stress has been implicated in the pathogenesis of various pregnancy-related disorders, including GDM. This cross-sectional study aims to evaluate and compare oxidative stress levels among GDM patients, shedding light on potential implications for maternal and fetal health.
Methods
A total of 47 pregnant women, comprising 27 GDM patients and 20 normoglycemic pregnant controls, were enrolled in this study. Oxidative stress levels were assessed using reliable biomarkers and assays, including photometric test system for the determination of the total antioxidative status/capacity (TAS/TAC) and for the determination of the total oxidative status/capacity (TOS/TOC). Demographic and clinical data, including age, gestational age, and relevant medical history, were collected and analyzed. GDM and the control group were matched to ensure no differences in age, weight, and BMI.
Results
The study revealed a statistically significant difference in oxidative stress levels between GDM patients and normoglycemic pregnant controls. GDM patients exhibited higher levels of oxidative stress markers during whole pregnancy and also 3 month postparum in comparison to control group. Significantly higher levels of oxidative stress markers was observed in first trimester of pregnancy, before GDM diagnosis, comprehensively suggesting an increased burden of oxidative damage. According to ANOVA results we hypothesize that TOS/TAS may be a potential future marker of GDM. Further subgroup analyses explored potential correlations between oxidative stress levels and key clinical parameters within the GDM group.
Conclusion
This cross-sectional study provides valuable insights into the heightened oxidative stress observed in GDM patients compared to normoglycemic pregnant individuals. Understanding the role of oxidative stress in GDM pathophysiology may contribute to the development of targeted therapeutic interventions aimed at mitigating maternal and fetal complications associated with GDM. Future longitudinal studies are warranted to explore the temporal dynamics of oxidative stress throughout the course of GDM and its impact on pregnancy outcomes.

Effect of chemotherapy on glucose metabolism in breast cancer patients

Simone Diedrichsen Marstrand[1], Djordje Marina[1], Valdemar Mendez[1], Michael Andersson[2], Kristian Buch-Larsen[1] & Peter Schwarz[1]
[1]Rigshospitalet, Department of Endocrinology, København, Denmark; [2]Rigshospitalet, Department of Oncology, København, Denmark

Background
Observational studies indicate that breast cancer survivors more often are diagnosed with type 2 diabetes mellitus (T2DM) up to several years after treatment completion. As the population of breast cancer survivors increase due to improved diagnostic and treatment methods the importance of understanding possible long-term side effects of the treatment such as T2DM becomes more central. It is reported that women receiving adjuvant chemotherapy experience weight gain and altered body composition with loss of muscle mass and increasing fat mass. Furthermore, studies have shown elevated fasting insulin levels in breast cancer patients before and after treatment. Obesity can lead to insulin resistance and thereby a risk of developing T2DM. It is relevant to consider if changes in glucose and insulin metabolism are seen in relation to breast cancer treatment to further explore the risk of T2DM.
Aim
to examine if adjuvant chemotherapy negatively affects glucose metabolism, outlined by changes in glucose and HbA1c.
Method
Women with early breast cancer stages I-III eligible for chemotherapy were prospectively recruited by Department of Oncology at Rigshospitalet, Denmark. Exclusion criteria were prior malignancy or endocrine disease. Blood samples were drawn immediately before initiation of chemotherapy and after completed chemotherapy. Furthermore, in a subgroup of women an oral glucose tolerance test (OGTT) was performed after completed chemotherapy. Patients drank a concentrated glucose solution and blood samples were drawn at times 0 min, 30 min, 45 min, 60 min, 90 min, and 120 min.
Results
103 women with early breast cancer were include in the study. 79 patients completed examinations before and after chemotherapy. All women underwent breast surgery and chemotherapy regimens including at least one of the following drugs docetaxel, paclitaxel, epirubicin, and cyclophosphamide. High-dose prednisolone was given as antiemetics. Statistical analysis showed no significant difference in HbA1c before and after chemotherapy with mean values 37.1 mmol/mol and 36.7 mmol/mol respectively and $P = 0.28$. The OGTT was performed in 11 of the breast cancer patients after completed chemotherapy. Furthermore, 7 healthy controls completed an OGTT. Glucose levels at 120 min did not significantly differ between patients and controls with $P = 0.44$ and mean glucose for patients 6.9 mmol/l and controls 6.2 mmol/l.
Conclusion
HbA1c is not significantly altered by chemotherapy in early breast cancer patients. In addition, we find no significant difference in response to a glucose load between a subgroup of patients and controls.

DOI: 10.1530/endoabs.99.EP542

EP561

Effects of vitamin D on the heart failure with preserved ejection fraction in women with prediabetes

Lileia Petrovska[1], Iryna Kostitska[1] & Anna Hryb[2]
[1]Ivano-Frankivsk National Medical University, Endocrinology, Ivano-Frankivsk, Ukraine; [2]Ivano-Frankivsk National Medical University, Ivano-Frankivsk, Ukraine

Introduction
Heart Failure with Preserved Ejection Fraction (HFpEF) morbidity and mortality are increasing at an alarming rate in patients with prediabetes, insulin resistance and obesity. Vitamin D deficiency is associated with the risk of impaired glucose and lipid metabolism. All this substantiates the need to monitor the concentration vitamin D in women with this comorbid pathology.
Aim of the study
is to investigate the severity of vitamin D deficiency in females with prediabetes and HFpEF.
Materials and methods
Participants were comprehensively phenotyped including physical examination, laboratory results and echocardiography (left ventricular ejection fraction (LVEF) $>50\%$). Main group included 30 women with prediabetes and HFpEF (initially mean aged 49.54 $\pm$1.63 years, body mass index (BMI) - 35.24$\pm$2.21 kg/m^2, glycated hemoglobin (HbA_1C) - 6.05$\pm$0.13% and duration of prediabetes - 3.22$\pm$2.19 years, N-terminal pro-brain natriuretic peptide (NT-proBNP) - 161.51$\pm$7.27 pg/ml, left ventricle (LV) mass index 112$\pm$24, LVEF – 59.43$\pm$7.39%) were divided into groups: I group (Gr I, $n=15$) females with insufficiency of 25-hydroxycholecalciferol (25(OH)D - 20-30 ng/ml) and II group (Gr II, $n=15$) subjects with hypovitaminosis D (25(OH)D below 20 ng/ml. The patients were treated metformin XR (daily dose - 500-1500 mg) combination cholecalciferol (vitamin D3) (daily dose Gr I – 5000 IU and Gr II– 20 000 IU) during 3 months. The physical examination and all laboratory, instrumental results were measured at baseline and 3 months following the treatment. Results were analyzed with IBM SPSS Statistics. Significance level $P<0.05$ was considered.
Results
The mean of 3 months after add metformin XR and vitamin D3 on BMI and HbA_1C level was lowered by 0.77% and 0.81% each in two groups. On comparing with the baseline the mean deference of 25(OH)D after combination therapy were increase mean 52.5% in Gr I and 63.8% in Gr II. After adjustment, higher serum levels 25(OH)D were associated with decreased hazard for NT-proBNP (102.11$\pm$3.14 pg/ml) and LV mass index overall (101$\pm$ 22) driven by a significant association with HFpEF (increase mean LVEF (71.32$\pm$8.89%) for 1.2 time).
Conclusions
Particularly the association between vitamin D deficiency and comorbid diseses: prediabetes, obesity in women with HFpEF. During the war in Ukraine, there is a probable deepening hypovitaminosis D. Increased NT-proBNP, HbA_1C, BMI and LV mass index were associated with vitamin D deficiency. The insufficiency and deficiency vitamin D negatively influenced ejection fraction in females with prediabetes.

The use of subcutaneous instead of intravenous insulin in a hypothyroid and diabetic patient with hypertriglyceridemia-induced pancreatitis - a case report

Kurt Bryan Tolentino[1], Abigail Kristine Juat[2], Trisha Gia Mae Viernes[2] & Monica Therese Cating-Cabral[2]
[1]St. Luke's Medical Center - Global City, Endocrinology, Taguig, Philippines; [2]St. Luke's Medical Center - Global City, Taguig, Philippines

Hypertriglyceridemia is a rare cause of acute pancreatitis occurring 1-35% of patients. Management of hypertriglyceridemia includes the use of intravenous insulin, however, requires close monitoring of capillary blood glucose every 1-2 hours and might warrant ICU admission, increasing the financial burden of patients. This case report explores the use of subcutaneous long-acting insulin, instead of intravenous insulin, on top of conventional therapy and Levothyroxine supplementation in a 47 year-old hypothyroid and diabetic female newly-diagnosed with severe hypertriglyceridemia. The patient initially came in for a 2-day history of new onset epigastric pain radiating to the back, aggravated by eating. Due to persistence, sought consult in the emergency room. Vital signs were stable. Workup done showed microcytic hypochromic anemia, leukocytosis with neutrophilic predominance (Hemoglobin 10.1 g/dl, Hematocrit 28.3%, WBC 11840 mm^3, 84% neutrophils, 10% leukocytes, Platelets 266,000 mm^3, MCV 58 fL, MCHC 36%), elevated CRP 48 mg/l, elevated ESR 24 mm/hr, elevated TSH 32.556 uIU/ml, low FT4 and FT3 of 0.76 ng/dl and 1.14 pg/ml respectively, normal transaminases (ALT 11 U/l, AST 12 U/l), normal bilirubin (total 0.2 mg/dl, direct 0.02 mg/dl, indirect 0.18 mg/dl), normal alkaline phosphatase (82 U/l), albumin (3.5 g/dl), elevated HbA1c 9.5%, normal ionized calcium (1.11 mmol/l), creatinine 0.74 mg/dl, BUN 6 mg/dl, potassium 3.6mEq/l, chloride (99 mEq/l), low sodium (131.4mEq/l), bicarbonate (19.9 mEq/l). Lipase was 4.1x elevated (222 U/l). Triglycerides and VLDL were elevated at 5177 mg/dl and 1035.4 mg/dl respectively. Capillary blood glucose was 237. ABG done showed a pH 7.42, pCO2 33, HCO3 21.4 O2 sat 96%, and a lactate of 1. BISAP score was 0. She was initially hydrated with 125 ml/hr of D5NSS, given Hyoscine N-Butylbromide for pain control, and placed on NPO. Since the patient had limited funds, the use of subcutaneous long acting insulin of approximately 0.2units/kg/day was given (15 units Glargine). The gastroenterologist also cleared the patient to be started on Levothyroxine 100 mg once daily (~1.76 mg/kg/d) and Fenofibrate 160 mg once daily. Serial monitoring of triglycerides was done noting a decreased trend of 1634 mg/dl on the 2nd day, 989 mg/dl on the 3st day, and 651 mg/dl on the 5th day. VLDL was also decreasing to 326.8 mg/dl on the 2nd day, 197.8 mg/dl on the 3st day, and 130.2 mg/dl on the 5th day. The patient was sent home well. Severe hypertriglyceridemia should still be considered in all patients with acute pancreatitis. Subcutaneous instead of intravenous insulin can be considered as a treatment modality in patients with hypertriglyceridemia-induced pancreatitis on top of conventional therapy.

Prevalence of metabolic and cardiovascular diseases in Hidradenitis Suppurativa

Malek Cherif[1], Rim Chaabouni[1], Lina Bessaâd[1], Abdel Mouhaymen Missaoui[2], Fatma Hammami[1], Emna Bahloul[1], Nabila Rekik[2] & Hamida Turki[1]
[1]Hedi Chaker University Hospital, Dermatology, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Endocrinology, Sfax, Tunisia

Introduction & Objective
Hidradenitis Suppurativa (HS), or Verneuil's disease, is a chronic suppurative inflammatory condition. This study aims to determinate the association between HS and metabolic diseases.
Materials and Methods
We conducted a retrospective study between January 2012 and December 2022 enrolling all cases of HS in our dermatology department.
Results
Over 11 years, we collected 77 cases. The average age was 39 years, with a sex ratio M/F of 4.1. Regarding lifestyle habits, 74% of patients were sedentary, and 66,2% were active smokers. The average Body Mass Index (BMI) was 26.38$\pm$4,44 [15-38.4]. Overweight and obesity were observed in 32.5% and 20.8% of patients, respectively. In our sample, 10 patients (13%) had previously diagnosed diabetes mellitus (DM), and 5 others (6.5%) were newly identified with prediabetes (fasting blood glucose between 1.1 and 1.25 g/l). Furthermore, six patients had a history of dyslipidemia (7.8%). The lipid profile indicated elevated triglyceride levels (above 1.50 g/l) in 8 cases (10.4%), elevated total cholesterol levels (above 2 g/l) in 4 cases (5.2%), and low HDL-cholesterol levels (below 0.4 g/l) in one case. Finally, 4 patients were diagnosed with hypertension (HT) (5.2%), and only one exhibited coronary insufficiency, undergoing revascularization (1.3%).
Conclusions
The significant prevalence of obesity and overweight in our HS series aligns with existing literature suggesting an association between these two conditions. Indeed, adipose tissue can release pro-inflammatory cytokines, such as tumor necrosis factor-alpha (TNF-α) and interleukin-6, which are implicated in the pathophysiology of the dermatosis. For this reason, weight reduction is an essential non-pharmacological therapeutic approach in the management of HS. A literature review conducted in 2021 revealed that the prevalence of DM among HS patients is estimated to be between 7,1% and 20,8%. Similarly, the risk of dyslipidemia, hypertriglyceridemia, and low HDL levels is 1,4 to 4 times higher in the HS population compared to the control group. In addition, obesity and tobacco use are risk factors for HT and major adverse cardiovascular events (MACE). According to a literature review, patients with HS have a significantly higher prevalence of HT with adjusted odds ratios ranging from 1,2 to 2,1. In a cohort study, the adjusted incident risk of MACE among patients with HS is 1,5 times that of control individuals. In summary, metabolic and cardiovascular diseases constitute a cluster of comorbidities associated with HS, contributing to an increase in morbidity and mortality related to this chronic dermatosis.

Assessment of left ventricular systolic function in obesity

Cvetanka Volkanovska Ilijevska[1], Valentina Andova[2], valentina Velkoska Nakova[3], Marija Zivkovic Hristova[1] & Ljubica Georgievska Ismail[4]
[1]University Clinic of Endocrinology, diabetes and metabolic disorders, Medical Faculty, Ss. Cyril and Methodius University in Skopje, RN Macedonia, Skopje, Macedonia; [2]University Clinic of Cardiology, Medical Faculty, Ss. Cyril and Methodius University in Skopje, RN Macedonia, Skopje, Macedonia; [3]Faculty of Medical Sciences, Goce Delcev University, Internal medicine, stip, Macedonia; [4]University Clinic of Cardiology, Medical Faculty, Ss. Cyril and Methodius University in Skopje, RN Macedonia, skopje

Aims
Identifying the left ventricular systolic disfunction in obesity is crucial, due to its ability to predict cardiovascular morbidity. LV systolic function is traditionally assessed with the volumetric parameter LV ejection fraction (LVEF). However, normal values for LVEF in all categories of obesity are published in the literature. Furthermore, guidelines for the biomarkers of heart failure, NT-proBNP and BNP, in the obese population remain unclear. Given the restricted BNP and LVEF use, there is a need to use parameters with proven predictability for the occurrence of heart failure in obesity. This research aimed to explore left ventricular systolic function in obese and overweight subjects.
Methods
A total of 126 subjects aged 45,0 ± 9,6 years, were categorized in 4 groups: Group 1 – overweight (BMI 25-29.9 kg/m^2); Group 2 – class I obesity (BMI 30-34.9 kg/m^2); group 3-class II obesity (BMI 35–39.9 kg/m^2) and group 4-class III obesity (BMI $>$ 40 kg/m^2). The conventional functional parameters of the LV and myocardial deformation by 2D speckel tracking echocardiography were assessed.
Results
In 74 % of the subjects the duration of overweight/obesity was over 10 years. Arterial hypertension, dyslipidemia and diabetes mellitus were present in 54.8%, 53.2%, 19.8% of subjects respectively. The echocardiographic indices of systolic function were preserved: LVEF (67.2% ± 7.4), indexed cardiac output (37.5 ± 10.3 ml/m2) and indexed minute volume (3.1 ± 2.4 l/min/m2). An average value of the peak mitral annular descend velocity, estimated by Tissue Doppler (s'TDI), was reduced (7.5 ± 1.5 cm/s). The highest classes of obesity had insignificantly lowest values. The mean values of global longitudinal strain (GLS) and global radial strain (GRS) were within reference and mean value of global circumferential strain (GCS) was below the reference range. Subjects with the most severe obesity had the lowest GLS and GCS values (-19.8% and -13.4%, respectively). Significant differences were seen in GLS and GCS between class III and overweight individuals (GLS% $P = 0.002$ and GCS% $P = 0.033$). The GRS% values of the class III obese participants were higher than those of the other groups; nevertheless, no statistically significant differences were found between the groups ($P = 0.448$).
Conclusion
The importance of myocardial deformation assessment is emphasized in context of the identification of subclinical LV dysfunction in obesity

Homozygous familial hypercholesterolemia with resistance to Inclisiran (siRNA PCSK9i) – a case report

Mélina Michel, Hela Walha & Mohammed Barigou
Centre hospitalier universitaire vaudois, service d'endocrinologie, diabétologie et métabolisme, Lausanne, Switzerland

Introduction
Homozygous familial hypercholesterolemia (HoFH) is a rare inherited autosomal dominant disease (1/20000 Individuals) involving germline mutations in the LDL metabolism pathways (LDL receptor/PCSK9/APOB/IDLRAP) that results in very high levels of LDLc, usually $>$ 10 mmol/l, and premature cardiovascular disease. The EAS guidelines recommend the use of PCSK9 inhibitors (PCSK9i) as a third line therapy in HoFH, however they report no precision regarding the effect of monoclonal antibodies (MAB) vs small interfering RNA (siRNA) in this specific situation. Here we report a case of patient with HoFH and resistance to Inclisiran a siRNA PCSK9i.
Case series
Mrs M, 28-year-old woman, is a 4th of 6 siblings from a consanguineous (first degree cousins) marriage. She had a diagnosis of HoFH at the age of 10 with a baseline LDLc of 13.6 mmol/l (mutation LDLr: NM:000527.5:c.[(694 + 1_695-1)_(940 + 1_941-1)del]mat;[(694 + 1_695-1)_(940 + 1_941-1)del]pat). Despite an initiation of simvastatin and ezetimibe at a young age, LDLc remained very high due to adherence issues. Since 2023 we decided to conduct a stepped approach to treat her HoFH. We reinitiated rosuvastatin 40 mg plus ezetimibe 10 mg resulting in significant decrease of LDLc to 8.7 mmol/l. We then added inclisiran as a third line therapy for adherence purposes. However, LDLc decrease was insufficient: LDLc 7.5 mmol/l (additional 14% decrease) one month after the second injection. We then added bempedoic acid 180 mg and cholestyramine 3g/day, resulting in 16% additional decrease in LDLc (6.3 mmol/l). To better impact LDLc we decided to switch from inclisiran to evolocumab (MAB PCSK9i) since October 2023. In-fact, the patient's brother carrying the same mutation at homozygous state, showed a spectacular response to evolocumab 280 mg every 15 days, with LDLc decreasing from 9 mmol/l to 4.8 mmol/l (46% decrease).
Discussion
This case corroborates the recent results of Orion 5 Study reporting a non-significant decrease of LDLc with inclisiran compared to placebo in HoFH despite a potent effect on circulating PCSK9[1]. Real world data with monoclonal antibodies inhibiting PCSK9 in HoFH showed an excellent response (-57% of additional decrease in LDLc at 24 months) when added to other lipid lowering therapies[2].
Conclusion
in HoFH patients, the third line therapy after maximum statin/ezetimibe combination should be MAB PCSK9i, inclisiran showing poor efficacy in this context. Mechanisms explaining this discrepancy should be elucidated and future guidelines should precise this specificity.

A novel lipoprotein lipase mutation in familial chylomicronemia syndrome – two case reports

Telma Moreno[1,2], Sara Ribeiro[1,2], João Freixo[3], Sílvia Pinhão[4], Flora Correia[4] & Elisabete Rodrigues[1,2]
[1]Unidade Local de Saúde São João, Endocrinology, Porto, Portugal; [2]Universidade do Porto, Faculty of Medicine, Porto, Portugal; [3]Instituto de Investigação e Inovação em Saúde (i3S), Center for Predictive and Preventive Genetics, Porto, Portugal; [4]Unidade Local de Saúde São João, Nutrition, Porto, Portugal

Introduction
Familial chylomicronemia syndrome (FCS) is a rare inherited disorder of lipoprotein metabolism leading to severe hypertriglyceridemia and increased risk for acute pancreatitis. Mutations in the lipoprotein lipase (*LPL*) gene account for the majority of cases of monogenic chylomicronemia.
Methods
We report the cases of two white males with a novel homozygous mutation in position 332 of the *LPL* gene.
Results
The patients are siblings from a consanguineous marriage and presented the same homozygous mutation in the *LPL* gene identified as c.995C $>$ G [p.(Thr332Ser)]. This variant has not been previously described and was deemed a variant of uncertain significance (VUS). According to the clinical manifestations and genetic findings on both patients, the diagnosis of FCS was established. Both patients were diagnosed during childhood at 14-years-old with severe hypertriglyceridemia and have a previous history of recurrent acute pancreatitis (8 episodes in one sibling and 2 episodes in the other). One patient developed diabetes mellitus secondary to pancreatic disease. Dietary modification plays a key role on management of FCS and severe restriction of dietary fat to $<$20 grams per day is recommended. Therapeutic resistance to routine triglyceride-lowering medication is a hallmark of FCS and the patients currently have triglyceride levels ranging from 1217-2920 mg/dl, under fenofibrate and omega-3 fatty acids therapy. Treatment with apolipoprotein C-III inhibitor volanesorsen is under consideration.
Conclusions
We describe a novel *LPL* mutation related to familial chylomicronemia syndrome. Even though it was considered a variant of uncertain significance in light of current knowledge, the mutation appears to be pathogenic according to clinical characteristics, causing severe hypertriglyceridemia with increased risk of acute relapsing pancreatitis.

Munchausen syndrome in endocrinology: about two case reports of factitious hypoglycemia

Benabdelatif Katia[1], Aicha Lachkhem[1], Abdelkader Yahi[1], Redhouane Longo[2], Ould Kablia Samia[1] & Bensalah Meriem[1]
[1]Endocrinology department, Central Military Hospital, Algiers, Algeria.; [2]Endocrinology department, Regional university Military Hopsital of Oran, Algeria.

Introduction
The Munchausen syndrome, also known as factitious disorder, involves a compulsion to simulate illness or trauma. Individuals may go as far as taking medication or inflicting harm on their bodies to evoke compassion. The aim of this report is to illustrate the example of factitious hypoglycemia, one of the most common forms of factitious disorders in the endocrine-metabolic field, accounting for 4-11% of all non-diabetic hypoglycemias.
Observation
Case 1: A young women aged 23 years old, with a personal history of polycystic ovary syndrome and endometriosis, and a family history of a husband with type 1 diabetes mellitus on insulin therapy, was admitted for investigation of multiple hypoglycemic episodes which manifested by adrenergic and neuroglycopenic signs. The clinical examination found an overweight patient, with no signs of adrenal deficiency, the presence of several bruises related to injections on both arms. During her hospital stay, she presented a spontaneous hypoglycemia at 0.34 g/l on capillary blood, confirmed by a venous test at 0.33 g/l. Additional testing performed at that time revealed an inappropriately elevated level of insulin (38 uui/ml) and a low plasma C-peptide level (0.2 ng/ml). A qualitative serum and urinary sulfonylurea panel was negative, confirming the artificial origin of hypoglycemia. After psychological evaluation, she denied taking any glucose lowering agents, but she admitted to have taken blood thinner accidentally, which resulted in a hemorrhage. In light of these findings, a psychiatric evaluation was established which revealed an anxious, distressed patient with narcissistic personality traits. She was referred to a psychiatrist for follow-up. Case 2: 16-year-old young female, with no personal medical history, with a family history of diabetes mellitus in both her father and her maternal grandmother, treated with oral antidiabetic drugs and insulin respectively. She was admitted into the department of endocrinology to explore multiple severe hypoglycemic episodes (0.2-0.5 g/l) with adrenergic and neuroglycopenic symptoms. During her hospitalization, we did not objectify any hypoglycemic episodes on either capillary or venous tests. Oral glucose tolerance test was normal. The patient vehemently denied taking any hypoglycemic medication or having any affecting problem. After a psychological evaluation, she admitted to secretly taking insulin and oral antidiabetic drugs.
Conclusion
Factitious hypoglycemia is a real diagnostic challenge. Collaboration between endocrinologists, psychologists and psychiatrists is necessary for establishing this diagnosis and for follow-up.

EP615

Improvement of glycemic control after initiation of enteral nutrition through percutaneous endoscopic gastrostomy (PEG)

Andrea Fernández Valero & Silvia Alonso Gallardo
Hospital Costa del Sol, Marbella, Spain

We present the case of an 83-year-old woman with a medical history of moderate-severe Alzheimer's disease, which made her dependent. Despite this, she was able to communicate and go out in a wheelchair. Over the last 6 months, she experienced decreased intake and lost more than 10% of her body weight. In addition, she was diagnosed in 2006 with latent autoimmune diabetes of adults (LADA), treated initially with oral antidiabetic agents but later on, it was necessary to switch to insulin therapy and glucose monitoring. She presented difficult glycemic control with episodes of hypoglycemia due to refusal to eat after administration of rapid-acting insulin, even requiring emergency services care for severe hypoglycemia in some of these episodes. Thus, the family began to skip insulin doses due to fear of new hypoglycemic events. The sensor discharge data were TAR 50%, TIR 41%, TBR 9% (very low 1%). In mid-2023, the patient was transferred to the emergency room due to poor general condition and impaired level of consciousness. Blood test revealed a glycemia of 560 mg/dl, metabolic acidosis, and positive urine ketone bodies, leading to a diagnosis of diabetic ketoacidosis and intensive fluid therapy and intravenous insulin perfusion were initiated. Once stabilized, she was admitted to the unit. On the hospital ward, intakes continued to be erratic, again presenting severe hypoglycemias that led to a reduction in insulin doses and subsequently resulted in hyperglycemia of >300 mg/dl when adequate intakes were taken. Finally, it was decided that the most appropriate approach was to initiate enteral nutrition by PEG, as this would improve nutritional status by guaranteeing adequate caloric intake and hydration, along with a fixed carbohydrate intake, enabling the administration of a consistent insulin dose at all times. After initiation of enteral feeding, there was a significant improvement in glycemic control, with flatter curves and no severe hypoglycemia, presenting a TAR 36%, TIR 63% and TBR 1% (very low 0%).
Conclusion
The treatment of insulinopenic diabetes can be challenging due to the varying amount of insulin needed based on carbohydrate consumption. This can be especially difficult for patients with irregular eating habits, such as those with advanced dementia. In these cases, establishing enteral nutrition through PEG may be an option, as long as the risks and benefits are carefully considered, and it is appropriately indicated. This approach will not only help manage diabetes but also ensure proper nutritional status.

Hemoglobin Wayne as a cause for falsely high HbA1C in pregnancy

Nwe Aung[1], Amina Al-Qaysi[2] & Chitrabhanu Ballav[1]
[1]Buckinghamshire NHS Trust, Diabetes and Endocrinology, Aylesbury, United Kingdom; [2]Buckinghamshire NHS Trust, Endocrinology & Diabetes, Aylesbury, United Kingdom

Introduction
Diagnosis of Gestational Diabetes Mellitus (GDM) is with 75-g 2-hour Oral Glucose Tolerance Test (OGTT) at presentation and at 24 to 28 weeks when the first OGTT is normal. Although HbA1C is not recommended as a diagnostic test for GDM, this was used instead of OGTT during the Covid pandemic in the United Kingdom. Hemoglobin Wayne (Hb Wayne) is a rare variant of hemoglobin which may produce falsely high HbA1C level in some assays. We report a patient who was a carrier for Hb Wayne who presented with high HbA1C in pregnancy although her fructosamine and capillary blood glucose levels were in reference range.
Case report
A 30-year-old non-diabetic primigravida with family history of Type 2 diabetes and BMI of 24 kg/m^2 was screened for Gestational Diabetes Mellitus (GDM) at 14 weeks gestation using HbA1C instead of OGTT. Her HbA1c level at presentation was 89 mmol/mol (less than 42), although her capillary blood glucose levels were within euglycemic ranges, and fructosamine level was 257 umol/l (less than 330). Her Glutamate Decarboxylase and Islet autoantibodies were not raised. The fetal growth scans were within satisfactory parameters throughout pregnancy. She remained on diet and lifestyle with home monitoring of capillary blood glucose levels until the third trimester when she required treatment with metformin. She had elective Caesarean session at 39 weeks for personal preference, delivering a healthy baby (birth weight of 3.025 kg). In the postnatal period, her capillary blood glucose levels remained within euglycemic ranges after discontinuing Metformin. Her HbA1C remained high at 86mmol/mol with fructosamine level of 257 umol/l without treatment. She was found to be a carrier of Hb Wayne on haemoglobinopathy screening. This alpha chain variant heterozygous state is likely to have caused the falsely high HbA1C.
Conclusion
We report falsely high HbA1C in early pregnancy from Hb Wayne which may lead to overdiagnosis if used to screen for GDM instead of OGTT. Strategies to overcome this may include hemoglobinopathy screening and fructosamine level when HbA1C is high despite euglycemia on capillary blood glucose monitoring.

Sometimes It's Lupus – A Case of Hydroxychloroquine-Induced Hypoglycemia

Gustavo Rodrigues[1,2], Alice Monsanto[1], Tânia Carvalho[1], Cristina Ribeiro[1], Sofia Gouveia[1], Dircea Rodrigues[1,2] & Isabel Paiva[1]
[1]Centro Hospitalar Universitário de Coimbra, Endocrinology, Coimbra, Portugal; [2]Faculdade de Medicina da Universidade de Coimbra, Portugal

Introduction
Therapy with hydroxychloroquine (HCQ) and chloroquine (CQ) constitutes a rare but documented cause of hypoglycemia in non-diabetic adults. The physiopathological mechanism is not fully understood, and symptoms may appear several years after starting treatment. In this paper, we describe the clinical presentation and investigation of a case of hypoglycemia attributed to HCQ therapy.

Clinical Case
A 60-year-old female patient was referred for an Endocrinology consultation due to recurring symptomatic hypoglycemia (headache, tremors, nausea) documented by capillary blood glucose measurement at home. The patient had a history of Systemic Lupus Erythematosus with nephropathy, treated with HCQ, mycophenolate mofetil, and prednisolone, with no history of diabetes mellitus or insulin or sulfonylurea therapy. The patient underwent a 72 h-fasting test, which induced symptomatic hypoglycemia at 24 hours (48 mg/dl, confirmed by laboratory assay) without biochemically evident hyperinsulinism (Insulin 0.6 umol/l, C-peptide 0.3 ng/l). The remaining etiological study was negative: laboratory testing for adrenal function was normal (ACTH, Cortisol within normal range). Sulfonylurea dosing was negative, IGF-1, IGF2, and anti-insulin antibody levels were within normal limits. β-hydroxybutyrate levels were slightly elevated (1.10 mmol/ml). Thoracic and abdominal CT scan did not reveal morphological changes, most notably in the pancreas; 18F-FDOPA PET scan did not show areas of increased radionuclide uptake. Given the absence of aetiologically suggestive biochemical or structural findings, as well as the existence of reported cases of hypoglycemia secondary to HCQ therapy, a decision was made to discontinue the drug. To date (approximately 5 months), there has been complete absence of symptoms, with no recurrence of hypoglycemia.
Conclusion
Although a rare condition, hypoglycemia due to HCQ therapy should be considered as a possible aetiology in patients with proven hypoglycemia under this therapy.

Improvement of cardiovascular risk estimated by the SCORE2-Diabetes calculator in patients with type 2 diabetes treated with extended release metformin

Francisco Javier Martinez Martin[1,2], Agnieszka Kuzior[2], Claudia Arnas-Leon[2,3], Ana Delia Santana-Suarez[2], Paula Maria Fernandez-Trujillo-Comenge[3], Jennifer Maria Perez-Rivero[4], Alba Hernandez-Lazaro[5], Ricardo Jose de Leon-Durango[3], Borja Santana Ojeda[3] & Inmaculada Molinero-Marcos[3]
[1]Hospital Universitario de Gran Canaria Doctor Negrin, Outpatient Hypertension Clinic, Las Palmas de Gran Canaria, Spain; [2]Hospitales Universitarios San Roque, Endocrinologia y Nutricion, Las Palmas de Gran Canaria, Spain; [3]Hospital Universitario de Gran Canaria Doctor Negrin, Endocrinologia y Nutricion, Las Palmas de Gran Canaria, Spain; [4]Centro de Salud de Escaleritas, Medicina Familiar y Comunitaria, Las Palmas de Gran Canaria, Spain; [5]Hospital Universitari Parc Tauli, Endocrinologia i Nutricio, Sabadell, Spain

Introduction and Objectives
Extended-release (ER) metformin may reduce the gastrointestinal adverse effects of conventional metformin, increasing compliance, adherence and persistence. In mid 2022, a single-pill combination (SPC) containing 50 mg sitagliptin plus 1000 mg ER metformin was released in Spain, while monocomponent ER metformin is still unavailable. We rechallenged patients with T2DM labelled as metformin-intolerant and treated with a DPP4i with the mentioned SPC in order to assess its tolerability. With the recent availability (mid 2023) of the cardiovascular risk calculator SCORE2-Diabetes we retrospectively calculated the cardiovascular risk of our patients at baseline and after 3-4 months on treatment with this SPC.
Patients and Methods
Consecutive patients with T2DM patients, HbA1c $>7\%$ and GFR (CKD-EPI) $>$ 45 mL/min/1.73m^2 labelled as metformin-intolerant due to gastrointestinal symptoms, and treated with a DPP4i (with or without additional hypoglycemic medication) were switched to the 50 mg sitagliptin plus 1000 mg ER metformin SPC, taking 1 pill daily in the first month and afterwards 2 pills if the tolerance was good. Additional antidiabetic medication, if any, was unchanged; however in many patients lifestyle, antihypertensive and cholesterol-lowering medication were adjusted. Tolerance data were obtained by questionnaire in the follow-up visit. Data are given as mean $\pm$ sd. The calculations were done by intention to treat. All patients included gave informed consent. The SCORE2-Diabetes calculator was obtained at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC10361012/bin/appendix_2.xlsx
Results
We calculated the CV risk by SCORE2-Diabetes in 58 patients (39 women, age 53 $\pm$ 8 years, 8 $\pm$ 3 years since the diagnosis of T2DM), of which 47 tolerated 2 tablets of metformin ER + sitagliptin (1000/50 mg); 6 tolerated 1 tablet and 5 did not tolerate any dose. The baseline CV risk (major event in the next 10 years) was estimated as 12.7 $\pm$ 2.2%; 6 patients were classified as intermediate risk, 39 as high risk and 13 as very high risk patients. After 3-4 months of treatment the CV risk was reduced to 10.4 $\pm$ 1.9% ($P<0.001$); 23 patients were classified as intermediate risk, 29 as high risk and 6 as very high risk patients ($P<0.001$).
Conclusions
A large majority of the patients with T2DM labelled as metformin-intolerant did tolerate the ER metformin plus sitagliptin SPC. Their cardiovascular risk was significantly reduced. The study intervention only added metformin ER as an antidiabetic drug, but in many of the patients there were additional interventions in lifestyle, antihypertensive and cholesterol-lowering drugs. Therefore, the changes in cardiovascular risk must be considered as multifactorial.

Continuous glucose monitoring (CGM) satisfaction in patient with Type 1 Diabetes (T1DM), An audit of Irish population attending Diabetes outpatient clinic

Hurmat Walli[1], Derek O'Keefe[2], Donal O'Shea[1] & Catriona Jennings[2]
[1]St. Vincent's University Hospital, Ireland; [2]University of Galway, Galway, Ireland

Aims
- To audit CGM satisfaction in adult patients with T1DM, in Irish outpatient setting.
- To compare CGM satisfaction of patients attending public vs private setup.
- To compare CGM satisfaction of patients to perception of Diabetes Educators regarding CGM satisfaction of their patients.

Methods
This audit is a cross-sectional survey, conducted from April 2023 to June 2023, using a validated questionnaire; The Glucose Monitoring Satisfaction Survey (GMSS)[1]. Total 114 patients with T1DM, attending Diabetes Outpatients Clinic in St. Vincent's University Hospital and St Vincent's Private Hospital participated in the survey and completed the questionnaire. 8 Diabetes Educators (7 Diabetes Specialist Nurses and 1 Dietician), also completed the GMSS to express their perception of device satisfaction of their patients with T1DM using CGM. Participants were also invited to make any additional comments they have, to have qualitative data.
Results
All patients with T1DM were found to have high overall device satisfaction (M = 4.07, SD 0.66787). No statistically significant difference was observed among CGM satisfaction of patients attending public vs private setups (t (96) = -0.088, ρ = 0.381). Diabetes Educators also perceived high device satisfaction of their patients and comparison with CGM satisfaction of patients did not yield any statistically significant difference (t (102) = 0.311 ρ = 0.756).
Conclusion
High device satisfaction was found in patients with T1DM attending Diabetes clinic in St. Vincent's university and St. Vincent's private hospital. Diabetes Educators also perceive that their patients are satisfied with their device use.

Real-world effectiveness of dapagliflozin and sitagliptin fixed-dose combination in indian patients with type 2 diabetes: a retrospective analysis of electronic medical records stratified by BMI

Rajiv Kovil[1], Rajesh Deshmane[2], Prakadeesh Bharathi B[3], Prachi Ahire[3], Vinay Kudrigikar[3], Shruti Dharmadhikari[3], Chintan Khandhedia[3], Neeraj Markandeywar[3], Amey Mane[3] & Suyog Mehta[3]
[1]Kovil's Diabetes Care Centre, Mumbai, India; [2]Shree Mahalaxmi DIATONE Institute, Kolhapur, India; [3]Sun Pharma Laboratories Ltd, Mumbai

Introduction and Objective
Escalating prevalence of type 2 diabetes mellitus (T2D) in India presents a significant health challenge. Dapagliflozin and sitagliptin are important treatments for achieving glycaemic control in patients with T2D. Dapagliflozin promotes weight loss benefiting overweight and obese patients, while sitagliptin enhances incretin hormone activity with modest weight loss. This is a BMI-stratified analysis of electronic medical record (EMR) based real world, retrospective study assessing effectiveness of dapagliflozin + sitagliptin FDC in patients with T2D.
Methods
In this study, data of adult patients (age $\geq$18 years) of either gender with T2D having HbA1c $\geq$7% at baseline were included. Patients who were prescribed dapagliflozin + sitagliptin FDC in any visit other than baseline visit on EMR platform were included. Patients on insulin or other injectable antidiabetic medication were excluded. Primary endpoint was mean change in HbA1c from baseline to 3 months in patients with HbA1c $\geq$ 8% at baseline. This is a BMI Stratified-analysis of primary outcome.
Results
Total 3112 patients fulfilled selection criteria, of which 838 patients were eligible for primary endpoint. Mean HbA1c at baseline was 9.29% which reduced to 7.98% at end of 3 months with reduction of -1.31% ($P<0.001$). Patients were stratified per BMI ($n=466$): Group 1 (Normal: 18.50-22.99 kg/m^2; $n=41$), Group 2 (Overweight:23.00-24.99 kg/m^2, $n=64$), and Group 3 (Obese: $\geq$25.00 kg/m^2; $n=361$). Significant reduction in HbA1c from baseline to 3 months in all BMI groups was seen; Group 1: 9.26% to 7.90% [change -1.36%]; Group 2: 9.34% to 7.90% [-1.44%]; Group 3: 9.19% to 7.97% [-1.22%] ($P<0.001$ for all comparisons). Fasting and Postprandial blood glucose (FBG and PPBG) reduced significantly in all BMI strata. FBG changes -Group 1: 165.21 to 139.78 [-25.43 mg/dl; $n=35$], Group 2: 162.85 to 124.73 [-38.12 mg/dl; $n=56$], Group 3: 163.91 to 134.17 [-29.74 mg/dl; $n=303$]. PPBG changes -Group 1: 248.24 to 200.69 (Change -47.55 mg/dl; $n=34$), Group 2: 231.96 to 188.74 (-43.22 mg/dl; $n=51$), Group 3: 244.22 to 197.97 (-46.25 mg/dl; $n=249$) ($P<0.001$ for all comparisons) . In patients with BMI $>$23 kg/m^2;, weight reduced from 74.2 to 73.6 kg [change -0.6] at 3 months ($n=649$) and 73.76 to 73.12 kg [-0.64 kg] at 6 months ($n=334$). In patients with BMI $>$25 kg/m^2;, weight reduced from 76.31 to 75.65 kg [-0.66 kg] at 3 months ($n=537$) and 75.92 to 75.12 [-0.8 kg] at 6 months ($n=273$) ($P<0.0001$ for all changes).
Conclusions
Dapagliflozin + sitagliptin FDC demonstrated significant improvement in HbA1c reduction in patients with T2DM and higher HbA1c across BMI groups suggesting it as an effective therapeutic option in patients with varying BMI.

Predictors of glycemic control monitoring in diabetic pregnant women from 449 patients

Rakia Bachir Moctar, Bensbaa Salma, Essabah Nassim, El Aziz Siham & Asma Chadli
CHU Ibn Rochd, Casablanca, Morocco, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Casablanca, Morocco

Introduction
Diabetic pregnancy is a high-risk pregnancy, hence the importance of perfect glycemic control. The objective of this study is to assess glycemic control in pregnant women as well as the factors involved.
Patients and methods
Retrospective study, including 449 patients with diabetic pregnancies followed at the Endocrinology-Diabetology department between January 2016 and January 2022. To do this work, we used SPSS software.
Results
The study included 449 patients with a mean age of 32 years, 19.82% had type 1 diabetes, 39.64% had type 2 diabetes and 40.53% had gestational diabetes. The mean preconception HbA1c was 8.5%. For treatment, 62.47% of patients were on insulin and 37.53% on hygienic and dietary rules. Physical activity was practiced in 58.12% of patients, 41.88% of patients were sedentary. 5.8% are on a free diet and consume fast sugars. Glycemic control was perfect in 49.32% of patients while it was insufficient in 50.68%. A significant relationship was found between glycemic control and adherence to treatment ($P<0.05$) as well as the type of diabetes ($P<0.02$).
Discussion and conclusion
It has been established that optimized management, including perfect glycemic control, reduces the risks associated with pregnancy, several factors intervene as demonstrated in our study, namely: eating habits and the type of diabetes.

The Relationship between Precocious/Early Puberty and Obesity with Metabolic Abnormalities: A Comprehensive Review

Ashraf Soliman, Nada Alaaraj, Fawzia Alyafei, Noor Hamed & Shayma Mohamed
Hamad General Hospital, Pediatric Endocrinology, Doha, Qatar

The Relationship between Precocious/Early Puberty and Obesity with Metabolic Abnormalities: A Comprehensive Review
Introduction
The impact of pubertal timing on the development of obesity and metabolic abnormalities has been the subject of extensive research with variable outcomes.
Objective
We systematically reviewed studies (Medline, Pubmed, Google scholar, and Web of Science) 2000 until March 2023 evaluating the relation between early puberty and occurrence of obesity and metabolic abnormalities including T2DM.
Results
12 studies were examined and analyzed. The Gothenburg Osteoporosis and Obesity Determinants study followed 579 subjects. Early pubertal onset predicted central fat mass distribution, while high prepubertal BMI strongly predicted subcutaneous obese phenotype. A twin cohort analysis revealed strong heritability estimates for age at onset of pubertal growth spurt, and adult height. These traits were associated with childhood BMI and early adulthood stature due to shared genetic factors. A Finnish cohorts supported strong genetic etiology in the correlation between early puberty and higher childhood BMI especially in girls. A meta-analysis (34 studies) demonstrated that early menarche correlated with increased adult BMI, while late menarche correlated with decreased BMI. Another meta-analysis (28 studies) found that earlier age at menarche was associated with a higher risk of T2DM even after adjusting for adiposity. A Swedish study of 30,697 men demonstrated that earlier pubertal onset was linked to a higher risk of early diabetes, and early need for insulin therapy even after BMI adjustments. Late puberty correlated with reduced diabetes risk. Analysis of the Nurses' Health Study cohorts revealed that early menarche was associated with increased risk of type 2 diabetes. Adiposity partly mediated this association. A meta-analysis of 28 observational studies ($n=1,228,306$) identified that without adjustment for adult adiposity, T2DM/IGT risk was lower per year later onset of menarche and higher for early vs later menarche. In a UK Biobank study indicated that both in women and men separately, earlier puberty timing was associated with higher risks for angina, hypertension and T2D. A study in Brazil involving 8,075 women demonstrated that early menarche ($<$11 years) was linked to a higher risk of diabetes, even after controlling for socio-demographic factors and maternal diabetes.
Conclusion
Collectively, early puberty appears to contribute to an increased risk of obesity and T2DM in both men and women, often mediated by factors such as childhood BMI and genetic predisposition. Monitoring and early diagnosing these conditions are important for successful management.

EP649

Prevalence of Metabolic Syndrome Components and High Atherogenic Index in Obese Nondiabetic Children

Ashraf Soliman, Noor Hamed, Fawzia Alyafei, Nada Alaaraj & Shayma Mohamed
Hamad General Hospital, Pediatric Endocrinology, Doha, Qatar

This study aimed to explore the prevalence of distinct Metabolic Syndrome (MetS) components and plasma AIP among obese children and adolescents, and

to evaluate their anthropometric measures in comparison to their parents, thereby considering genetic and environmental influences.
Methodology
Anthropometric and biochemical profiles of 91 randomly selected obese children and young adolescents (mean age: 10.5 ± 2.7 years) were meticulously analyzed. This cohort attended the Pediatric Clinic of Hamad Medical Center (HGH) in Doha (Qatar) between January 2018 and December 2020. Recorded data encompassed age, gender, weight, height, body mass index (BMI), systolic and diastolic blood pressures, as well as key biochemical parameters such as lipid profile, glycated hemoglobin (A1C), and alanine transferase (ALT) levels, which were subsequently compared to age-matched normative values.
Results
Among mothers, 44% were overweight (BMI $>25 <$ 30 kg/m^2), while 52.7% were obese (BMI $>$ 30 kg/m^2; range 24.5 - 51.5 kg/m^2). Similarly, 18% of fathers were overweight, while 64% were obese (range 21.5 - 51.2 kg/m^2). A significant correlation emerged between the BMI of obese children and young adolescents and their maternal BMI (r: 0.34, $P=0.01$), although not with paternal BMI. Obese children exhibited heightened prevalence rates of dyslipidemia, dysglycemia, and non-alcoholic fatty liver disease (NAFLD). Applying modified adult MetS criteria, MetS was evident in 30.2% of this obese cohort, with 76.7% displaying elevated AIP.
Discussion and Conclusion
The 30% prevalence of MetS among our obese, nondiabetic children and young adolescents underscores the pressing need for early detection and nationwide preventive strategies. Moreover, the notable 76.7% occurrence of high AIP emphasizes the augmented risk of future cardiovascular diseases (CVDs), necessitating early interventions to normalize atherogenic lipemia. The strong relationship between parental overweight and child obesity underscores the complex interplay between genetic predisposition and environmental factors.
Recommendations
studies suggest that interventions aimed at reducing dietary carbohydrate intake and promoting weight loss may hold potential in mitigating atherogenic dyslipidemia and its associated cardiovascular risks.

Prevalence (%) of different metabolic components in obese children.

Obese children and young adolescents($n=91$)	Prevalence
AIC > 5.7%	21%
Fasting blood glucose >5.6 mmol/l	32%
Low Hb < 11g/l	10%
LDL > 2.9 mmol/l	16.2%
HDL < 1.1 mmol/l	40%
Triglycerides > 1.7 mmol/l	18.6%
Cholesterol > 4.5 mmol/l	32.6%
Atherogenic index of plasma > 0.23	76.7%
Pre-hypertension BP >85th percentile	16.2%
Hypertension BP >95th percentile	11.2%
ALT > 35 IU/l	12%
Vitamin D < 50 nmol/l	78.50%

Impact of obesity and diabetes in colorectal cancer
Wafa Khemiri, Myriam Ayari, Mtir Maha, Abdelaali Imen, Douggui Hedi & Taieb Jomni
FSI hospital, Internal Medecine, Tunisia

Background
Colorectal cancer is the world's third most common cancer. The prognosis is mainly determined by the stage of the tumor, but several other factors related to the patient, such as co-morbidities, may also have an impact on the disease course. The aim of our study was to assess the prognostic value of diabetes and obesity in colorectal cancer.
Methods
We conducted a retrospective study including patients diagnosed with primary colon or rectal cancer, over an 8-year period [January 2014-June 2022]. Patients were compared according to the presence or absence of diabetes and obesity, that was defined by a body mass index (BMI) greater than 30 kg/m^2. Data were entered and analyzed via SPSS 26 software. Prognostic analysis was performed using the Kaplan Meier method.
Results
A total of 83 patients were included, with a mean age at disease diagnosis of 60 ± 12 years and a sex ratio M/F = 1.96. Liberkhunian adenocarcinoma was the dominant histological type (90%). Eleven patients had metastatic disease at diagnosis, with the majority classified as TNM stage 2 and 3 (25% and 47% respectively). Twenty-three patients had diabetes (28%). Thirty-one patients were obese (31%). The cancer was in the rectum in 30% of the cases and in the colon in 70%. For treatment, 24% of patients received neoadjuvant chemotherapy (24%), 74 patients underwent surgery (89%), with urgent surgery in 20% of the cases, and 60% required adjuvant chemotherapy. In a univariate study, diabetes was significantly associated with an age of cancer's discovery greater than 50 years ($P=0.018$). The presence of pulmonary metastases was higher in diabetic patients, without a significant difference ($P=0.06$). In terms of endoscopic characteristics, patients with a BMI greater than 25 kg/m^2 were more likely to have a stenosing and circumferential tumour, with a difference at the limit of signification ($P=0.05$ and $P=0.06$ respectively). Comparing Kaplan-Meier survival curves, there was no significant difference in survival in diabetic patients (log rank test = 0.86) and also in obese patients (log rank test = 0.72).
Conclusion
Diabetes and obesity are known as risk factors for colorectal cancer and could influence tumor characteristics, but they do not appear to impact prognosis in our study.

Eating habits in obese children: a comparative study
Rym Ben Othman, Salma ABADLIA[1,1], Ramla Mizouri, Berriche Olfa, Emna Talbi, Syrine Trabelsi & Henda Jamoussi
National Institute of Nutrition and Food Technology, tunis

Introduction
Childhood obesity rates have globally increased in the last five decade. It is well known that eating habits are a crucial contributing factor. Our study aimed to understand the impact of dietary habits on this global issue.
Methods
It was a comparative study including 50 obese children (G1) and 35 normal-weight children (G2) aged between 6 and 13 years old. Our study was conducted in the outpatient department of Bechir-Hamza Children's Hospital of Tunis, Tunisia from December 26, 2016 to February 1, 2017. Obesity was determined by World Health Organization growth charts sex-specific Body Mass Index for age.
Results
The average age was 8.9 ± 3 years for G1 and 8.1 ± 3 years for G2 ($P=0.22$). G1 were mainly females (64%). We noted that G1 had significantly an earlier food diversification during the first year of life (5.11 months with a minimum of 2 months vs 5.8 with a minimum of 3, $P=0.05$). During childhood, the majority of participants had 3 meals per day (G1: 95% vs G2: 97%, $P=0.86$). Nevertheless, 60% of meals were consumed in front of TV for G1 vs 40% for G2 ($P<0.01$). Eating disorders were noted in G1 as following: 8% prandial hyperphagia, 26% binge-eating disorder, 26% night-eating syndrome and 28% bulimia. Furthermore, nearly all obese children (98%) reported the intake of snacks.
Conclusion
These findings highlight the importance of addressing not only the nutritional aspects but also the behavioral and psychological dimensions of eating habits to combat the increasing prevalence of childhood obesity.

Comparative analysis of nutritional status in obese and non-obese children
Rym Ben Othman, Salma Abadlia, Ramla Mizouri, Olfa Berriche, Emna Talbi, Rihab Yamoun, Amal Salem & Henda Jamoussi
National Institute of Nutrition and Food Technology, tunis

Introduction
Childhood obesity is a growing public health concern worldwide, necessitating a comprehensive understanding of the nutritional disparities between obese and non-obese children. This study presents a comparative analysis aiming to elucidate the distinctive nutritional profiles in these two groups
Methods
We undertook a comparative study involving 50 obese children (G1) and 35 normal-weight children (G2) aged 6 to 13 years. The research was conducted at the outpatient department of Bechir-Hamza Children's Hospital in Tunis, Tunisia, from December 26, 2016, to February 1, 2017. Obesity was determined by World Health Organization growth charts sex-specific Body Mass Index for age.
Results
The average ages for G1 and G2 were 8.9 ± 3 years and 8.1 ± 3 years, respectively ($P=0.22$). Among G1, two-thirds (64%) were female. We observed that G1 had a significantly higher consumption of white bread (94% vs 80%, $P=0.04$) as well as cheese (50% vs 20%, $P<0.01$) for breakfast. Additionally, lunchtime

consumption showed a higher prevalence of sodas in G1 compared to G2 (86% vs 37%, $P<0.01$). Furthermore, the average daily caloric intake was significantly higher in G1 (2646±320 vs 1792±340 Kcal/j, $P<0.01$). The diet of G1 was characterized not only by hypercaloric content but also by a lower fiber intake (G1: 19 g fiber/day vs G2: 32.9 g fiber/day, $P=0.01$). No significant difference was noted between the two groups regarding the intake of water-soluble vitamins. However, for fat-soluble vitamins, G1 had a significantly higher vitamin E intake (42 mg/day vs 26 mg/day, $P<0.01$). In terms of trace elements, iron intake was similar in both groups, whereas zinc intake was significantly greater in G1 (54 mg/day vs 20 mg/day, $P<0.01$). As for minerals, magnesium and sodium intake were comparable in both groups ($P=0.74$, $P=0.12$, respectively), while a significant higher intake of phosphorus, potassium and calcium was noted in G1 ($P<0.01$, $P<0.01$, $P<0.01$, respectively).

Conclusion

These findings underscore the importance of targeted interventions and public health initiatives to address and modify dietary behaviors among obese children.

Is Freeze-dried Superfood Kale Supplementation Healthier than Common Green Peas? Outcomes of a Cross-Over Trial

Dara Aldisi[1], Shaun Sabico[2], Amani Alfarraj[1] & Al-Daghri Nasser[2]
[1]King Saud University, College of Applied Medical Colleges, Riyadh, Saudi Arabia; [2]King, Biochemistry, College of Science, Riyadh, Saudi Arabia

Kale (Brassica oleracea species) is considered a functional food whose macronutrient and phytochemical contents are considered beneficial and as such widely considered as a superfood. In the present 6-week cross-over trial with a 2-week washout period we compared the beneficial effects of freeze-dried kale over peas among Arab women with obesity. A total of 124 Saudi women with obesity were allocated to receive either freeze-dried kale ($n=62$) or freeze-dried peas ($n=62$) given in the form of 3-gram sachets thrice daily for two weeks followed by a 2-week washout period and a cross-over of 4 weeks. Anthropometric measurements, glucose, lipids and markers of gut barrier function were assessed at baseline and post-intervention. Participants who took kale supplementation first resulted in significant weight reduction ($P=0.02$) which was not observed among those who took peas first. Participants receiving pea supplementation first experienced a significant decline in Hba1c ($P=0.005$) and CD14 ($P=0.03$), but C-peptide increased ($P=0.05$). Crossover analysis revealed significant carryover effects in most variables with non-significant combined treatment effects. Among the variables with no carryover effect with significant combined treatment effect include HbA1c which was in favor of the pea group ($P=0.005$) and C-peptide modestly in favor of the kale group ($P=0.05$). While both freeze dried kale and pea supplementation appear beneficial, supplementation of freeze-dried pea appears to be more effective in terms of acute glycemic control than kale. The study demonstrates that common by less-hyped vegetables such as pea maybe equally, if not more beneficial than those categorized as superfoods such as kale.

Assessment of motor activity of patients undergoing medical rehabilitation

Valeriia Vasileva & Larisa Marchenkova
Federal State Budgetary Institution "National Medical Research Center of Rehabilitation and Balneology" of the Ministry of Health of the Russian Federation, Department of Somatic Rehabilitation of Reproductive Health and Active Longevity, Moscow, Russian Federation

Introduction

Problem of evaluation of the motor activity patients undergoing medical rehabilitation and sanatorium treatment remains relevant, including obesity.

Aim.

To study the nature and degree of disorders of muscle strength, motor and coordination functions in patients undergoing medical rehabilitation and sanatorium treatment.

Material And Methods

Single cross-sectional study included 160 patients aged 40 to 65 years with normal and overweight. The complex of the study included: functional tests and assess muscle strength and balance.

Results

In patients with obesity, compared with persons with normal body weight of the same age, significantly ($P< 0.05$) lower indicators of muscle strength of the right and left arms, strength of the abdominal and back muscles, lower endurance of the abdominal muscles and back muscles and longer time to complete the "Get up and walk" test. Also, in obesity, it turned out to be significantly less time to maintain balance in the 'Stand on one leg' tests on the right and left legs with open eyes. A statistically significant direct relationship was found between the level of back muscle strength ($\gamma = –0.82$, $P=0.0038$) and body weight. A significant relationship was also found between the level of endurance of the back muscles to physical activity and BMI, $\gamma = -0.79$, $P=0.01$. At the same time, there was no relationship between age and the level of endurance of the back muscles to physical activity ($\gamma = 0.107$, $P=0.36$).

Discussion

In patients undergoing medical rehabilitation and health resort treatment, obesity is associated with a decrease in muscle strength and motor activity.

Conclusion

In patients with obesity at the age of 40–65 years, compared with persons with normal body weight of the same age and gender, there is a statistically significant decrease in the muscle strength of the arms, abdomen and back, a longer time to complete the "Get up" test and walk', as well as deterioration in the function of static balance according to the results of the 'Stand on one leg' test.

Bidirectional association between fat mass and 25-hydroxyvitamin D in male with type 2 diabetes mellitus

Iryna Kostitska[1], Tetiana Fostun[2], Nadiia Zherdova[3], Oleg Voloshyn[1] & Olga Zhurakivska[1]
[1]Ivano-Frankivsk National Medical University, Ivano-Frankivsk, Ukraine; [2]Communal Non-commercial Enterprise "Bogorodchanska Central Hospital", Ivano-Frankivsk, Ukraine; [3]Centre of Innovative Medical Technologies, Kyiv, Ukraine

Introduction

To date, there was evidence for an association between lower serum 25(OH)D levels and higher prevalence of obesity in individuals with type 2 diabetes mellitus (DM). Vitamin D status is inversely associated with the prevalence of obesity in patients with insulin resistance syndrome. Actually, no study that has been specifically performed to investigate the association between vitamin D levels and all the parameters of body composition in obese males with type 2 DM in Ukraine.

Aim of the study

was detect 25-hydroxyvitamin D (25(OH)D) level in obese male with type 2 DM depending on fat mass (FM).

Materials and methods

A total of 31 males with type 2 diabetes have been examined and divided into II groups according to body mass index (BMI): I group ($n=15$) overweight subjects (BMI 26.0-29.9 kg/m^2) and II group ($n=16$) male with obesity (BMI $\geq$ 30.0 kg/m^2). The participants were on average 54.6±6.9 years, type 2 diabetes duration of 12.2± 7.6 years, mean value of glycated hemoglobin (HbA_1C) – 7.7±1,1%. BMI was calculated by a ratio of body weight (in kilograms) and square of height (in meters), expressed in kg/m^2. Body composition parameters (FM, fat free mass (FFM), body cell mass (BCM), total body water (TBW)) were measured by electrical bioimpedance analysis. Serum level of 25(OH)D was detected by electrochemiluminescent method (Roche Diagnostics, Germany) and cobas test system.

Results

Analysis of 25(OH)D level depending on BMI showed revealed the highest level 25(OH)D in male with overweight (28.5±7.3 ng/ml), while the lowest level were in male group II (14.8 ±8.2 ng/ml). Male with type 2 DM of II group have a higher FM level than patients of I group (35.8±6.8 kg vs 31.2±1.9; $P<0.001$). Univariate analysis showed significant differences in FFM(II group: 68.5±9.7 kg vs I group: 50.2±1.8 kg, $P<0.01$); BCM (II group: 41.1±5.5 kg vs I group: 33.2±1.1 kg, $P<0.01$); TBW (group: 52.7±6.3 kg vs I group: 40.4±5.9 kg, $P<0.01$) between II and I groups. The highest correlation between the 25(OH)D levels and FM was observed in patients with obesity ($r= -0.26$; $P<0.01$), and significantly and negatively correlated with BMI ($P<0.001$) and HbA_1C ($P<0.01$).

Conclusion

This study confirms that obesity in males with type 2 DM is associated with vitamin D deficiency and it shows detected significant influence FM on the progression lower serum vitamin D.

Psycho-emotional status in patients with metabolic syndrome

Olga Moskalenko & Eduard Vilyamovich Kasparov
Federal Research Center «Krasnoyarsk Science Center» of the Siberian Branch of the Russian Academy of Sciences, KSC SB RAS, Krasnoyarsk, Russian Federation

Metabolic syndrome (MS) is a widespread clinical syndrome, the incidence of which is increasing annually in both developing and developed countries. The prevalence of MS among the working population is quite high (20-25%) and tends to increase. The presence of MS increases the risk of developing type II diabetes and cardiovascular diseases, and anxiety and depression are considered as independent risk factors for the development of MS. It has also been found that the prevalence of anxiety is approximately 10% higher among the group of patients with MS compared to those without MS.

Purpose

to study the psycho-emotional status in patients with metabolic syndrome.

Methods

This study was conducted at the clinic of the Scientific Research Institute of Medical Problems of the North. Inclusion criteria: age (20-60 years); absence of mental, infectious and chronic somatic diseases in the stage of decompensation. All patients were divided into 2 groups: 1) group No. 1 - 76 patients with MS, 2) group No. 2 - 42 practically healthy volunteers who had no concomitant diseases and were not obese. The patients were examined and anthropometric parameters were determined: waist circumference (cm), body weight (kg), BMI (kg/m^2;). The assessment of quality of life (QOL) was determined using the questionnaire «SF-36». The assessment of the psycho-emotional status of patients was carried out using a questionnaire: HADS.

Results

in the course of our study, we found that according to the SF-36 questionnaire, QOL indicators were statistically significantly different in the group of patients with MS relative to the group of patients without MS. Thus, indicators of the level of quality of life are significantly higher in healthy individuals than in obese patients. The differences in all groups are significant ($P \leq 0.05$). It was also found that the average level of parameters on the scale 'physical functioning' decreased by 19.7% ($P < 0.05$), 'role functioning' by 35.2% ($P < 0.05$), 'general health' by 15, 1% ($P < 0.05$), 'vitality' by 18% ($P < 0.05$), 'emotional functioning' by 53.1% ($P < 0.05$). The assessment of the level of anxiety and depression in patients with MS corresponded to a subclinically expressed level, and the level of depression exceeded the indicator in group No. 2 by 19.3%. The level of quality of life in obese patients is significantly lower than in healthy individuals.

Conclusion

The results obtained show that the patterns established in this study should be taken into account when carrying out preventive measures among patients with MS.

Environmental factors on childhood obesity: a comparative study

Ben Othman Rym[1], Abadlia Salma[2], Mizouri Ramla[1], Berriche Olfa[1], Talbi Emna[1], Yamoun Rihab[3] & Salem Amal[4]
[1]National Institute of Nutrition and Food Technology, Nutrition A, tunis; [2]Faculty of Medicine of Tunis, Tunis, Tunisia; [3]National Institute of Nutrition and Food Technology, Outpatient department, tunis; [4]National Institute of Nutrition and Food Technology, Nutrition C, tunis

Introduction

Childhood obesity is a major global health problem that has reached alarming levels. We conducted our study to determine the influence of environmental factors on this international scourge.

Methods

It was a comparative study involving 50 obese children (G1) and 35 normal-weight children (G2) aged between 6 and 13 years old. Our study was conducted in the outpatient department of Bechir-Hamza Children's Hospital of Tunis, Tunisia from December 26, 2022 to February 1, 2023. Obesity was determined by WHO growth charts sex-specific BMI for age

Results

We included 85 participants with a mean age of 8.9 ± 3 years for G1 and 8.03 ± 3 for G2 ($P = 0.22$). Obese participants were predominately females (64%). No significant difference in educational levels between G1 and G2 was found ($P = 0.41$), nor in those of their parents ($P = 0.8$). While a tendency for working mothers to have obese children was noted, the association wasn't significant (G1: 48% vs G2: 35%, $P = 0.23$). Besides, socio-economic status was comparable between the two groups ($P = 0.53$). Both G1 and G2 lived mostly in urban areas (G1: 66% vs G2: 68%, $P = 0.7$). Furthermore, G1 and G2 had comparable TV-watching time ($P = 0.06$). However, almost all participants of G1 used cell phones (98%) vs 85% for G2 ($P = 0.03$). In addition, the daily duration of mobile phone use was significantly higher in G1 than in G2 ($P < 0.01$).

Conclusion

These findings emphasize the complex link between environmental factors and childhood obesity, highlighting the need for targeted interventions in addressing this public health challenge

EP658

Impact of maternal factors on childhood obesity

Ben Othman Rym[1], Abadlia Salma[2], Mizouri Ramla[1], Berriche Olfa[1], Talbi Emna[1], Ghamgui Wissal[3] & Jamoussi Henda[1]
[1]National Institute of Nutrition and Food Technology, Nutrition A, tunis; [2]Faculty of Medicine of Tunis, Tunis, Tunisia; [3]National Institute of Nutrition and Food Technology, Outpatient department, tunis

Introduction

Childhood obesity is influenced by various factors. Maternal health plays a crucial role in this public concern. We carried out our study aiming to uncover key insights into this relationship.

Methods

It was comparative study in the outpatient department of Bechir-Hamza Children's Hospital of Tunis, Tunisia, from December 26, 2022 to February 1, 2023. The study included 50 obese children (G1) and 35 normal-weight children (G2) aged between 6 and 13 years old. World Health Organization growth charts sex-specific Body Mass Index (BMI) for age were used to define obesity.

Results

The average age of participants was 8.9 ± 3 years for G1 and 8.03 ± 3 for G2 ($P = 0.22$). The majority of G1 were females (64%). Maternal pre-pregnancy BMI of G1 was significantly higher than that of G2 (29.9 ± 5 kg vs 27.4 ± 4, $P = 0.02$). Pregnancy was complicated by gestational diabetes in 32% of cases for G1 vs 11.4% for G2 ($P < 0.01$). In addition, average maternal weight gain during pregnancy was significantly greater for G1 (15.6 ± 8 kg vs 8.13 ± 3 k g, $P < 0.01$). Moreover, macrosomic infants were more likely to develop childhood obesity (46% of G1 were born macrosomic vs 14.3%, $P < 0.001$). We also noticed that G1 exhibited lower rates of breastfeeding compared to G2 (80% vs 94.3%, $P = 0.04$). It's interesting to also note that the average duration of breastfeeding was shorter for G1 (6.2 months vs 9.9 months, $P = 0.04$).

Conclusion

These findings highlight the significant link between maternal health and childhood obesity, emphasizing the need for targeted interventions.

Hyponatremia in patients receiving total enteral nutrition (TEN): the importance of appropriate treatment

Cristina Serrano Valles[1], Emilia Gómez Hoyos[2], Ana Ortolá Buigues[2], Rebeca Jiménez Sahagún[2], Susana García Calvo[3], Juan Jose Lopez Gómez[2], Beatriz Torres Torres[2], Esther Delgado García[2] & Daniel de Luis Román[2]
[1]Hospital General de Segovia (HGSE), Servicio de Endocrinología y Nutrición, Segovia, Spain; [2]Hospital Clínico Universitario de Valladolid., Servicio de Endocrinología y Nutrición, Valladolid, Spain; [3]Complejo Asistencial de Palencia. Hospital Rio Carrión, Servicio de Endocrinología y Nutrición, Palencia, Spain

Introduction

Hyponatremia is the most frequent disturbance in hospitalized patients. The appropriate treatment of non-severe hyponatremia according to the clinical guidelines is essential to achieve an effective response defined as eunatremia (Serum sodium >135 mmol/l). The aim of this study was to know the relationship between appropriate treatment and effective response in patients with enteral tube feeding (TEN).

Methods

An observational, prospective study during 24 months. The study was designed in non-critically hyponatremic patients receiving TEN and presenting hyponatremia. Data collected included sex, age, clinical volemia, type of treatment and serum sodium levels before, 72 hours and one week after started treatment.

Results

87 patients were included, 62,1% males, age 76 (IR 67–84) years. 8,0% were hypovolemic, 86,0% were euvolemic and 6,0% were hypervolemic. 39 patients

(44,8%) received appropriate treatment, in 100% hypovolemic, 83,3% euvolemic and 100% hypervolemic patients. Eunatremia was reached by 74%: 5,1% of hypervolemic; 64,1% of euvolemic patients and 5,1% in hypovolemic patients. The percentage of patients achieving eunatremia following one week was 38,4% and the median of time between hyponatremia diagnostic and the start of treatment was 3,0 [RIQ 3,9-14,0] days.
Conclusion
The appropriate treatment was established in almost half of the hyponatremic patients with TEN. An effective response was achieved in the majority of patients within a week of the beginning treatment.

Evaluating Unhealthy dietary habits: A Study on Fast Food and Sugary Beverage Consumption Among Teachers in Southern Tunisia

Ahmed Trigui[1], Houda Ben Ayed[2], Mariem Ben Hmida[1], Mouna Baklouti[2], Mondher Kassis[1] & Sourour Yaich[3]
[1]Habib Bourguiba University Hospital, Preventive Medicine and Hospital Hygiene Department, Sfax, Tunisia; [2]Hedi Chaker University Hospital, Preventive Medicine and Hospital Hygiene Department, Sfax, Tunisia; [3]Hedi Chaker University Hospital, Preventive and Community Medicine Department, Sfax, Tunisia

Introduction
Unhealthy dietary habits, such as the consumption of fast food and carbonated beverages, are associated with various health risks. Given their significant role in society, teachers are a group of particular interest in the context of health-related concerns. This study aimed to assess the prevalence of fast food and carbonated beverage consumption among teachers and to explore the influencing factors of these habits.
Methods
This cross-sectional study was conducted among a randomized sample of public-school teachers at all educational levels, including primary, middle, and high schools, within Sfax Governorate in Southern Tunisia during the period March-April 2021.
Results
Among the 525 teachers, 80.8% ($n=424$) were of urban origin. The sex ratio was 1.23. The median age of teachers was 48 years, ranging from 20 to 68 years. We noted that 101 teachers (19.2%) were obese. Regarding weight perception, suboptimal adherence to healthy weight perception was observed among 70.9% of teachers ($n=372$). In terms of dietary habits, 20.2% ($n=106$) reported consuming fast food or carbonated beverages more than twice a week, while 52.2% ($n=274$) consumed fruits or vegetables daily. A significantly higher prevalence of fast food or carbonated beverage consumption was observed among teachers with post-university educational level compared to those with university educational level (34% vs 19.5%; $P=0.02$). Multivariate analysis showed that age (Adjusted odds ratio ORA) = 0.96; 95% confidence interval (CI) [0.93, 0.98]; $P=0.01$) and female gender (AOR = 0.44; 95%CI [0.27, 0.7]; $P=0.01$) were independently associated with a lower prevalence of fast food or carbonated beverage consumption. Additionally, fast food or carbonated beverage consumption was independently associated with higher alcohol consumption (AOR = 2.16; 95%CI [1.06, 4.4]; $P=0.03$) and pasta consumption (AOR = 1.73; 95%CI [1.1, 2.7]; $P=0.01$).
Conclusion
This study highlighted the prevalence of fast food and carbonated beverage consumption among teachers and identified significant associated factors. These findings underscore the need for targeted interventions to promote healthier dietary habits, especially among teachers at specific risk.

Effect of low muscle mass on total mortality related to metabolic disease in patients with chronic kidney disease in US adults

Dong Sun Kim & Jung Hwan Park
Hanyang University College of Medicine, Department of Internal Medicine, Seoul, Korea, Rep. of South

Background
Sarcopenia is associated with mortality in patients with chronic kidney disease (CKD). However, the extent to which sarcopenia contributes to this risk, either independently or in conjunction with metabolic abnormalities and frailty, remains unclear. Therefore, this study aimed to explore the associations among sarcopenia, frailty, central obesity, metabolic abnormalities, cardiovascular risks, and mortality.
Methods
This study used data from the National Health and Nutrition Examination Survey (NHANES) 1999–2006 and 2011–2018. Low muscle mass was defined as Appendicular Skeletal Mass Index <7 kg/m^2 in men or <5.5 kg/m^2 in women. The follow-up duration was from the first anthropometric and clinical measurements to death or the last follow-up (December 31, 2019).
Results
This study enrolled 2072 patients with CKD. Low muscle mass was associated with a significantly reduced risk of metabolic abnormalities. Conversely, central obesity was associated with a significant increase in the risk of metabolic abnormalities and frailty. Notably, although low muscle mass was associated with an elevated mortality risk, central obesity did not show a significant association. Subsequent analysis using propensity score matching showed similar results. Furthermore, mediation analysis indicated that the effect of low muscle mass on mortality was mediated directly through frailty and metabolic abnormalities. Despite the inverse relationship between low muscle mass and metabolic abnormalities, low muscle mass is directly associated with an increased risk of all-cause mortality.
Conclusion
Low muscle mass may play a direct role in the pathogenesis of mortality in patients with CKD, independent of metabolic abnormalities and frailty.

Eating behavior patterns, metabolic parameters, and circulating levels of oxytocin in patientswith obesity: a prospective pilot study

Giorgia Maria Baldazzi, Davide Masi, Chandra Massetti, Maria Letizia Spizzichini, Fiammetta Cipriani, Elena Colonnello, Maria Ignazia Curreli, Mikiko Watanabe, Stefania Mariani, Lucio Gnessi & Carla Lubrano
Sapienza University of Rome, Department of Experimental Medicine, Rome, Italy

Introduction
Obesity is a chronic disease, significantly influenced by maladaptive eating patterns. Oxytocin (OT), recognized for its central role in regulating energy metabolism and eating behavior, represents a potential link in understanding this intricate relationship.
Objective
This study aimed to investigate the potential association between circulating levels of OT and maladaptive eating behaviors, assessed through the Eating Behaviors Assessment for Obesity (EBA-O) questionnaire, in correlation with clinical, anthropometric, metabolic and body composition parameters in a population with obesity.
Materials and Methods
Our prospective, observational study was conducted at the Highly Specialized Center for the Treatment of Obesity at La Sapienza University of Rome. The cohort included adult individuals with obesity. Comprehensive evaluations included anthropometric analysis, body composition analysis by bioimpedance analysis, complete biochemical and hormonal profile, measurement of plasma OT concentration by ELISA, and an in-depth assessment of dysfunctional eating behavior using the EBA-O questionnaire.
Results
21 participants (16 females, 5 males) with a mean age of 45.67 ± 15.07 years, a mean BMI of 40.89 ± 8.02 kg/m^2;, and a mean plasma OT concentration of 1365.61 ± 438.03 pg/ml were enrolled. Interesting associations emerged, demonstrating significant correlations between various dysfunctional eating behaviors. Specifically, individuals exhibiting food addiction tendencies often had concomitant manifestations in multiple EBA-O domains ($P<0.05$), excluding night eating. Lower waist-to-hip ratios were observed in individuals exhibiting food addiction. In addition, the Receiver Operating Characteristic (ROC) analysis demonstrated that OT levels below 1312.55 pg/ml were predictive of food addiction, displaying a sensitivity of 100% and a specificity of 62.5%. The presence of night eating was correlated with elevated lipid profiles - triglycerides ($P<0.001$) , total cholesterol ($P=0.05$), and TG/HDL ratio ($P=0.02$) - while hyperphagic behaviors were correlated with increased hepatic steatosis index (HSI) ($P=0.05$). Positive correlations were established between circulating OT levels and BMI ($r=43$; $P<0.05$), HOMA-IR ($r=0.55$; $P=0.014$), HSI ($r=0.46$; $P=0.049$), and estradiol in the female population ($r=0.72$; $P=0.002$).
Conclusions
This study highlights the complex interaction of maladaptive eating traits assessed through the EBA-O, showing associations and predictive potential, particularly in identifying markers of food addiction. Further in-depth clinical investigations are essential to validate the utility of EBA-O and circulating OT as diagnostic markers of dysfunctional eating behaviors in the context of obesity.

Exploring the Genetic Landscape of Obesity: A Family Report of a Genetic Variant of BBS10 Gene

Leandro Augusto Silva[1,2], Gonçalo Varela Cunha[1,2], Rui Pina[2], Benilde Barbosa[2,3], José Pereira de Moura[2,3] & Lèlita Santos[2,3]
[1]Portuguese Institute of Oncology of Coimbra Francisco Gentil; [2]Local Health Unit of Coimbra; [3]Faculty of Medicine of University of Coimbra

Introduction
Bardet-Biedl Syndrome is a rare autosomal recessive disease characterized by defects in multiple organ systems, presenting with diverse clinical manifestations such as retinopathy, polydactyly, obesity, intellectual developmental disorders, hypogonadism, renal dysfunction, among others.
Clinical Case 1
49-years-old female, case index, followed multidisciplinary since the age of three due to progressive night blindness from generalized retinal dystrophy, learning difficulties, primary amenorrhea and polycystic ovary syndrome, epilepsy, metabolic syndrome (grade 2 obesity, grade 1 hypertension, dyslipidemia), chronic kidney disease and musculoskeletal alterations (macrocephaly, short stature, and scoliosis). It is worth highlighting parental consanguinity. Given the phenotype clinically suggestive of Bardet-Biedl Syndrome, a whole exome sequencing was performed revealing the genetic variant c.1542del p.(Asp515IIefs*9), in apparent homozygosity, of the *BBS10* gene, classified as likely pathogenic, confirming the diagnosis.
Clinical Case 2
45-years-old male, brother of case index, followed since childhood for retinal dystrophy with progressive bilateral night blindness, intellectual developmental disorder, metabolic syndrome (grade 3 obesity, dyslipidemia, type 2 diabetes under insulinotherapy), chronic kidney disease, moderate unilateral sensorineural deafness requiring hearing aid and musculoskeletal alterations (scoliosis and macrocephaly). As in the index case, the patient was advised in a medical genetics' consultation and the same genetic variant was identified, confirming the genetic diagnosis of Bardet-Biedl Syndrome.
Clinical Case 3
36-years-old male patient, first cousin of the above-mentioned individuals, also followed since childhood for bilateral retinal dystrophy, intellectual developmental disorder, cryptorchidism treated with orchidopexy in childhood, grade 1 obesity and arterial hypertension. Additionally, post-axial bilateral polydactyly in the feet. Given the similar phenotype, genetics consultation was performed and the same genetic variant was identified in homozygosity. Genetic counseling for the family was provided.
Conclusion
This report presents three cases of Bardet-Biedl Syndrome within a family, detailing the associated diagnosis process, emphasizing the role of identifying a clinical phenotype and guiding genetic studies. The cases underscore the importance of early recognition of characteristic phenotypes where obesity is a key element, often overlooked, limiting proper patient management.

The impact of weight and BMI on prostate cancer severity through PSA levels - real-world data from a Romanian center

Theodor Mustata[1], Dan Jinga[2], Ioana Lazar[2] & Simona Fica[1,3]
[1]Carol Davila University of Medicine and Pharmacy, Endocrinology, Bucharest, Romania; [2]Neolife Medical Center, Oncology, Bucharest, Romania; [3]Elias Emergency University Hospital, Endocrinology, Bucharest, Romania

Introduction
Prostate cancer is the second most frequent malignancy in men, with more than 1.4 million new cases diagnosed in 2020[1]. Obesity, on the other hand, has reached epidemic proportions, with 59% of adults living with overweight or obesity in Europe[2]. Our aim was asses the impact of weight and BMI on prostate cancer (PCa) severity, reflected in PSA levels.
Methods
We analyzed 225 patients diagnosed with PCa between August 2001 and May 2022 through transrectal prostate biopsy and referred to the Oncology Department of Neolife Medical Center in Bucharest, Romania. Weight, BMI and PSA levels were noted at diagnosis. Lining up with the NCCN risk stratification[3], we divided the patients into two PSA groups: <20 ng/ml and ≥ 20 ng/ml.
Results
Obesity was seen in 71 (31.6%) patients. Median PSA level (IQR) was 12.8 (29.4) ng/ml. 143 (63.6%) patients had PSA <20 ng/ml, while 82 (36.4%) ≥ 20 mg/ml. Binary logistic regression analysis was performed to asses the effects of weight on the risk of having PSA levels >20 ng/ml. An increase in weight was associated with a decreased likelihood of having PSA >20 ng/ml (OR $=$ 0.974, 95% CI: 0.954 – 0.994, $P=0.011$). Similarly, binary logistic regression analysis was performed to asses the effects of BMI on the risk of having PSA levels >20 ng/ml. An increase in BMI was associated with a decreased likelihood of having PSA >20 ng/ml (OR $=$ 0.925, 95% CI: 0.864 – 0.989, $P=0.023$). There was a good capacity of weight (AUROC $=$ 0.604, 95% CI: 0.527 – 0.682, $P=0.009$; cut-off $=$ 81.5 kg, Se $=$ 57.3%, S$P=60.8$%) and BMI (AUROC $=$ 0.583, 95% CI: 0.505 – 0.661, $P=0.038$; cut-off $=$ 24.7 kg/m^2, Se $=$ 32.9%, S$P=81.1$%) to predict the presence of PSA levels >20 ng/ml.
Discussions
It is known that the hemodilution and lower testosterone levels in patients with obesity are associated with lower PSA levels. Ultimately, obesity could delay PCa diagnosis through lower PSA levels.

Predictive factors of Cardiovascular and metabolic complications of obesity:About 502 cases

imane HASBI[1], Nassim Essabah Haraj[2], Siham El Aziz[2] & Asma Chadli[2]
[1]Ibn Rochd University Hospital, Endocrinology and Metabolic Diseases Department, Casablanca, Morocco; [2]Ibn Rochd University Hospital, Endocrinology and Metabolic Diseases, Casablanca, Morocco

Introduction
Obesity, a multifactorial chronic disease resulting from the interplay of genetic and environmental factors, is associated with numerous complications that can impact both vital and functional prognosis. The aim of our study was to analyze the epidemiological, clinical, and paraclinical characteristics of cardiovascular and metabolic complications related to obesity while identifying associated predictive factors.
Patients and methods
In this retrospective study, 502 obese patients were included, recruited from the Endocrinology Department of Ibn Rochd University Hospital in Casablanca. A clinical evaluation including anthropometric parameters and a biological assessment was conducted. The statistical analysis was performed using the SPSS software, version 25.
Results
The average age of our patients was 51.7 ± 3 years, with a clear female predominance (83.5%). The mean body mass index (BMI) was 35.2 kg/m^2, and the mean waist circumference (WC) was 113.8 cm. Notably, 88.4% of patients had at least one obesity-related complication, with an average of 4.5 complications per patient. Metabolic complications were predominant (88.6%), including 79.3% with diabetes, 66.5% with dyslipidemia, and 7.8% with hyperuricemia. Cardiovascular complications were present in 37.4%, dominated by hypertension (90.5%), followed by coronary insufficiency (7.4%), heart failure (6.2%), and myocardial infarction (5.6%) . Age and waist circumference (WC), but not gender and BMI, were identified as predictive factors for metabolic complications. However, cardiovascular complications were significantly correlated with age, BMI, and waist circumference.
Conclusion
Obesity is associated with a range of complications that impact quality of life and pose a threat to vital prognosis. Understanding the predictive factors for these complications allows for anticipation and early intervention, thereby reducing the morbidity and mortality associated with obesity.

Monogenic obesity prevalence and response to bariatric surgery in a cohort of Emirati patients

Tanveer Ashraf[1], Budour AlKaf[1], Saradalekshmi Radha[1], Esphie Fojas[1], Amal Baqer[1], Rayan Khaled[1], Sara Suliman[2], Matthew Allum[2] & Nader Lessan[1]
[1]Imperial College London Diabetes Centre, Research Institute, Abu Dhabi, United Arab Emirates; [2]Imperial College London Diabetes Centre, Diabetes & Endocrinology, Abu Dhabi, United Arab Emirates

Introduction
We have previously shown good short-term but variable long-term weight loss outcomes of bariatric surgery (BS) in a cohort of obese patients with MC4R deficiency. This study aims to elucidate the epidemiological landscape of Monogenic Obesity (MO) and quantify bariatric surgery's effectiveness in weight reduction among Emirati patients with severe obesity.
Methods
We selected a group of patients with extreme obesity (>50 kg/m^2) from our prospective BS cohort for genetic testing (MO genes including LEPR, PCSK1, POMC, MC4R and *BDNF*. Combined Annotation-Dependent Depletion (CADD) and Sorting Intolerant From Tolerant (SIFT) tools were used to measure variant deleteriousness. Relevant linked information including anthropometry, type (and number) of bariatric surgery, diabetes status and glycosylated haemoglobin were available from prospectively conducted questionnaires and patient records. Patients confirmed to have mutations (cases) with complete follow-up data ($n=14$) were compared to controls who were tested and in whom no mutations were found ($n=35$); relevant comparisons were made over 2 years (baseline, median of 3-, 6-, and 12-months post-surgery).
Results
The bariatric surgery cohort included 1089 patients (56% were males); 828 had recorded information on the type and number of surgeries (mean age of 38.6 ± 11.3 years). Diabetes status was identified as T2DM (64), IFG (54), IGT (17) and IFG+ IGT (15). 129 (42%) patients were NGT; 41 patients had unrecorded diabetes status. 84 patients (11 %) underwent multiple (79 with two) surgeries. 190 morbidly obese patients (age 40.0 ± 5.1 years; BMI 54.73 ± 10.49 kg/m^2) were selected and genotyped. 29 mutations (15.2 %, $n=26$) were found, of which four were novel polymorphisms of the UCP2 and MC4R genes. Baseline HbA1c was 6.02 ± 1.25%. Compared to baseline, there were significant decreases in HbA1c, total weight and BMI at all time points over 24 months. The largest drop in weight occurred at 3 months post-surgery (172.10 ± 31.31 to 119.05 ± 17.70 kg). There was a reduction in HbA1c to 5.14 ± 0.45 twelve months post-surgery. Percentage and excess weight loss were significantly less, compared to baseline, at all time points when comparing the cohort with mutations with controls without mutations.
Discussion
The prevalence of monogenic obesity is high (15.2% in our cohort, including four novel mutations) in patients with extreme obesity (BMI >50 kg/m^2) undergoing bariatric surgery. Overall, the response to BS is acceptable but less than a comparator group without MO.

Osteocalcin: relation to glucose metabolism in young women with obesity

Piterschi Carolina[1], Vudu Stela[2], Rizov Cristina[2] & Lorina Vudu[1]
[1]'Nicolae Testemitanu' State University of Medicine and Pharmacy, Laboratory of Endocrinology, Chisinau, Moldova; [2]'Nicolae Testemitanu' State University of Medicine and Pharmacy, Department of Endocrinology, Chisinau, Moldova

Introduction
Osteocalcin is a bone-specific hormone also involved in regulation of glucose and fat mass metabolism. It regulates energy expenditure by acting on adipocytes and pancreatic islet cells. The aim of the present study was to examine the relation between serum osteocalcin and glucose metabolism in young women with obesity.
Material and methods
A total of 66 healthy women were included in the analysis. Data on body mass index (BMI), waist circumference (WC), serum osteocalcin, fasting plasma glucose (FPG) and insulin levels were collected. Insulin sensitivity was estimated by homeostasis model assessment for insulin resistance (HOMA-IR = [glucose (mmol/l) × insulin (mIU/l)]) and by quantitative insulin sensitivity check index (QUICKI index = 1/[log (insulin in mIU/l) + log (glucose in mmol/l)]). All measurements were done in the morning after an 8-h overnight fast.
Results
The participants of the study were classified according to their weight status, 36 women with obesity (BMI ≥30 kg/m^2, WHO) and 30 normal weight women (BMI $\leq$ 25 kg/m^2). The mean age was 33.1 ± 5.9 years and was similar in both groups. Serum osteocalcin was significantly lower in women with obesity than in normal weight women (8.9 ± 4.1 vs 13.8 ± 6.9 ng/ml, $P=0.009$). Insulin resistance was detected by HOMA-IR in 55.5% and by the QUICKI index in 68.2% in women with obesity and no cases of insulin resistance in normal weight women. Serum osteocalcin was inversely associated with BMI ($P=0.02$), waist circumference ($P=0.021$), FPG ($P=0.003$) and fasting insulin ($P=0.004$). Moreover, osteocalcin was inversely associated to HOMA-IR ($P=0.028$) and QUICKI index ($P=0.020$).
Conclusion
These results suggests that serum osteocalcin concentration was significantly lower and inversely associated with blood markers of glucose metabolism, insulin secretion, insulin resistance and adiposity in young women with obesity.

EP668

Evolution of metabolic-associated fatty liver desase measured by fibroscan and biopsy in patients with morbid obesity undergoing bariatric surgery

Miguel Damas-Fuentes[1], Victor Simon-Frapolli[1], Marta Generoso-Piñar[1], José María Pinazo-Bandera[2], Francisco José Tinahones Madueño[1] & Lourdes Garrido Sánchez[1]
[1], Endocrinology and Nutrition; [2], Hepatology

Introduction
Metabolic dysfunction-associated fatty liver disease (MAFLD) is present in a high percentage of obese patients undergoing bariatric surgery (BS), being an effective strategy for the remission of MAFLD. A significant proportion of patients still have steatohepatitis even after considerable weight loss and metabolic improvements. Liver biopsy remains the definitive test to classify a patient with steatohepatitis, but it is an invasive test. The use of non-invasive techniques such as Fibroscan would avoid the limitations and risks that biopsy can cause in this group of patients.
Objective
To evaluate the effect of CB on the improvement of steatohepatitis in patients with morbid obesity (MO), classified according to type 2 diabetes (T2D).
Material and Methods
Patients with morbid obesity and steatohepatitis undergoing CB and classified according to T2D (non-T2D vs T2D). Liver biopsy was performed during BC in order to determine the status of steatohepatitis or fibrosis. Patients underwent Fibroscan before surgery and one year after. Clinical, anthropometric and biochemical variables were measured and liver fibrosis scores (FLI, NFS, APRI, FIB4, Hepamet) were calculated.
Results
Previous BMI (49 kg/m^2) and the average weight (135 kg.), as well as the liver biopsy result were similar in the two cohorts studied, diabetics and non-diabetics. Likewise, BMI (33) and average weight (91) were similar one year after surgery in both groups. Fibroscan was equally similar in both groups, prior to the surgical intervention, reflecting a significant improvement, especially in the non-diabetics, but also in the diabetics, after surgery.
Conclusions
The impact of bariatric surgery improving different parameters associated with metabolic syndrome, achieving regression of most serious stages of MAFLD and remission of T2D in a high percentage of patients, makes it as a valid metabolic therapy, especially in cases of severe obesity.

EP669

Pre-surgical Factors and Their Influence on Therapeutic Response to Bariatric Surgery

Alice Monsanto[1], Tânia Carvalho[1], Gustavo Rodrigues[1], Mara Ventura[1,2,3], Dírcea Rodrigues[1,2] & Isabel Paiva[1]
[1]Hospitais da Universidade de Coimbra - Unidade de Saúde Local de Coimbra, Endocrinology, Diabetes and Metabolism, Coimbra, Portugal; [2]Faculdade de Medicina – Universidade de Coimbra; [3]Faculdade de Ciências da Saúde - Universidade da Beira Interior

Introduction
Bariatric surgery continues to stand as the most effective therapeutic intervention in treating severe obesity. However, a portion of patients experiences less satisfactory outcomes, diminishing the overall beneficial impact of this intervention. Identifying predictive factors for unsatisfactory responses to bariatric surgery could represent a crucial step in evaluating candidates, enabling the establishment of personalized care.
Methods
Retrospective cohort study, including patients submitted to bariatric surgery (gastric bypass or vertical gastrectomy) between January 2016 and December 2020. Initial suboptimal clinical response/insufficient weight loss (IWL) assessed based on the criteria of Total Weight Loss (TWL) at nadir <20% and Excess Weight Loss (EWL) at nadir <50%. Late post-operative clinical deterioration/significant weight regain (WR) evaluated by weight gain ≥10 kg compared to the nadir weight. Follow-up over 36 to 60 months. The relationship between IWL and WR was assessed, considering preoperative factors: comorbidities (cardiovascular and psychiatric),

anthropometric characteristics, and pharmacology. The statistical evaluation was conducted using the chi-square test, t-test, Mann-Whitney U test.
Results
98 patients were evaluated, 52% undergoing gastric bypass, 79.6% having a preoperative BMI $\geq$ 40 kg/m^2. The prevalence of cardiovascular comorbidities was: 50% hypertension, 51% dyslipidemia and 24.5% diabetes mellitus. Postoperative follow-up was conducted for up to 60 months in 55.1% of the patients. At the nadir weight, TWL was 31.9$\pm$8.6%, and EWL was 63.6$\pm$18.8%. Insufficient weight loss occurred in 11.2 to 18.4% of patients, and weight regain occurred in 34.7%, median increase of 13.6 (10; 22.6) kg. The following relationships were observed: IWL and dyslipidemia (P=0.03), type of surgery (P=0.017), and use of antiepileptics (P=0.001); WR with preoperative BMI (P=0.005), diagnosis of psychiatric disease (P=0.020), use of antidepressants (P=0.007), and use of antiepileptics (P=0.005). The relationship between the initial suboptimal clinical response and the remission of comorbidities in the postoperative period was assessed. A lower remission rate of diabetes in patients with IWL relationship was observed (P=0.037).
Conclusions
The initial suboptimal clinical response was found to be influenced by the type of surgery, the preexistence of a dyslipidemia diagnosis, and the use of antiepileptic medications. On the other hand, late postoperative clinical deterioration was mainly influenced by psychiatric disease and the use of antidepressants and antiepileptic medications. It was also observed that the occurrence of an initial suboptimal clinical response may impact the rate of remission of diabetes, reinforcing the importance of weight loss in the course of metabolic diseases.

Weight variation in diabetic women during and after pregnancy

Chaima Sdiri, Haifa Abdesselem, Emna Bornaz, Mariem Cheikhrouhou, Fatma Boukhayatia, Asma Ben Brahim, Rim Yahyaoui, Kamilia Ounaissa & Chiraz Amrouche
National Institute of Nutrition, Department of Nutritional Diseases (D), Tunis, Tunisia

Background
According to several previous studies, breastfeeding offers mothers an opportunity to lose weight and improve their metabolic profiles. The aim of the present study was to investigate weight variation in a population of postpartum diabetic women.
Methods
We conducted a prospective descriptive study in pregnant women treated for pregestational diabetes and followed at the Department of Nutritional Diseases «D» of the National Institute of Nutrition of Tunis. Women's weight was monitored during pregnancy and two months postpartum. A dietary survey was carried out by the department's dietician. Women who had an abortion or had been lost to follow-up were excluded from the study.
Results
We collected 51 diabetic patients with a mean age of 35.4$\pm$4 years [ext:23-44]. Most patients had type 2 diabetes (80%). Before pregnancy, the average body mass index (BMI) was 28.3$\pm$4.7 kg/m^2;. Pre-pregnancy obesity and pre-obesity affected 26% and 48% of the population, respectively. The average weight gain during pregnancy was 9.6$\pm$3.5 kg [ext:5-20]. This weight gain was 27.7$\pm$3.6 kg/m^2; for exclusive breastfeeding, 28$\pm$5.2 kg/m^2; for partial breastfeeding and 30.9$\pm$6.6 kg/m^2; for formula feeding. We noted that weight loss was correlated with breastfeeding pattern (P=0.015). When asked about their knowledge of the nutritional needs of breastfeeding women, 48% of patients had no idea of the nutritional requirements of breastfeeding women. By analyzing patients' dietary intake, women who exclusively breastfed their babies had a more high-calorie energy intake (63% of cases) than women who did not breastfed (38% of cases) or who partially breastfed (2% of cases) their babies (P<0.001). In addition, all patients were not physically active during pregnancy or after childbirth.
Conclusion
We can conclude that breastfeeding is associated with weight loss, but this remains modest in our sedentary diabetic patients. Nutrition education is the cornerstone of care for postpartum patients.

Perceived obesity among patients with type 2 diabetes in albania

Dorina Ylli[1,2], Arbi Mulhaxhia[1], Sigi Mehalla[1], Violeta Hoxha[2], Klodiana Poshi[1,2], Marjeta Kermaj[2] & Agron Ylli[1,2]
[1] University of Medicine Tirana, Tirana, Albania; [2]Mother Teresa University Hospital Center, Endocrinology, Tirana, Albania

Background
This study seeks to assess the precision of obesity perception among patients diagnosed with type 2 diabetes (DMT2), acknowledging obesity as a pivotal modifiable risk factor crucial for diabetes prevention. Furthermore, it is important to unveil and analyze the factors that contribute to the misperceptions of obesity within DM patients.
Methods
This study aims to investigate a cohort of consecutive patients treated at the Endocrinology Unit of Mother Teresa University Hospital Center in Tirana during the period from September to November 2023. A questionnaire was used to collect subjective information as weight perception, lifestyle factors, and glycemic knowledge. Complementary objective measures were extracted from medical records, such as Body Mass Index (BMI), Hemoglobin A1c (HbA1c) levels, High-Density Lipoprotein (HDL), Low-Density Lipoprotein (LDL), and Triglyceride levels.
Results
In our cohort of 59 participants, 59.32% had diabetes. 74.30% of the DM patients had a misperception of their weight classification. The mean age was 56.2$\pm$15 years. Among patients with misperception, 65.3% perceive themselves as overweight but were obese, 19.23% perceive themselves as normal weight but were overweight or obese, and 15.38% perceive themselves as underweight but were normal weight. Despite this misperception, a strong correlation exists between their self-reported weight and the real weight. DM patients with misperception mainly attribute the cause of their obesity to the administration of multiple medications (31.71%), followed by lack of movement (27.23%), diabetes (22.76%), overeating (13.62%), and genetic factors (4.66%). In contrast, patients with accurate perceptions primarily attribute obesity to overeating (65.75%).
Conclusions
The study reveals a notable prevalence of body misperceptions (74.30%) regarding weight classification among DM patients, emphasizing the need for targeted interventions to improve awareness. Various factors identifying as the causes of obesity among patients with DM underscore the importance of tailored education and counseling for effective diabetes management.

DOI: 10.1530/endoabs.99.EP671

EP672

Impact of cakut syndrome and UTI on pediatric BMI

Svitlana Suchok, Oleksandr Yakymenko & Nitin Gupta
National Pirogov Memorial Medical University, Vinnytsya, Pediatric Surgery, Vinnytsia

Background
Several recent studies suggest that continuous low-dose antibiotics prophylaxis used in VUR may affect the growth of children. Guidos P.J. *et al*. (2018) found a significant increase in BMI in children who had prior antibiotic usage. CAKUT syndrome involves both the kidney and urinary tract and generally is associated with antibiotic therapy among pediatric patients and metabolism of waste products.
Aim
We aimed to evaluate the impact of congenital genitourinary defects (CAKUT syndrome) on BMI in pediatric patients compared to patients without structural pathology.
Materials and methods
We prospectively enrolled 49 pediatric patients admitted to the surgical and nephrological departments from June 1 to November 31, 2023. All patients were divided into two groups: study group (n=27) – CAKUT syndrome (VUR, PKD, horseshoe kidney, renal agenesis/hypoplasia, etc.) and prior/current episodes of CAP; control group (n=22) – UTI, without CAKUT (proved by US, VCUG or CT). All patients underwent complete work-up including clinical examination, evaluation of BMI according to WHO standards(underweight, healthy weight, overweight, obese, renal function tests (creatinine, urine, GFR), and imaging studies (US and/or VCUG/CT). Written informed consent was obtained from the parents. P<0,05 was considered significant.
Results
In the study group, 7.4% of patients were obese; 14.8% - overweight; 51.8% -healthy weight; 26% -underweight. BMI distribution in the control group: 4.5% -obese; 4.5% -overweight, 72.7% -healthy weight; 18.3% -underweight. We observed no significant risk of obesity (OR=1.68; 95% CI 0.1422 to 19.8541; P=0.06805), being overweight (OR=3.6522; 95% CI 0.3774 to 35.3435; P=0.2633) or underweight (OR=1.575; 95% CI =0.3948 to 6.2839; P=0.5199) among children with CAKUT syndrome comparing to their peers without congenital defects of urinary system.
Conclusion
CAKUT syndrome does not affect pediatric BMI. There is the same risk of being obese, overweight, or underweight among children with and without congenital defects of urinary system and UTI.

DOI: 10.1530/endoabs.99.EP672

Anthropometric profile in asthma

Mehrez Achwak[1], Chaima Jemai[1], Tesnim Farhat[2], Khouloud Chaabi[3], Hichem Aouina[3], Zohra Hadj ali[1], Yosra Htira[1] & Faika Ben Mami[1]
[1]The national institut of nutrition of Tunis, Department C, Tunisia; [2]Nutrition studies university, Tunisia; [3]Charles Nicole Hospital, Pneumology Department, Tunisia

Introduction
Asthma is a multifactorial disease, resulting from the interaction of genetic, environmental, behavioral and social factors. These components can play a role in disease onset, progression and control. More specifically, one of the factors that could influence asthma control is obesity. The aim of this study was to analyze the anthropometric profile and body composition of a population with asthma.
Methods
Descriptive cross-sectional study over 6 weeks, involving 40 patients followed up at the pulmonology outpatient clinic. Patients included in the study had their weight, height and BMI measured. Body composition was studied using a professional bioelectrical impedance meter.
Results
The population comprised 32 women and 8 men, with a mean age of 46.15 ± 14.13 years. Mean weight was 75.9 ± 12.6 kg with a mean BMI of 29.1 ± 5.7 kg/m^2;. Three quarters of the study population were overweight: 27.5% were overweight, 30% were obese class 1 and 17.5% were obese class 2. Regarding the results of the body composition study: mean body fat was 34.96 ± 10%; mean fat mass was 27.56 ± 10.76 kg; mean lean mass was 48.92 ± 6.65 kg and bone mass was 2.38 ± 0.30 kg. Mean visceral fat was 8.88 ± 4.07 kg. Poor asthma control was associated with higher fat mass, but p was not significant.
Conclusion
Obesity is among the key factors contributing to poor asthma control. By adopting a multidisciplinary approach involving dieticians and physiologists, it is possible to optimize clinical outcomes and provide patients with comprehensive management to facilitate the adoption and maintenance of good dietary habits, by providing specialized and personalized support.

Nutritional deficiencies in obese patients

Benzineb Sara[1], Imane Motaib[2], Saloua Elamari[2], Soukaina Laidi[1] & Marouan Fatima[2]
[1]Cheikh Khalifa Bin Zayd Al Nahyan Hospital-University Mohamed VI of Health Sciences, Endocrinology, Casablanca, Morocco; [2]Cheikh Khalifa Bin Zayd Al Nahyan Hospital-University Mohamed VI of Health Sciences, Endocrinology, Casablanca

Introduction
Nutritional deficiencies are a lesser-known complication of obesity despite their frequency. The aim of this study was to identify nutritional deficiencies in obese patients.
Materials and methods
This was a prospective study, which included all patients with a BMI greater than 30 kg/m^2 followed up in the endocrinology department of the Cheikh Khalifa Ibn Zaid Hospital in Casablanca, Morocco. The study began in January 2023. For each patient, we collected anthropometric data, evaluated the dietary survey, traced vitamins and elements such as vitamin D, folic acid, ferritinemia and albuminemia.
Results
The preliminary results of the dietary survey of the 20 patients showed insufficient consumption of fruits (13.3%), vegetables (6.7%) and dairy products by 26.7%, with consumption of foods with a high caloric value but of low nutritional quality, reduced physical activity, and a prevalence deficiencies of 33%, of which 46% were vitamin D deficient, 33% vitamin D deficient, 46% iron deficiency, 6.7% hypoalbuminemia and hypoalbuminemia and 6.7% folic acid deficiency.
Discussion
Our study highlighted the high prevalence of nutritional nutritional deficiencies in obese patients, which can be explained by the poor nutritional quality of meals, and repetitive restrictive diets.

DOI: 10.1530/endoabs.99.EP674

EP675

A study of nutritional profile in a population with asthma

Mehrez Achwak[1], Chaima Jemai[1], Tesnim Farhat[2], Khouloud Chaabi[3], Hichem Aouina[3], Zohra Hadj Ali[1], Yosra Htira[1] & Ben Mami Faika[1]
[1]The national institut of nutrition of Tunis, Department C, Tunisia; [2]Nutrition studies university, Tunisia; [3]Charles Nicole Hospital, Tunisia

Introduction
The influence of diet on asthma outcomes is of growing interest. The aim of our work is to assess the nutritional intake of a population of patients followed for asthma.
Methods
This was a cross-sectional descriptive study conducted over a 2-month period. It concerned all asthma patients who presented to the consultation for follow-up of their disease, having benefited from an interrogation, a somatic examination and a dietary survey.
Results
The study involved 40 asthmatic patients with a mean age of 46.15 ± 14.13 years and a sex ratio of 0.25. Mean weight was 75.9 ± 12.6 kg with a mean BMI of 29.1 ± 5.7 kg/m^2;. Mean spontaneous caloric intake was 1938.20 ± 753.35 kcal/day, with 67.5% of the study population having a caloric intake in excess of their mean energy requirement estimated by calculating basal metabolic rate and physical activity level at 1714.54 ± 420.30 kcal/day. Average daily carbohydrate intake was 246.84 ± 110.43 g/day, as 29.22 ± 8.90% of total energy intake (TEI). Protein intake was 75.50 ± 31.77 g/day, as 15.63 ± 4.35% of TEA. Fat intake was 62.56 ± 31.08 g/day, as 51.43 ± 10.07% of TEA. Ten percent of the population had higher protein and fat intakes than established recommendations. While 22.5% of the population had a carbohydrate intake higher than recommended. Average fiber intake was 22.61 ± 8.42 g/day. In terms of daily water consumption, 60% of the population consumed less than 1.5 l.
Conclusion
The results of our study highlight worrying eating habits. It is vital to make asthma patients aware of the importance of a balanced diet and a healthy lifestyle, in order to minimize the risks associated with obesity and improve asthma control.

Differences in the nutritional status and cardiac function between type 2-diabetes and non diabetes patients with heart failure

Carlos Manuel Alzás Teomiro, Ana María Moyano Sánchez, Mireia Isabel García Ramírez, Concepción Muñoz Jiménez, Ángel Rebollo Román & Aura D. Herrera Martínez
Reina Sofía University Hospital, Endocrinology and Nutrition

Backround and objectives
Heart failure (HF) has a rising incidence and is one of the most prevalent diseases worldwide. The number of patients with type 2 diabetes (T2DM) with heart failure is very high. Serum NT-proBNP and systolic ejection fraction correlate with the severity and prognosis of this condition. The nutritional evaluation of patients with HF, who usually have normal weight, overweight or obesity, has acquired a novel approach due to the incorporation of novel techniques (bioelectrical impedance, nutritional ultrasonography), and functional tests. The main objective is to evaluate the relation between nutritional parameters and clinical outcomes in patients with HF and check the possible differences in the ones affected with T2DM.
Methods
Patients with at least one hospital admission during the previous year were included. Anthropometric, biochemical, ultrasound, cardiac and functional tests were collected. Statistical analysis was performed with SSPS v.24.
Results
Thirty-eight patients were included (72.2% males). 44.4% patients of the sample presented diabetes at the moment of inclusion (100% T2DM). During the previous 12 months, patients affected with T2DM required more hospital admissions due to heart failure when compared to the ones without T2DM. Mean systolic ejection fraction measured by echocardiogram in T2DM patients was lower than the ones with no T2DM (39.5 vs 34.9%, $P > 0.05$), and serum NT-proBNP levels were higher (4950.13 vs 9513.37, $P > 0.05$). T2DM patients of the sample tended to have a higher lean mass and lower fat mass percentage measured by bioelectrical impedance than the no T2DM, and showed a higher phase angle (5.47 vs 4. 93º, $P > 0.05$). T2DM also presented lower results in hand grip dynamometer in both dominant and non-dominant arms. Nutritional biochemical parameters showed that T2DM patients had a better control of LDL colesterol and trglycerides than no T2DM patients.
Conclusions
T2DM is associated with worse clinical outcomes in patients with heart failure. Routine nutritional evaluation and early nutrition intervention, if required, should be implemented in order to improve the clinical outcome in these patients. Prospective, interventional studies should be performed.

Regulation of Kv2 potassium channel expression in pancreatic β cells in a rat metabolic syndrome model induced by arsenic and sucrose

Alberto Aguirre Ponce[1], Juan Pablo Pánico[2], Marcia Hiriart[1] & Myrian Velasco Torres[1]
[1]Instituto de Fisiología Celular, Neurociencia Cognitiva, Ciudad de México, Mexico; [2]Institute of Biomedical Research, Ciudad de México, Mexico

Metabolic syndrome (MS) is a group of signs that increase the risk of developing cardiovascular diseases and type 2 diabetes mellitus (DM2). MS includes at least 3 of these signs: central obesity, dyslipidemia, hypertension, fasting glucose disorders, and insulin resistance. The consumption of sugar drinks, a high-calorie diet, a sedentary lifestyle, and environmental pollutants such as arsenic increase the risk of developing MS. Arsenic affects beta-cell function and insulin secretion. This study aimed to evaluate the effect of SM induced by the additive effect of sucrose and arsenic on the expression Kv2 potassium channels (Kv2.1 and Kv2.2) in pancreatic islets. Male Wistar rats were treated with water (C), 20% sucrose (S), 50 mg/l sodium arsenite (A), or both (A + S) in drinking water for 8 weeks. We assessed the abundance of proteins by Western blot and expression genes for Kv2 channels by real-time qPCR. Previous work in our laboratory showed that S, A, and A + S groups developed hyperinsulinemia. However, only group A showed a reduction in Kv2 potassium current. In this work, we observed that the arsenic treatment decreased the abundance of the Kv2.1 channel but not of the Kv2.2 channel. However, the *Kcnb1* gene expression didn't change. Interestingly, there were no changes when the animals were treated with sucrose and arsenic. In conclusion, arsenic produces hyperinsulinemia through the abundance of proteins for the Kv2.1 channel.

Moringa oleifera and hypoglycemia: the causal link!

Talbi Dounia, Sebbar Ghizlane, Rifai Kaoutar, Hinde Iraqi & Gharbi Mohamed El Hassan
Ibn Sina University Hospital, Endocrinology, Morocco

Introduction
Moringa oleifera (MO) (also known as 'drumstick') is a tree belonging to the family Moringaceae, genus Moringa, originally native from the Himalayans but currently cultivated in many tropical and subtropical regions around the world. It has been used as a food source and for traditional medicine purposes due to possible antihyperglycemic, antioxidant, anti-inflammatory, and lipid regulating properties, and have been reported earlier by different scientific groups using animal models.
Case Report
44 year old patient, chronic haemoldialysis since 2017 for nephropathy of undetermined aetiology. Has been reporting hypoglycemia at 0.4 g/l for 3 months, with no disturbance of consciousness. His history includes regular intake of moringa leaves, coinciding with the onset of hypoglycemia. The Hypoglycemia assessment was negative, and the abdomino-pelvic CT scan did not reveal a pancreatic mass. The evolution was marked by the disappearance of hypoglycemia after moringa was stopped.
Discussion and Conclusion
The tree Moringa oleifera (MO) MO has been used in traditional medicine for the treatment of various conditions and, more recently, has been proposed to be of benefit in numerous diseases including cardiovascular, diabetes, cancer, neurological, gastroenterological, and inflammatory. MO aqueous leaf extract has been shown to inhibit the activity of α-glucosidase, pancreatic α-amylase, and intestinal sucrose, contributing to antihyperglycemic properties. These inhibitory effects are possible thanks to phenols, flavonoids, and tannins present in MO. A delay in carbohydrate digestion, caused by the inhibition of these enzymes, leads to a reduction in post-prandial hyperglycemia and hemoglobin A1C (HbA1C). These inhibitory effects of flavonoids, including quercetin and kaempferol, have been biochemically explained due to an increase in the number of hydroxyl groups on the B ring, and to the presence of a 2,3-double bond. In addition, these compounds have been studied regarding protective and regenerative properties on pancreatic beta-cells, augmenting insulin production and release. However, the hypoglycemic effects of MO on humans are not as clear given the scarce number of human studies, together with a diverse range of methodologies and MO doses. Therefore, more structured studies are needed to clarify if MO has an effect on insulin levels or activity.

Audit on initial assessment of hyponatraemia in hospitalised patients and it's subsequent outcome

Kavinga Kalhari Kobawaka Gamage[1], Rachel Livingstone[2], Natasha Steven[2], Sophie Edwards[2], Daniel Slack[2] & Neil McGowan[2]
[1]Sheffield Teaching Hospitals NHS Foundation Trust; [2]NHS Greater Glasgow and Clyde

Introduction
Hyponatraemia is the commonest electrolyte disturbance encountered in the clinical practice. However, its initial evaluation is commonly found inadequate. We conducted a retrospective audit on evaluation of inpatient hyponatraemia in a large district general hospital.
Study methodology
Retrospective data of patients admitting with or who developed moderate to severe hyponatraemia during the hospital stay were collected over 4 week's period (1st to 28th of July 2023). Out of them, 84 randomly selected patients' clinical records were assessed regarding initial evaluation.
Results
Eighty-four cases with moderate to severe hyponatraemia were identified and included in the study. 38 (45.2%) were male and 55 (65.4) % were above 65 years old. Patients with age range from 27 years to 92 years were included. 68 (80.9%) had hyponatraemia on admission while rest had hospital acquired hyponatraemia. Severe hyponatraemia was found only in 3 (3.5%), while the rest had moderate hyponatraemia. Serum osmolality, urine osmolality and urine sodium were documented in 26(30.9%), 12 (14.2%), 9 (10.7%) respectively. 16 (19%) had hypotonic hyponatraemia, however volume status was documented only in 11 out of the above 19 patients and only 4 had fluid balance charts maintained. Out of the patients with hypotonic hyponatraemia 9 (56%) had their cortisol levels done and hypothyroidism was excluded in 10 (62.5%) despite the unavailability of rest of the investigations such as urine osmolality or urine sodium. Out of the 3 patients with severe hyponatraemia, only one had osmolality studies available. 14(16%) of hyponatraemic patients succumbed to death during the same admission.
Conclusions
Hyponatraemia is a frequently occurring condition associated with high mortality rates. However, it is evident that the initial evaluation remains insufficient despite the widespread availability of guidelines. Therefore, it is necessary to take steps to improve the initial investigation process.

Unpredicted diagnosis of type 1 diabetes after delivery

Mohamed Khairi Arous, Najla Bchir, Anaam Ben Chedida, Chadia Zouaoui & Haroun Ouertani
The Military Hospital of Tunis, Endocrinology, Tunis, Tunisia

Introduction
Gestational diabetes mellitus (GDM) is a common and increasing complication, concerning 2–17% of pregnancies [1]. This glucose intolerance often resolves after delivery, and rarely becomes permanent type 2 diabetes, exceptionally type 1 diabetes (T1D). We present a case of a patient with GDM, which unexpectedly revealed T1D.
Case report
A 33-year-old woman consulted for GDM. Her family medical history includes hypothyroidism in her maternal aunt and psoriasis in her daughter. Our patient has had two COVID-19 infections. During her first pregnancy, she had gestational hypertension but no history of GDM or macrosomia. Prior to her pregnancy, the patient had a BMI of 30.8 kg/m^2;. Her GDM was diagnosed at 26 weeks' amenorrhoea through systematic screening. The patient had no previous carbohydrate assessment. Dietary management was sufficient to achieve glycemic targets for the rest of the pregnancy. Maximum weight was 82 kg. Five months after delivery, our patient lost 5 kilograms in 2 weeks. The glycemic cycle was between 0.86-2.02 g/l and HbA1C at 8.1%. The patient benefited from a basal insulin regime as she was breastfeeding. The evolution was marked by an increase in glycemia with the appearance of a polyurea-polydipsic syndrome despite insulin therapy, reaching a plateau of 2.5-3 g/l. Diabetes antibodies were requested (after 9 months postpartum), and were positive: Anti-GAD65 = 18.84 IU/ml, anti-IA2 = 88 IU/ml confirming T1D.
Discussion and conclusion
Our patient presented with a picture typical for T2DM. T1DM was unlikely given the good response to dietary management. The predictive factors for T1DM in patients with GDM are the presence of diabetes-related autoantibodies, which is the main factor, age < 30 years, the need for insulin treatment, and multiparity. The familiar history of autoimmunity should raise the possibility of T1D, even

with such an atypical metabolic phenotype. Some studies have assessed phenotypic traits associated with autoimmunity among women with gestational diabetes: a lower BMI, a lower waist measurement, a lower weight gain during pregnancy, which was the case of our patient, and lower fasting insulin levels. Most studies identified an increased risk for many autoimmune diseases among patients with COVID-19. The explanation for our patient would be a partial and slowly progressive autoimmune destruction of pancreatic β cells, during pregnancy. In fact, many autoimmune diseases go into remission during pregnancy secondary to natural immune tolerance.

The influence of age on the morpho-constitutional characteristics of urolithiasis in diabetic patients in southern tunisia

Ines Mezghani, Aida Elleuch, Mouna Turki & Fatma Ayedi
Habib Bourguiba University Hospital, Laboratory of biochemistry, Sfax, Tunisia

Background-Aim
Urolithiasis is a frequent and recurrent pathology. Diabetes has a very important role in the formation of kidney stones. The objective of our study was to study the influence of age on the morpho-constitutional characteristics of urolithiasis in diabetic patients in southern Tunisia.
Methods
This is a mono-centric retrospective and descriptive study of urinary lithiasis cases in diabetic patients. The lithiasis were identified by the morpho-constitutional study, they were collected in the Laboratory of biochemistry, during the period from January 2011 to December 2020. We were interested in diabetic patients over the age of 18. To study the influence of age, we subdivided our diabetic lithiasis patients into 2 groups: Group1 (G1): group of diabetic lithiasis patients with an age less than 59 years. Group 2 (G2): group of diabetic lithiasis patients having an age more than or equal to 60 years.
Results
Our study involved 76 stones which represents 7.08% of all urinary stones analyzed during the study period. Our patients were aged from 33 to 85 years. Sex ratio = 2.16. Nephritic colic was the most common discovery circumstance (44.8% for G1and 61.3% for G2). Renal localization was the most frequent (58.6% for G1 and 58.1% for G2) followed by the ureter(37.9% for G1and 29% for G2). The notion of recurrence was present in 31% of G1 patients and 38.7%of G2 patients. The constitutional study of the calculi showed that oxalocalcic lithiasis was the major component of the calculi for the two groups:the C1 monohydrate type was the most frequent in 36.7% and 42.9% of the cases (respectively for G1 and G2), followed by the mixed type (C1 + C2):10% and 14.3% (respectively for G1 and G2) and the dihydrate type C2 (3.3 and 3.6% respectively for G1 and G2). Purine lithiasis represented by pure purines (6.7% and 25% respectively for G1 and G2) and mixed purines (23.3% and 14.3% respectively for G1 and G2), followed by phosphocalcium lithiasis (20% for G1and no patient for G2). The difference by age was not significant for the different stone types.
Conclusions
The influence of age on the morpho-constitutional characteristics of urolithiasis in diabetic patients in southern Tunisia were comparable to those reported in many countries. The modifications are generally due to the expression of nutritional disorders and metabolic modifications linked to cellular aging

Not all ketosis is type 1 diabetes - think of flatbush

Sarah Craus[1], Abigail Mula[1] & David Coppini[2]
[1]Mater Dei Hospital, Malta; [2]University Hospitals Dorset NHS Trust

A 35 year old otherwise healthy gentleman from Togo, was referred to our clinic with new onset diabetes and a glycated haemoglobin (Hba1c) of 119mmol/mol (13.1%). He initially presented to his general practitioner with polyuria and polydipsia, and 5 kg of weight loss. He denied any change in bowel habit and had no recent illnesses. Both parents had Type 2 Diabetes Mellitus (T2D). Initial blood tests revealed a blood glucose of 22.84 mmol/l, with positive ketones (1.2 mmol/l). Urinalysis showed glycosuria (1000 mg/dl) but was negative for nitrites and white cells. Renal, liver and thyroid function tests were all within normal limits. In addition, the patient had mild metabolic acidosis (Table 1). The markedly elevated blood glucose levels in association with ketoacidosis strongly suggested a diagnosis of Type 1 Diabetes Mellitus (T1D). The patient was admitted to the diabetes ward and treated with a fixed rate insulin infusion as per diabetic ketoacidosis (DKA) protocol. There was a fairly rapid improvement in both hyperglycaemia and ketonaemia within a few hours. Anti-glutamic acid (GAD), anti-insulinoma antigen 2 antibodies (IA2) and anti-insulin antibodies were all negative. The next day, the patient was discharged on a basal bolus regime of glargine and aspart after review by the inpatient diabetes team. The patient continues with regular clinic reviews. His glucose levels continued to improve with incremental insulin dose reductions and he remains on low dose metformin (500 mg daily), with normalisation of his Hba1c after 6 months.
Conclusions
A rapid response to insulin, negative testing for type 1 autoimmunity, in a young gentleman of African origin, suggested a diagnosis of ketosis prone/Flatbush diabetes was most likely. The aetiology of ketone-prone diabetes remains unknown. Further studies may help future therapies. A diagnosis of ketosis prone diabetes should always be borne in mind in patients of African ethnicity presenting with new onset diabetes and ketosis. Misdiagnosing patients with KPD as T1D can lead unnecessary treatment with long-term insulin therapy, with all its implications (e.g. hypoglycaemia, occupational impact).

Table 1 Initial investigations

	On admission	Reference range
Glucose	22.84	
Creatinine (umol/l)	48	59-104
Urea (mmol/l)	5.4	1.7-8.3
Sodium (mmol/l)	130	135-145
Potassium (mmol/l)	4.07	3.5-5.1
Hba1c (mmol/mol)	119	28-46
Venous Blood Gases		
pH	7.34	7.35-7.45
pCO2 (kPa)	5.5	5.1-5.6
pO2 (kPa)	6.2	10.5-13.5

Bacteriological and mycological profile of necrotizing otitis externa in diabetics

El Omri Malika[1], Jemli S[1], Bellakhdher Mouna[1], Meherzi Abir[1], Houas Jihene[1], Ghammem Monia[1], Ach Taieb[2], Kermani Wassim[1] & Abdelkefi Mohamed[1]
[1]ENT Department Farhat Hached Hospital, Sousse, Tunisia; [2]Endocrinology Department Farhat Hached Hospital, Sousse, Tunisia

Introduction
Necrotizing otitis externa (NOE) is a rare but serious condition which is mainly seen in diabetics. This condition has a poor prognosis, due to the complexity of the terrain in which it occurs. The aim of our work is to study the clinical, paraclinical and therapeutic data of NOE.
Material and methods
This is a retrospective study covering 64 cases followed and treated in our ENT department over a period of 12 years between 2000 and 2022.
Results
Our serie includes 29 women and 33 men, with an average age of 67 years, 90% of our patients were diabetic. The bacteriological sample isolated *Pseudomonas aeruginosa* in 54% of cases. Culture was negative in 19 samples; among the latter, 10 cases had a mycotic origin. The temporal computed tomography scan performed for all patients was in favor of NOE in 22 cases and showed an extension of the infection in 29 cases. Fluoroquinolone was prescribed in all cases associated with a Cephalosporine 3rd generation (C3G) in 58 cases, and a C3G with Metronidazole in 6 cases. The treatment was revised in 15 patients, 9 patients had fungal involvement, 4 patients developed resistance to Ceftazidine and 2 cases were allergic to Ceftazidine. The total duration of antibiotic treatment was on average 54.43 days. Healing was achieved in 98.4%.
Conclusion
The bacteriological profile of NOE in diabetic patients a is predominated by the presence of *Pseudomonas aeruginosa* and characterized by the emergence of mycotic infections nowadays.

Type 1 diabetes: Diagnosis rectified years after treatment with oral hypoglycemic drugs

Mohamed Khairi Arous, Najla Bchir, Roua Mankai, Anaam Ben Chedida, Chadia Zouaoui & Haroun Ouertani
The Military Hospital of Tunis

Introduction
Type 1 diabetes (T1D) is a progressive autoimmune disease, the diagnosis is obvious in classic forms. However, misleading forms are possible, sometimes leading to inappropriate treatment. We report the case of two type 1 diabetic patients who were treated for years with oral hypoglycemic drugs.
Case report
Patient 1: Mr. M, aged 34, with a family medical history of type 2 diabetes (T2D), was diagnosed with diabetes revealed by a polyurea-polydipsic syndrome (PPS), 8 years ago, without acute decompensation. He was treated with oral dual therapy: glimiperide 2 mg and metformin. He recently consulted for unintentional weight loss of 3 Kg in 3 months with non-controlled diabetes: fasting plasma glucose (FPG) = 10 mmol/l, glycated hemoglobin (HbA1C) = 10.7%. Biology showed peptide C = 1.06 ng/ml, anti-GAD65 antibodies were negative but anti-AI2 antibodies were positive at 28 IU/ml ($^n < 8$), confirming autoimmune T1D. Patient 2: Mr. N, aged 34, with no previous medical history, was diagnosed with diabetes revealed by PPS with no weight loss or acute decompensation. His BMI was 25.05 kg/m^2; and biology showed an HbA1C = 12%. The patient received oral dual therapy: glimepiride 2 mg/d and metformin. At 6-month follow-up, PPS disappeared and HbA1C fell to 6.7%. The patient described occasional hypoglycemia, leading us to decrease the dose of glimiperide to 1 mg/day. HbA1C has remained stable at around 7.5-8.5% for 5 years, then rose sharply to 12%, associated with weight loss. Increasing the dose of glimepiride was ineffective. We asked for anti-GAD65 antibodies, which were markedly positive at 1625 IU/ml ($^n < 10$), thus indicating T1D.
Discussion and conclusion
T1D is easy to diagnose in the presence of abrupt onset, inaugural ketosis, and young age, especially in the presence of autoimmune stigmata. The absence of these elements makes T1D unlikely. The diagnosis was more diverted by the clinical-biological improvement with oral hypoglycemic drugs for years, classically incompatible with T1D. This equilibrium would be explained by the autoimmune destruction, slowly progressive and incomplete, of the beta cells of the islets of Langerhans. This persistent insulin secretory capacity, enabled good glycemic balance to be achieved for a while. Reascension of glycemic parameters reflected an utter decline in pancreatic beta cells. Although T2D is increasingly seen at a younger age, the diagnosis of diabetes at an age <35 should raise the possibility of T1D.

Hyperuricemia predictive factors among type 2 diabetes mellitus patients

Wafa Ben Hilel, Ramla Mizouri, Skander Msolly, Faten Mahjoub, Rym Ben Othman, Nadia Ben Amor, Olfa Berriche & Jamoussi Henda
National Institute of Nutrition, Tunis, Tunisia

As type 2 diabetes mellitus (T2DM) is a metabolic disorder, it frequently poses challenges for patients in metabolizing uric acid, resulting in hyperuricemia (HUA). In this study, our objective is to investigate the risk factors of HUA among T2DM patients.
Method
Patients with T2DM who were attended in the National Institute of Nutrition in Tunis, Tunisia, between August and November 2023 were included in this retrospective observational study. Diagnosing HUA was based on sound diagnostic criteria (i.e. SUA of greater or equal to 420 mmol/l and 360 mmol/l for male and female respectively). Patients younger than 18 years old, effected by another type of diabetes, pregnant women, patients undergoing urate-lowering therapy or taking medications that affect blood uric acid levels, suffering from a serious liver or kidney damage or chronic heart failure were not included in the study.
Results
A total of 131 T2DM patients were included: 23 in the HUA group and 108 in the non-HUA group. In simpler terms, the prevalence of HUA among patients with T2DM was 17.5%. The mean ages of the non-HUA group and the HUA group were 60.3 ± 9.5 and 66.3 ± 9.5 respectively. the sex ratios (female/male) were respectively 1.8 and 1.3. The average diabetes duration of the non-HUA group and the HUA group was 13.5 ± 5.5 and 15.1 ± 6 respectively. Participants with HUA were older and more likely to have hypertension ($P < 0.01$). Additionally, there were higher values of body mass index, creatinine, triglycerides and gamma-glutamyl transferase (GGT) in the HUA group compered to non-HUA group ($P < 0.5$) but lower values of high-Density Lipoprotein cholesterol (HDLc) ($P < 0.05$). Findings did not reveal any notable difference in other indicators including sex, diabetes complications, diabetes duration, HbA1C, total cholesterol, low-Density Lipoprotein cholesterol (LDLc), aminotransferases (SGAT, SGPT) and albumin between HUA group and non-HUA group ($P > 0.05$).
Conclusion
Our study indicates HUA occurrence among patients with T2DM and establishes independent risk factors associated with HUA, suggesting promising potential for early detection and diagnosis of HUA in T2DM patients.

Involvement of social networks in the education of young people with type 1 diabetes

Sofia Ouhessaine, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
Endocrinology, Diabetology, Nutrition and Metabolic Diseases Department Ibn Rochd University Hospital of Casablanca, Morocco Neurosciences and Mental Health Laboratory Faculty of Medicine and Pharmacy-University Hassan II-Casablanca-Morocco

Introduction
Diabetes is one of the most complex chronic health conditions of our time. Daily management of the disease as well as its acute and chronic complications requires a certain level of education; social media could play a role in disseminating appropriate information.
Objectives of the study
Evaluated the involvement of social media in the education of young people with type 1 diabetes.
Material and methods
Descriptive cross-sectional study, carried out at the endocrinology department-diabetology at Ibn Rochd University Hospital of Casablanca, of interest to young type 1 diabetics followed at the transition consultation. Results: Our study included 54 patients. The average age was 16.2 years with a female predominance of 62%. The duration of diabetes was 7.93 ± 4.02 years. Mean HBA1c = $11.19 \pm 2.12\%$). 95% of our patients said they go to social media looking for information about their illness. The most searched subjects were: complications of diabetes in 67%, therapeutic perspectives in 45%, the pathophysiology of diabetes in 35%, diabetes and physical activity in 40%, the impact of diabetes on fertility in 16%. Our patients judged that the information acquired on social networks was useful in 89%.
Conclusions
Social media is widely used nowadays, and provides a valuable digital education tool providing an opportunity for medical staff to support diabetic patients by disseminating useful and authentic knowledge and information related to diabetes management and of its complications.

EP788

Twists and turns of diabetology – immune checkpoint inhibitor-mediated diabetes

Ana Majic Tengg[1] & Tanja Palaversa[2]
[1]Clinical Hospital Dubrava, Department of Endocrinology, Diabetes, Metabolic Diseases and Clinical Pharmacology, Zagreb, Croatia; [2]Levanger Hospital, Department of Medicine, Levanger, Norway

Introduction
Immune checkpoint inhibitors (ICIs) have revolutionized oncological treatment and substantially improved a prognosis for patients with advanced malignancy. ICIs inhibit the immunological pathways controlling T-cell activation or anergy. The most frequently used classes of ICIs are those that targeted and inhibit cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), programmed cell death receptor 1 (PD-1) or its ligand PD-L1. The initiation of ICIs therapy is often associated with immune-related adverse events that can lead to destruction and permanent loss of function of various tissues, including the endocrine glands, with the thyroid gland being the most commonly affected. The overall incidence of ICI-induced diabetes mellitus ranges from 0.4% to 2%, resembling type 1 diabetes. It is characterized by the acute onset of hyperglycaemia with severe

insulin deficiency and diabetic ketoacidosis very frequent at diagnosis. Autoantibodies and HLA genotypes associated with type 1 diabetes are often present. The standard treatment mode is a multiple insulin injection regimen.
Case presentation
A 71-year-old woman was admitted to the emergency department due to hyperglycaemic hyperosmolar syndrome, metabolic acidosis, and diarrhoea. Prior to admission, she had received eight cycles of nivolumab therapy for metastatic skin melanoma, and had been on glucocorticoid therapy for more than 10 years due to seropositive rheumatoid arthritis. She had no history of diabetes. Upon assessment, she was found to have severe hyperglycaemia [plasma glucose level of 55.2 mmol/l (993.6 mg/dl)] with positive urine ketones, acute renal insufficiency (urea level of 17.0 mmol/l, creatinine level of 269 umol/l), and hyperkalaemia (potassium level of 6.6 mmol/l). HbA1c was 9.4% (79 mmol/mol). She was treated per standard-of-care fluid resuscitation and insulin infusion protocols, and discharged as fully recovered to the outpatient diabetes clinic with basal insulin, a DPP-4 inhibitor, and repaglinide. During the follow-up visit, the glycaemic control was unsatisfactory with high glycaemic variability, and ICI-induced diabetes was suspected. Additional laboratory examinations showed immeasurable C-peptide level of < 0.02 nmol/l (normal range: 0.27 – 1.28) while GAD, ICA, and IA-2 autoantibodies were negative. A multiple insulin injection regimen was initiated, and glycaemic control significantly improved.
Conclusions
ICI-related diabetes is a rare but often life-threatening condition. As the increasing number of patients will be exposed to ICIs, healthcare professionals and patients should be aware of ICI-mediated endocrinopathies, with the regular monitoring of plasma glucose level being a part of comprehensive care for all patients treated with ICIs.

Prevalence and characteristics of chronic obliterating arteritis of the lower limbs in a population of patients with type 2 diabetes

Nesrine Dhieb, Chaima Jemai, Maryam Cheikhrouhou, Chaima Sdiri, Zohra Hadj Ali, Olfa Lajili, Yosra Htira & Faika Ben mami
National Institute of Nutrition, Department C, Tunis, Tunisia

Introduction
Chronic obliterating arteritis of the lower limbs is common in patients with type 2 diabetes (T2D). Our aim was to determine the prevalence and characteristics in a tunisian population.
Methods
This was a cross-sectional study including 100 patients with T2D hospitalized in department C of the national institute of nutrition of Tunis. For each patient, we carried out a physical examination, we measured the systolic pressure index (SPI) and we retrieved biological parameters from medical records.
Results
Average age was 57.20 ± 8.48 years. Women made up 74% of the population. 29% were smokers. Diabetes mean duration was 14.79 ± 4.55 years. All patients were treated with insulin. The majority (70%) were on NPH insulin. Median BMI was 30.46 kg/m^2; with extremes of 22.5 and 38.28 kg/m^2. Mean HbA1C was 10,33% with extremes of 8 and 12%. Ischemic coronary artery disease and stroke was frequent by 10% and 3% respectively. The mean IPS was 0.86 ± 0.12, with extremes of 0.4 and 1. The median value was 0.8. 18% of our population had chronic obliterating arteritis of the lower limbs. It was predominant in men (66.6%). All of these patients had hypercholesterolemia. Associated factors were smoking ($P = 0.03$), BMI ($P = 0.008$) and diabetic peripheral neuropathy ($P < 0.001$).
Conclusion
Chronic obliterating arteritis of the lower limbs constitutes a risk factor for the development of diabetic foot ulcers. Early screening, smoking cessation and weight reduction to prevent this complication of reserved prognosis.

Management of chronic diseases in elderly diabetics

Mouna Elleuch, Wissal Ghamgui, Dhouha Ben Salah, Lilia Affes, Mouna Mnif, Ftama Mnif, Nadia Charfi, Feten Hadj Kacem, Nabila Rekike & Mohammed Abid
Hedi Chaker Hospital, Sfax, Tunisia

Introduction
Tunisia is a country classified as high cardiovascular risk with a population tending towards aging and the appearance of chronic diseases.
Objective
Analyze the management of chronic diseases in elderly subjects with type 2 diabetes (T2DM)
Material and methods
This is a retrospective study of T2D patients hospitalized in the endocrinology-diabetology department of Hedi Chaker Sfax University Hospital between January and March 2023.
Results
We included 50 patients, with a median age of 69.5. The sex ratio (F/M) = 1.7. The associated diseases were hypertension (74%) and hyperlipidemia (70%). The average number of tablets was 6.75 ± 3 tablets/day. For diabetes, the treatment regimen includes oral antidiabetics (OADs) exclusively in 52% of cases, insulin in 26% of cases and mixed treatment in 22% of cases. Only 12% met the glycated hemoglobin targets (mean HbA1c = 10.81 ± 2.74). For hypertension, 68% were on ACE inhibitors, 34% on calcium channel blockers, 20% on diuretics and 18% on ARA2. Hypertension was uncontrolled in 68% of patients. For dyslipidemia, 68% of patients were placed on statins. LDL targets were not achieved in 76% of diabetic patients.
Discussion
We deduce that the elderly in Tunisia require intensification of education on hygienic and dietary rules and encouragement for the prescription of medicinal combinations.

Interrelation of TNF-α concentrations with the onset and progression of diabetic complications

Elvira Ibragimova[1], Talat Saatov[1], Timur Alimov[1,2], Sanobar Irgasheva[1,3], Tokhir Ishankhodjaev[1], Gulnora Artykbaeva[1], Nigora Maksutova[4], Abdunabi Tashtemirov[1] & Zulaykho Shamansurova[1,5]
[1]Institute of Biophysics and Biochemistry, Mirzo Ulugbek National University of Uzbekistan, Tashkent, Uzbekistan; [2]Republican Specialized Scientific Practical Medical Center of Hematology and Blood Transfusion, Uzbekistan Public Healthcare Ministry, Tashkent, Uzbekistan; [3]Alfraganus University, Tashkent, Uzbekistan; [4]Ya. Kh. Turakulov Center for Scientific and Clinical Study of Endocrinology, Uzbekistan Public Healthcare Ministry, Tashkent, Uzbekistan; [5]Central Asian University, Tashkent, Uzbekistan

As a cytokine, TNF-α plays a role of key anti-inflammatory mediator involved in the onset and progression of insulin resistance and type 2 diabetes mellitus. TNF-α is known to inhibit insulin-stimulated of auto-phosphorylation of insulin receptors by tyrosine kinase; as the result, insulin sensitivity decreases in its turn resulting in insulin resistance and glucose transport damage. TNF-α is a trigger in the onset of obesity, diabetes mellitus and its complications. Studies on concentrations of TNF-α in peripheral blood are of high importance in assessment of extent in type 2 diabetes mellitus progression.
Materials and methods
68 patients with type 2 diabetes mellitus, 50 persons with diabetic neuropathy of various degrees and 18 persons without any 2DM complications among them, were examined. Non-diabetics were included into the control group. ELISA was used to determine TNF-α concentrations in the blood serum of the examinees.
Results
Determination of TNF-α concentrations in blood serum of the examinees demonstrated their significant increase as compared to those in the non-diabetics (3.05 ± 0.44 vs 1.1 ± 0.05 pg/ml). In patients with moderate diabetic neuropathy, the serum concentrations of TNF-α turned out significantly lower than those in patients with severe disease (3.62 ± 0.89 vs 7.13 ± 1.14 pg/ml). Thus, paralleling disorders in carbohydrate and lipid metabolism in 2DM, concentrations of TNF-α in blood serum of the patients were found to be in direct dependence with the disease severity.

Damages of the central and peripheral nervous systems as peripheral neuropathy and encephalopathy of mixed vascular and metabolic genesis, respectively, are known to take place in diabetes mellitus, ultimately resulting in progressing decline of cognitive function and development of dementia. Findings of many studies demonstrated interrelation between increases in the TNF-α concentrations and onset of inflammation, tumor processes and a number of metabolic, autoimmune and neurodegenerative disorders. The work was initiated to compare the TNF-α concentrations in the blood of serum of patients with type 2 diabetes mellitus and neurodegenerative disorders.
Methods and materials
115 persons were included into the experimental group, 50 patients with diabetic neuropathy, 50 patients with vascular dementia and 15 patients with Alzheimer's disease among them. The control group included the non-diabetics and those without cognitive disorders. Concentrations of TNF-α in blood serum were measured using ELISA.
Results
Our findings demonstrated significant increases in concentrations of the cytokine both in patients with type 2 diabetes mellitus and those with Alzheimer's disease, in contrast to the non-diabetics and people with normal cognitive function. Type 2 diabetes mellitus complications including diabetic neuropathy progressed, the TNF-α concentrations were found to significantly increased in blood serum of patients; the concentrations of the cytokine being significantly higher than those in patients with neurodegenerative disorder. This could be the evidence for the more severe effect of inflammatory load on an organism upon progression of type 2 diabetes mellitus. Comparison of the TNF-α concentrations in blood serum of patients with vascular dementia of various severities helped find significant differences ($P<0.05$) in the parameter. The disease progresses, concentrations of the cytokine increase twice. Comparison of the TNF-α concentrations in blood serum of patients with vascular dementia and in those with Alzheimer's disease demonstrated no significant differences ($P>0.05$). Thus, comparison of TNF-α concentrations in groups of patients under study as compared to healthy subjects demonstrated significant increases in the concentrations of the cytokine in both patients with type 2 diabetes mellitus and those with neurodegenerative disease.

An extream case of malabsorption in a patient with type 1 diabetes and celiac disease

Dorsaf Ben Salem, Chaima Jemai, Yasmine Fakhfekh, Yosra Ben Hmida, Chaima Sdiri, Mohamed Bacha, Sami Fitouri, Olfa Lajili, Zohra Hadj Ali, Yosra Htira & Faika Ben Mami
National institute of nutrition of Tunis, C

Introduction
Type 1 diabetes and celiac disease are two autoimmune pathologies that frequently coexist. This association implies specific nutritional management whose application by the patient is not always simple. We report An extream case of malabsorption in a patient with type 1 diabetes and celiac disease.
Case presentation
This was the case of a 34-year-old with type 1 diabetes (T1D), celiac disease and vitiligo evolving since 13, 7 and 2 years respectively. She reported poor socio-economic conditions and no compliance with insulin therapy and gluten-free diet. Her weight and height were of 52.4 kg and 154 cm respectively, i.e. a BMI of 22.1 kg/m^2. On impedancemetry, her body composition was characterized by a fat mass of 29.2%. Her total energy intake was hypocaloric (TEI) (1931.6 cal/d), hypoglucidic (2.8 g/kg/d), hypolipidic (0.73 g/kg/d) and hypoprotidic (0.85 g/kg/d), according to WHO recommendation. Likewise, her diet was rich in high glycemic index carbohydrates (15.5% of TEI) and sodium (2195 mg/d), and poor in fiber (21.5 g/d), B12 vitamin (1.78 µg/d), calcium (617 mg/d), iron (7.6 mg/d) and potassium (2020 mg/d). Her diabetes was uncontrolled (HbA1C = 9.1%) and complicated by pathologic microalbuminuria (36.4 mg/24H) put on ACE inhibitors. She had no hypoglycemia. Her celiac disease was complicated by a malabsorption syndrom: She had chronic hypocalcemia (2.24 mmol/l) and chronic hypovitaminosis D, complicated with secondary hyperparathyroidism with Looser Milkman streaks on her pelvis x-ray, well tolerated microcytic hypochromic anemia (9.8 g/dl) due to iron deficiency (Ferritinemia = 6.65 ng/ml) and chronic hypolkaliemia (3.6 mmol/l). Liver test and TSH were normal. She was put on gluten-free diet and supplementation (calcium carbonate 500 mg 2 times a day, Ergocalciférol 2000UI/d, ferrous sulfate 80 mg 2 times a day, potassium chloride 600 mg/d and B 12 vitamin an injection of 1000 µg each month).
Conclusion
Managing the case of our patient was challenging. Multiple supplementation effectiveness is discussed given the risk of interaction between micronutrients. Likewise, their bioavailability is not guaranteed given the intestinal lesions of celiac disease. Total adherence to free-gluten diet remains the cornerstone of the treatment.

Prevalence of depression in type 2 diabetic patients and its impact on glycemic control

Rym Ben othman[1], Syrine Trabelsi[2], Yasmine Jallouli[3], Ramla Mizouri[1], Yosra Ben Hmida[2], Olfa Berrich[1] & Henda Jammousi[1]
[1]National Institute of Nutrition and Food Technology, Department A; [2]National Institute of Nutrition and Food Technology, C, Tunis; [3]National Institute of Nutrition and Food Technology

Introduction
Depression and type 2 diabetes are often associated, but until now their exact relationship has remained unclear. The aim of our work was to evaluate the prevalence of depression in type 2 diabetic subjects and to determine its impact on glycemic control.
Methods
This was a descriptive cross-sectional study conducted in the National Institute of Nutrition. We included 400 type 2 diabetic patients. To assess depression, we used the Hospital Anxiety And Depression Scale (HADS). A score of 11 or above was considered positive.
Results
The mean age of our patients was 59.19 ± 8.81 years. Female predominance was noted (67.5%). The mean age of diabetes was 13.31 ± 7.9 years, with a mean HbA1c of 10.03 ± 2.03% and fasting plasma glucose of 11.26 ± 4.81 mmol/l. The majority of patients had good medication compliance (82.3%), with 13.75% not accepting their diabetes. Obesity was present in 44.5% of subjects. The prevalence of depression was 36.8%. The presence of this psychological disorder was positively associated with female gender ($P<0.001$), obesity ($P=0.004$), diabetes duration ($P=0.012$), diabetes acceptance ($P=0.02$), diabetic retinopathy ($P=0.02$), peripheral neuropathy ($P=0.001$) and vegetative neuropathy ($P=0.03$).
Conclusion
The large number of diabetic patients with definite depression calls for systematic screening of all diabetics for this psychiatric disorder, for better management and quality of life.

EP801

Ramadan fasting prohibition among muslim individuals with diabetes: exploring cultural impacts on self-esteem

Abdel Mouhaymen Missaoui, Fatma Mnif, Siddiqa Soomauroo, Souhir Maalej, Rihab Khochtali, Mohamed Abid & Nabila Rekik
Hedi Chaker University Hospital, Department of Endocrinology, Sfax

Background and Aim
Besides its religious aspect, Ramadan Fasting (RF) represents a significant cultural affirmation practice for Muslim patients with diabetes. Despite the health risks related to this ritual, many Muslims with diabetes continue to fast against medical advice. This study aims to analyze the effect of RF contraindication on the self-esteem of Muslim patients with diabetes.
Methods
We conducted a cross-sectional study involving 25 Muslim patients with diabetes referred to the Department of endocrinology of Hedi Chaker University Hospital, Sfax, Tunisia, two months before Ramadan 2021. We stratified the fasting-related risk according to the 2021 IDF-DAR score. Rosenberg's self-esteem scale (RSES) was administrated immediately after announcing the medical decision about the possibility of fasting.
Results
The mean age was 58.7 ± 12.6 years, with a female predominance (78.3%). Hypertension (52.2%) and dyslipidemia (47.8%) were the leading comorbidities.

The mean duration of the evolution of diabetes was 10.9 ± 8.4 years, with an average A1C of 9.1 ± 1.7%. The mean 2021 IDF-DAR score was 5.5 ± 4 points. We stratified our patients into three risk categories:
- Low-risk patients (34.8%) who were allowed to fast.
- Moderate-risk patients (26.1%) who were discouraged from fasting.
- High-risk patients (39.1%) with a strict medical prohibition to fast.

The mean RSES was 30.7 ± 3.4 points. Lower self-esteem scores were recorded in the high-risk category (77.8%) compared with the moderate (50%) and the low-risk groups (50%). Higher self-esteem rates were observed in patients with low risk (50%), unlike those with moderate (12.5%) and high (0.0%) fasting-related risk ($P = 0.08$).

Discussion

The imposition of restrictions on certain community and cultural practices in response to medical considerations possesses the potential to exert a profound influence on the self-esteem and social integration of individuals grappling with diabetes. Recognizing the intricate interplay between health-related constraints and cultural identity underscores the imperative for healthcare providers to adeptly navigate the provision of culturally safe, patient-centered care. This nuanced approach ensures a holistic and sustainable health outcome for individuals navigating the intersection of medical considerations and cultural identity.

Ophthalmological complications in patients with diabetes and chronic kidney disease: a single center cohort study

Abdel Mouhaymen Missaoui, Fatma Mnif, Siddiqa Soomauroo, Hamdi Frikha, Souhir Maalej, Mohamed Abid & Nabila Rekik
Hedi Chaker University Hospital, Department of Endocrinology, Sfax

Background and Aim

Multiple studies support that chronic glycemic imbalance has deleterious effects on microcirculation. It is the central physiopathological factor in the development of chronic kidney disease (CKD) and several ophthalmologic complications in patients with type 2 diabetes mellitus (T2DM). This study aims to assess the peculiarities of eye complications in patients with diabetes and CKD.

Methods

We conducted a descriptive study including 88 patients suffering from T2DM and CKD who were admitted to the inpatient unit of the Endocrinology department of Hedi Chaker University Hospital between 2019 and 2020. Medical charts were reviewed retrospectively to identify the clinical, biochemical, and ophthalmological findings.

Results

The mean age was 68.7 ± 10.9 years old, with a male predominance (52.3%). A family history of diabetes (84.1%), hypertension (61.4%), and CKD (12.5%) were frequently reported. The average diabetes evolution was 13 ± 9 years. A glycemic imbalance was recorded in 80.2%. The mean A1C was 9.68 ± 2.5% in this population. The leading comorbidities were dyslipidemia (94.0%), hypertension (86.4%), and obesity (35.7%). The mean glomerular filtration rate (GFR) was 32.2 ± 13.81 ml/min. Patients who had reached advanced stages of CKD represent 43.2%. Macroalbuminuria was encountered in 52.2%. The main ophthalmologic conditions were diabetic retinopathy (DR) and cataracts, respectively, observed in 53.3% and 11.1% of cases. Glaucoma and hypertensive retinopathy were also reported in 2.8% of patients. DR was non-proliferative in 29.7%. Intravitreal hemorrhage and maculopathy complicated the course of DR in 2.7% of patients. Panretinal photocoagulation was performed in 27%. Cecity affected 4.3% of our sample.

Discussion

DR represents a vision-threatening complication that may increase the risk of functional impairment and dependence in patients with CKD. Screening for this condition with a specialized annual eye exam is recommended. Optimal control of glycemic profile, blood pressure, and lipid parameters are efficient measures that could prevent the onset and the progression of this disease.

EP804

Assessment of the diabetes mellitus prevalence dynamics in the republic of belarus

Olga Salko[1], Marina Shchaveleva[2] & Tatsiana Mokhort[3,4,4]
[1]Republican Center for Medical Rehabilitation and Balneotherapy, Minsk, Belarus; [2]Minsk City Clinical Endocrinological Center, Minsk, Belarus; [3]Belarusian State Medical University, Minsk, Belarus; [4]Belarusian State Medical University, Endocrinology, Minsk, Belarus

Objective

To assess the dynamics of Diabetes Mellitus (DM) prevalence in the Republic of Belarus in the period from 1993 to 2023.

Materials and Methods

There were the data from the Ministry of Health official statistics in the Republic of Belarus used for the analysis

Results

In the Republic of Belarus, since 1993, there has been a steady increase in the prevalence of types 1 DM and type 2 DM. The total prevalence of type 1 DM increased from 185.30 to 847.6 per 100,000 population, in the absence of an increase in primary incidence. These data indicate that the availability of insulin and self-monitoring tools have a positive impact on the life expectancy of this category of patients. The total prevalence of type 2 DM increased 7.8 times - from 510.99 to 3981.3 per 100,000 population. The marked increase in the incidence of type 2 DM is the result of active detection of the disease in risk groups and popularisation in the media in accordance with the State program. The estimated prevalence rate of DM in the Central European region, including the Republic of Belarus, should be 5-7% of the population. The World Health Organization and the International Diabetes Federation have determined that by 2030, DM should be detected in 80% of sufferers with these desease. When taking the calculated indicator of the number of patients with DM from the general population of a approximately 6% at the beginning of 2024, there are 3,889,395 patients with DM in the Republic of Belarus, which is 4.1%.

Conclusion

It is necessary to intensify measures to identify type 2 DM through further screening and expansion of risk groups, as well as increased popularisation in the media.

EP805

Mean platelets volume and diabetic retinopathy in patients with diabetes mellitus

Hadhemi Belhassen[1,1], Mizouri Ramla, Siwar Saoudi, faten mahjoub, Chaima Sdiri, Nadia Ben Amor, Olfa Berriche & Jamoussi Henda
National Institute of Nutrition, A, Tunis, Tunisia

Introduction

Mean platelet volume (MPV) is an indicator of the average size and activity of platelets. Higher levels of MPV are encountered in conditions with increased production in response to increased destruction of platelets. Some studies suggest an association between impaired platelet function and vascular complications in patients with diabetes mellitus. The aim of our study is to prove this association.

Methods

Descriptive cross-sectional study conducted over 4 months in ward A of The National Institute of Nutrition Tunis which included patients with diabetes mellitus.

Results

Sixty patients were included of whom 41 were women and 19 men. The characteristics of the patients were: age: 50 ± 16.46 years, 44 patients with type 2 diabetes mellitus and 16 with type 1 diabetes mellitus, 20% were treated with oral medication, 35% with human insulin and 13% with insulin analogs, HbA1C: 10.2% ± 1.8. Mean values for MPV in patients with diabetic retinopathy, without diabetic retinopathy were 10.97 ± 0.74 fL and 11.01 ± 0.9fL, respectively. There was no statistically significant correlation between MPV and the development of diabetic retinopathy ($P = 0.751$).

Conclusion

Although MPV can be a predictor of the platelets' high activity in diabetes mellitus, other risk factors of micro or macroangiopathy must be taken into consideration while monitoring the disease progression.

EP807

Characteristics of diabetes in a group of tunisian women at procreative age

Chaima Sdiri, Haifa Abdesselem, Emna Bornaz, Nesrine Dhieb, Fatma Boukhayatia, yahyaoui rim, Ben Brahim Asma, Kamilia Ounaissa & Chiraz Amrouche
National Institute of Nutrition, Department of Nutritional Diseases (D), Tunis, Tunisia

Background
Type 1 diabetes (T1DM) affects young women of childbearing age. Type 2 diabetes (T2DM) is also increasingly affecting this age group due to obesity increase. The aim of this study was to determine the characteristics of diabetes affecting a group of women at procreative age.
Methods
We conducted a descriptive cross-sectional study among pregnant women followed for pre-gestational diabetes at the Department of Nutritional Diseases « D » of the National Institute of Nutrition of Tunis, between January and December 2023.
Results
We included 100 diabetic patients with a mean age of 34.12 ± 4.9 years [ext:23-44 years]. The level of education was primary, secondary and high in 34%, 43% and 23%, respectively. Most patients (82%) had T2DM. The mean duration of diabetes was 13.61 ± 7.36 years for T1DM and 3.61 ± 2.92 years for T2DM. Before pregnancy, about the half of patients (51%) were treated with metformin and 21.6% with insulin (among them, 21.6% were treated with insulin analogs). At the first diabetes consultation in pregnancy, the mean glycated hemoglobin (A1c) was 7.8 ± 1.6% with extremes from 5.9% to 12%. More than the half of the patients (57%) had an A1c level higher than 7%. Hypoglycemic episodes were reported by 22% of patients. Diabetic retinopathy affected 39% of T1DM and 6% of T2DM. Diabetic nephropathy affected 12% of T1DM. However, none of the T2DM had this complication. Hypertension, dyslipidemia, anemia and hypothyroidism affected 3%,6%,3%,7% of patients, respectively. The prevalence of planned pregnancies was 28% in the T1DM group and 11% in the T2DM group. Pregnancy planning was associated with: the university level of education ($P=0.026$), the presence of microangiopathic complications before pregnancy ($P=0.036$) and pre-gestational treatment with insulin analogs ($P=0.004$).
Conclusion
The preconception consultation is essential in the management of the futur pregnant diabetic women to anticipate and prevent maternal and fetal complications. Then, educating women about the benefits of this consultation is essential.

Effect of habit modification on the likelihood of hospitalization with complications of patients with diabetes during the covid-19 pandemic social isolation

Liana Jashi[1,2], Tamar Peshkova[3], Nestan Bostoganashvili[4], Tamar Sharashenidze[2] & Koba Kamashidze[5]
[1]Avicena-Batumi Medical University, Georgia, Medicine, Batumi, Georgia; [2]David Aghmashenebeli University Of Georgia, Medicine, T'bilisi, Georgia; [3]Batumi Shota Rustaveli state University, Medicine, Batumi, Georgia; [4]Tbilisi Heart and Vaskular Clinic, Medicine, T'bilisi, Georgia; [5]University of Georgia, Medicine, T'bilisi, Georgia

Habits play an essential role in the treatment of chronic diseases. The main complaints of patients during isolation were sleep disturbance, eating patterns, increased tobacco and alcohol consumption, and reduced physical activity. The aim of the study is to examine the change in habits during social isolation during the COVID-19 pandemic as a predictor of the rate of hospitalizations with diabetes-related complications to determine the odds of impact.
Results
A retrospective cross-sectional study was conducted in Georgia from September 2022 to March 2023. 65 people participated in the survey—752 patients with early diabetes mellitus. Stenting/heart bypass during isolation increased the likelihood of hospitalization with sweet (OR = 3.3. CI 95% (1.16-9.71) $P=0.03$) and fatty (OR = 1.3 CI 95% (1.3-16.9) $P=0.018$) food. increase in consumption when quitting cigarette smoking (OR = 0, 103 CI 95% (0.11-1.0) $P=0.05$), protein diet (OR = 6,62. CI 95% (1.67-17.5) $P=0,000$) and physical activity up to 4-6 hours per week reduced (OR = 3,7. CI 95% (1.78-15.7), $P=0,000$). The probability of hospitalization for diabetic foot during isolation decreased with smoking cessation (OR = 0.108. CI 95% (0.011-1.034) $P=0.05$), increased with increased cigarette consumption (OR = 0.05. CI 95% (0.4-0.692) $P=0.025$), fatty foods (OR = 6.02. CI 95% (2.85-18.7) $P=0.000$) and hypodynamics (OR = 10.9. CI 95% (4.963-21.5) $P=0.000$). The probability of hospitalization for stroke was increased by insomnia (OR = 5.8. CI 95% (1.36-24.7) $P=0.017$), obesity (OR = 5.9. CI 95% (1.59-22.4) $P=0.008$) and intake increase in sugary food (OR) = 6.7. CI 95% (1.47-23.9) $P=0.014$).
Conclusion
Thus, changing habits (food, sleep, tobacco use, physical activity) during the COVID-19 pandemic was one of the critical predictors of the development of complications associated with diabetes mellitus, which significantly increased the likelihood of hospitalization of patients.

Association between microalbuminuria and thyroid gland function in patients with diabetes type 2 and diabetic nephropathy

Alina Urbanovych, Andriana Vereshchynska & Fedir Laniush
Danylo Halytsky Lviv National Medical University, Endocrinology, Lviv

Background and aims
Diabetes type 2 (DT2) is a chronic condition that damages the whole metabolism. It has a growing incidence and is recognized as epidemic of 21st century. One of the most common complications of DT2 is diabetic nephropathy (DN). It is caused by persistent hyperglycemia and kidney damage. Microalbuminuria is one of the most important hallmarks of DN. Besides, it increases a risk of cardiovascular and neurological complications. Microalbuminuria is defined as albumin/creatinin ratio (ACR) 30-300 mg/g or daily albumin excretion 30-300 mg/24 h. DT2 is often accompanied by thyroid dysfunction. According to literature reviews, microalbuminuria is associated with thyroid function disorders. Our research aimed to study structure and function of thyroid gland in patients with DT2 and microalbuminuria.
Materials and methods
our study included 87 individuals (mean age – 57.1 ± 0.86 years; mean ACR – 139 ± 5.5 mg/g) with DT2 and no history of thyroid gland disorders. All participants had HbA1c level below 8.0% and did not change glucose-lowering agents during the study. Thyrotropin-stimulating hormone (TSH), free T4 (fT4), free T3 (fT3), thyroid-peroxidase antibodies (anti-TPO) levels were obtained as well as thyroid gland ultrasound.
Results
TSH (mean level 2.75 ± 0,34) positively correlated with ACR ($r=0.09$, $P<0.05$). FT4 (14.32 ± 1.09) and fT3 (2.37 ± 0.18) levels negatively correlated with ACR ($r=$ -0.22, $P<0.05$ and $r=$ -0.17, $P<0.05$ respectively), whereas Anti-TPO level (57.26 ± 6.84) positively correlated with ACR ($r=0.09$, $P<0.05$). Total thyroid gland volume (17.72 ± 1.39 ml) positively correlated with ACR ($r=0.05$, $P<0.05$).
Conclusion
our study demonstrates a strong association between thyroid and renal function. Patients with DN more often have hypothyroidism, positive anti-TPO, and greater total thyroid volume. Effective treatment of hypothyroidism in these patients can improve clinical outcomes of DT2 and microalbuminuria.

EP811

Severe diabetic ketoacidosis following methamphetamine ingestion

Bethany Laquidara
Summa Health/Akron City Hospital, Internal Medicine, Akron, United States

Introduction
Diabetic ketoacidosis (DKA) can occur when the body is in an insulin-deficient state, which results in an inability to suppress lipolysis and thus ketone production[1]. Certain recreational drugs, particularly cocaine, have been found to increase the risk of developing DKA[2]. What is less clearly defined is whether methamphetamines act as a DKA-precipitant. This case depicts a patient with insulin-dependent diabetes and negative autoantibodies who was found to have severe DKA following methamphetamine ingestion.
Case Description
A 54-year-old male with a past medical history of insulin-dependent diabetes and polysubstance use disorder presented to the emergency department for altered mental status (AMS). History unable to be obtained secondary to AMS. Physical exam was notable for tachypnea, diffuse abdominal tenderness, and profound confusion. Initial work-up revealed severe DKA and hyperkalemia. Toxicology screen was positive for amphetamines and THC. Head imaging was

unremarkable. The patient was treated with regular insulin and bicarbonate drips, intravenous calcium, and fluids. Autoantibodies associated with type 1 diabetes were negative and C-peptide was low, suggesting a diagnosis of type 2 diabetes with depletion of pancreatic islet cells. The patient's DKA and hyperkalemia resolved with the above therapies. His hospital course was complicated by ongoing AMS and heavy oral secretions due to a lung abscess. This necessitated intubation and ultimately a tracheostomy. The patient was ultimately discharged to a long-term acute care facility.

Discussion

This case demonstrates severe DKA in a patient with insulin-dependent diabetes with negative autoantibodies following methamphetamine ingestion. While research on the interplay between methamphetamine use and DKA is scarce, one study examined autopsy and toxicology case files for the presence of methamphetamine in post-mortem blood samples[1]. They found a significantly increased rate of DKA in patients with insulin-dependent diabetes who use methamphetamine (66.7%) compared to patients with insulin-dependent diabetes alone (6%). While cause and effect cannot be established by that study or this patient case, further investigation into the role of methamphetamine as a possible precipitator for DKA is warranted.

Foot care knowledge and practices of diabetic patients

Mouna Elleuch, Maryam Cheikhrouhou, Dhouha Ben salah, Khouloud Boujelbene, Yasmine Abdelkafi, Souhir Maalej, Fatma Mnif, Nadia Charfi, Mouna Mnif, Faten Hadj kacem, Mohamed Abid & Nabila Rekik
Tunisia

Introduction

Diabetic foot is a significant public health issue, and its management remains challenging, emphasizing the importance of prevention through the screening of high-risk feet and educating diabetic patients about preventive care.

Objectives

To assess, using a questionnaire, the knowledge and practices of diabetic patients regarding diabetic foot care and to determine the level of podiatric risk in our diabetic patients according to the International Working Group of the Diabetic Foot (IWGDF) classification.

Methods

We conducted a cross-sectional observational study with 60 diabetic patients hospitalized for uncontrolled diabetes at the Endocrinology Department of CHU Hedi Chaker in Sfax. Each patient underwent an interview, a physical examination, and a questionnaire on foot care knowledge and practices.

Results

The mean age of our patients was 52 ± 13.68 years, with a male-to-female ratio of 0.53. The average duration of diabetes was 12.5 ± 5.9 years. Clinical examination of the feet revealed skin dryness in 63.3% of cases. The knowledge level was poor in 28.3% of cases, satisfactory in 43.3% of cases, and good in 28.3% of cases, with a significant association with the educational level ($P < 0.001$) and diabetes type ($P = 0.012$). The practice level was poor in 26.7% of cases, satisfactory in 48.3% of cases, and good in 25% of cases, with a significant association with the educational level ($P = 0.03$) and diabetes type ($P = 0.036$). In our study population, the podiatric risk level was high in 18.3% of cases, with a significant association with knowledge level ($P = 0.029$) and practice level ($P = 0.019$).

Conclusion

These results underscore the need to enhance therapeutic education regarding diabetic foot care to improve adherence to foot care among diabetic patients, thereby contributing to better prevention.

Clinical characteristics and complications of gestational diabetes mellitus: a single center spanish experience

Ana Paola Leon Ocando, Oliver Quintero Rodríguez, Selena Rodríguez Fernández, Kevin Díaz Gorrin & Itziar Aznar Ondoño
Hospital Universitario de Canarias, Endocrinology and nutrition, San Cristóbal de La Laguna, Spain

Introduction

Pregnancy involves distinct metabolic stages, initially characterized by maternal anabolism, followed by a catabolic phase driven by placental lactogen and various cytokines, leading to varying degrees of insulin resistance. DM is the most common metabolic disorder linked to pregnancy.

Objective

The study aimed to detail the clinical characteristics, obstetric complications, and neonatal outcomes of patients with GDM and their children.

Materials and Methods

This cross-sectional study utilized accidental sampling of 50 patients diagnosed with GDM (diagnosed in the 2nd or 3rd trimester, with no prior DM history), who were treated in our Hospital's Endocrinology and Nutrition clinic in 2022.

Results

The average age is 35.44 years. 68% were overweight or obese before pregnancy, and 16% had a history of GDM in previous pregnancies. 76% have a family history (of first or second degree) of T2DM. Regarding glycemic control, achieved through capillary glucometry, 60% was managed with dietary measures and physical activity, while the remaining 40% required insulin. 38% of the patients and their children lost follow-up so these results are unknown, however, during labor, 14% experienced complications, and 48% had normal vaginal deliveries. Concerning neonatal outcomes, 2% experienced hypoglycemia, another 2% were preterm, and 58% had no immediate complications. In the postpartum period, 10% of mothers showed carbohydrate intolerance, but DM was ruled out.

Conclusion

According to the literature, GDM is predominantly observed in individuals with a history of overweight or obesity and those with a family history of T2DM. While most cases are manageable through hygienic-dietary measures, a significant portion of patients require insulin therapy to maintain euglycemia throughout the pregnancy. It is important to note, however, that some patients may not adhere strictly to the recommended dietary guidelines. Furthermore, the incidence of complications during delivery and for the newborn is likely higher than reported in this study. This discrepancy can be attributed to the loss of patient follow-up, which is a notable limitation of this research.

DOI: 10.1530/endoabs.99.EP813

Characteristics of phenotypes in patients with diabetes mellitus type 2 and myocardial infarction

Yanina Saienko[1] & Borys Mankovsky[2]
[1]State Institution "Scientific and Practical Medical Center of Pediatric Cardiology and Cardiac Surgery of the Ministry of Health of Ukraine", Department of Cardiovascular Diabetology, Kyiv, Ukraine; [2]D.F. Chebotarev Institute of Gerontology of the National Academy of the Medical sciences of Ukraine, Kyiv, Ukraine

Cardiovascular (CV) diseases are the main cause of death in patients with diabetes mellitus. The different phenotypes can predispose to those disease in people with diabetes.

Aim

to identify phenotypic features in patients with type 2 diabetes mellitus (T2DM) and their impact on the development of myocardial infarction (MI).

Materials and methods

We examined 231 patients with T2DM with and without MI. The average age of patients was 61.57 ± 0.89 years, the duration of diabetes was 8.61 ± 0.56 years. The average level of HbA1c was 7.78 ± 0.12%, systolic blood pressure - 134.92 ± 1.04, diastolic blood pressure - 81.95 ± 0.68 mm Hg. Depending on the presence or absence of MI patients with T2DM were alienated into 2 groups. The number of patients with T2DM and MI was 59, and 172 without MI. For all patients were calculated BMI, creatinine level, albuminuria and the ratio of albumin to creatinine in the urine to diagnose chronic kidney disease (CKD). All patients received antidiabetic, antihypertensive and statin therapy. We analyzed the effect of age, BMI, duration of T2DM, HbA1c and CKD on the development of MI in patients with T2DM.

Results

Patients with T2DM without MI were significantly younger, their age was 62 [53-69] years, the duration of diabetes was significantly less than 6 [2-11] years, in compared to patients with T2DM with MI, where the age was 65 [61-72] years, and the duration of diabetes was 10 [2-17.5] years. BMI was significantly higher in the group of patients with T2DM without MI and amounted to 32 [28.1-36.2] kg/m^2, while in patients with T2DM with MI was 30 [28-34.3] kg/m^2. The level of HbA1c

in the groups of patients with T2DM with or without MI did not differ significantly. The risk factor of CKD III – IV was present in 21 of 172 patients without a history of MI and in 31 of 59 patients with MI and T2DM. The odds ratio for developing a heart attack in the presence of CKD was OR = 2,242 [1,21 - 4,125], $P=0,008$.
Conclusion
we identified the influence of age, duration of diabetes mellitus on the development of MI in patients with T2DM.

Disease perception in patients with type 2 diabetes

Ben Hamida Yosra[1], Htira Yosra[1], Fitouri Sami[2], Trabelsi Syrine[1], Jallouli yesmine[1], Hadj Ali Zohra[1], Jemai, Chaima[1,1] & Ben Mami Faika[1]
[1]Institut De Nutrition, Tunis, Tunisia; [2]Institut De Nutrition, therapeutic dietetics and nutritional diseases 'C', Tunis, Tunisia

Background
The aim of the study was to describe patients' cognitive and emotional representations of type 2 diabetes.
Methods
We conducted a cross-sectional study of 50 adults with type 2 diabetes hospitalized in November 2023 in ward C at the National Institute of Nutrition and Food Technology. We used the translated and validated Arabic version of the Brief Illness Perception Questionnaire. Data were analysed using SPSS 26.
Results
The mean age of patients was 57 years. the ratio females-to-males was around 1.5. Diabetes had been present for more than 10 years in 66% ($n=33$) of participants, and was unbalanced in 92% ($n=46$). Patients treated with insulin therapy alone accounted for 50% ($n=25$). Degenerative complications were present in 88% ($n=44$) of cases, with microangiopathic complications predominating 84% ($n=42$). The first five items of the questionnaire concerned cognitive perception of the disease. Of those questioned, 6% ($n=3$) had answered that diabetes is a disease that severely affects life and 78% ($n=39$) thought that the disease would last a lifetime. 2% ($n=1$) of patients thought they could totally control their diabetes, 6% ($n=4$) felt that treatment was not helpful at all and 10% ($n=5$) had very severe symptoms. Items 6 and 8 described the emotional aspects of the disease so that 24% ($n=12$) of patients felt extremely worried about the disease and 14% ($n=7$) said they were extremely emotionally affected by it. In item 7, we measured the degree of understanding of the disease, as 4% ($n=24$) of participants felt they could understand their disease very well and identified the three main causes cited in order, namely acute psychological stress (68% $n=34$), followed by dietary errors 48%(% $n=24$) and heredity 12% ($n=6$). The mean score was 49.6, with extremes ranging from 24 to 72. Half the participants had a score of 50 or more.
Conclusion and recommandations
Most patients have a negative perception of their diabetic condition. We recommend that family and friends become more involved, as they can provide essential support for lifestyle changes and treatment compliance.

Diabetic type 1 adolescents and physical activities: Between recommendations and obstacles

Sofia Ouhessaine, Nassim Essabah Haraj, Siham El Aziz & Asma Chadli
Endocrinology, Diabetology, Nutrition and Metabolic Diseases Department Ibn Rochd University Hospital of Casablanca, Morocco Neurosciences and Mental Health Laboratory Faculty of Medicine and Pharmacy-University Hassan II-Casablanca-Morocco

Introduction
Physical activity helps improve physical performance and glycemic balance in type 1 diabetics. Furthermore, these patients encounter obstacles to accessing a normal sporting life and therefore its benefits.
Objectives of the study
To evaluate the practice of physical activity (PA) among T1D people, their knowledge in terms of therapeutic adaptation and the obstacles facing its practice.
Material and methods
Descriptive cross-sectional study including adolescent T1D patients followed at the consultation in the endocrinology-diabetology department at Ibn Rochd University Hospital. During an interview, patients responded to a questionnaire consisting mainly of closed questions.
Results
Our study included 225 patients. The mean age was 16.9 years (14–18 years). The average HbA1c was 9.2%. Among our patients, 46% practiced regular sports activity as part of the school program, and only 19% practiced PA outside of school. Our patients had benefited from therapeutic education on PA in 23%. Our patients were reluctant to exercise by choice in 44% due to fear of hypoglycemia. Concerning treatment adaptations, the majority of patients resorted to reducing the doses of rapid insulin. Blood glucose self-monitoring was only ensured in 18% of patients. Hypoglycemia was found in 45% of cases, including 4% severe hypoglycemia. The occurrence of hyperglycemia was less frequent.
Conclusion
Our study showed the need for therapeutic education and patient support for better self-management of treatment, given that glycemic variations represent the main obstacle.

Assessment of nurses' knowledge levels of diabetic foot care management

Ben Salah Dhoha, Khouloud Boujelben, Hamdi Frikha, Mouna Elleuch, Younes Derbel, Faten Hadjkacem, Fatma Mnif, Nadia Charfi, Mouna Mnif, Mohamed Abid & Nabila Rekik
Hedi Chaker University Hospital, Department of Endocrinology

Introduction
The diabetic foot represents a major public health problem worldwide, as it exposes patients with diabetes mellitus to a high prevalence of ulceration and amputation, with potential repercussions on patients' quality of life and even the society through its economic impact. Health care personnel, particularly nurses, play a crucial role in the management and prevention of diabetic foot disease. The aim of our study was to assess nuses'Knowledge levels of diabetic foot care management.
Patients and methods
A cross sectional and descriptive study was performed between September and November 2021. Knowledge levels were assessed by referring to a questionnaire based on International Working Group on the Diabetic Foot (IWGDF) recommendations, designed to evaluate the knowledge of 50 randomly selected nurses working in different departments caring for diabetic foot.
Results
Mean age was 30,9 years (25-58 years). Forty five were female (90 %) with a sex ratio of 0.11. Forty percent of nurses had between 5 and 10 years of professional experience in their current departments. Thirty-four percent of our population were aware that patients with diabetes mellitus are considered to be at high risk of ulceration, particularly when they present peripheral neuropathy or arteritis. Only 10 % of the nurses knew that the foot at risk should be examined regularly. Fourt two percent of nurses know that patients with diabetes mellitus should monitor their foot temperature one a day. Half of our population recognized that patients with diabetes mellitus should avoid applying moisturizing cream into interdigital spaces of foot.
Conclusion
At the end of our study, we demonstrated the existence of gaps in the theoretical knowledge of diabetic foot care management among nurses, which underlines the importance of better planning of continuing education of health care personnel, as well as multidisciplinary management.

Survey to understand gaps in diabetes patient education resources and to identify potential lifestyle-modifying services

Banshi Saboo[1], Manoj Chawla[2], Rishi Shukla[3], Debasis Basu[4], Blessy Saju[5], Rahul Iyer[5], Amarnath Sugumaran[5] & Senthilnathan Mohanasundaram[5]

[1]Dia Care – Diabetes Care and Hormone Clinic, Ahmedabad, India; [2]Lina Diabetes Care Center, Mumbai, India; [3]Regency Hospital, Kanpur, India; [4]Apollo Multispecialty Hospital, Kolkata, India; [5]Cipla Ltd., Medical Affairs, Mumbai, India

Introduction & Objective
A vital but often disregarded pillar of diabetes management is effective patient education. The objective of this survey was to identify gaps in the existing patient education resources & to understand which patient services can help boost adherence to requisite lifestyle & therapy.
Methods
A cross-sectional study was conducted between January & March 2023, involving clinicians managing type 2 diabetes mellitus across India. Responses were collected, with prior informed consent, using a structured digital questionnaire. Data was analysed & expressed as descriptive statistics.
Results
This survey involved 903 clinicians pan India, of whom ~70% belonged to 30-50 years age group, had postgraduate degree in medicine & had private consulting practice. Clinicians opined that besides in-clinic counselling; 'physical counselling' (60%) & 'initial physical counselling followed-up on virtual platform' (35%) were the most effective. When enquired about the major gaps in existing patient education content, clinicians chose- 'content not being tailored as per regional/local preferences' (55%), 'lack of content simplicity' (54%) & 'quality of content' (39%). Most clinicians (84%) rated availability of patient education content in regional languages to be important/very important. The key challenges observed by clinicians in the existing dietary education resources were 'diet charts not tailored to local region' (48%), 'content unavailability in regional languages' (46%) & 'lack of qualified dietitians' (40%). Most clinicians mentioned that complimentary services were extremely/very useful {lab tests (86%), dietitian (83%) & gym (64%)} in helping to increase patient adherence to lifestyle & therapy.
Conclusion
This survey reveals that for patient education resources-quality, regional customization, simplification & availability in regional languages are important requisites. Furthermore, complimentary services including dietitian, gym & lab tests may help improve patient adherence to lifestyle & therapy.

Comparative analysis of clinical, bioelectrical and ultrasound characteristics in a cohort of post-critical patients after severe pneumonia covid-19, according to serum vitamin d levels

Víctor José Simón Frapolli[1,2], Miguel Damas Fuentes[1], Isabel Vegas Aguilar[1], José Manuel García Almeida[1] & Francisco Tinahones Madueño[1,2]
[1]Hospital Universitario Virgen de la Victoria, Endocrinology and Nutrition, Málaga, Spain; [2]BIONAND, Málaga, Spain

Introduction
Vitamin D deficiency is a common health problem worldwide, particularly in elderly patients. Vitamin D is considered a key hormone in mineral and bone metabolism, as well as in functions such as the regulation of cell proliferation and differentiation, its immunoregulatory activity, its effect on the cardiovascular system and its neuroprotective and anti-ageing effects, among others. Hypovitaminosis D has been linked in multiple studies to a higher incidence and severity of COVID-19 infection, as well as to increased mortality. It is also involved in muscle function, maintaining strength and physical performance, and there is evidence to support the association between vitamin D deficiency and an increased risk of sarcopenia, frailty and sarcopenic obesity. The aim of this study is to compare different clinical, bioelectrical and ultrasound characteristics according to serum vitamin D levels in a cohort of patients after having been admitted to the ICU for severe SARS-COV2 pneumonia.
Methods
Vitamin D levels, in no case supplemented, as well as other demographic, anthropometric, ultrasound, bioelectric, analytical and hospital stay-related variables were collected in a cohort of 29 patients 15 days after hospital discharge following admission to the ICU for severe SARS-COV2 pneumonia. These variables were then compared according to serum vitamin D levels. For this purpose, patients were classified into 3 categories according to vitamin D levels ($\leq$20 ng/ml, 20-29.99 ng/ml, $\geq$30 ng/ml).
Results
Statistically significant differences were observed in the degree of obesity according to BMI ($P=0.037$) and age ($P=0.032$) as a function of serum vitamin D concentration, while a trend towards statistical significance was observed in other variables such as skeletal muscle mass (SMM)/kg. No differences were observed in other variables such as sex, diabetes, sarcopenia, sarcopenic obesity, malnutrition (according to GLIM criteria), ultrasound or bioelectrical variables. In the correlation analysis, vitamin D levels correlated significantly positively with albumin levels ($r=0.499$, $P=0,022$).
Conclusion
Vitamin D only shows a significant positive correlation with albumin levels. In our cohort, only the degree of obesity and age showed statistically significant differences according to vitamin D levels, but no differences were found in other clinical, bioelectrical and ultrasound parameters.

Polymedication in the elderly

Yesmine Jallouli[1], Rym Ben Othman[2], Syrine Trabelsi[3], Yosra Ben Hmida[3], Ramla Mizouri[3], Olfa Berriche[3], Henda Jamoussi[3] & Faten Mahjoub[3]
[1]Tunis, dapartment A, tunis; [2]Tunisia, dapartment A, tunis, Tunisia; [3]National Institue Of Nutrition and food technology, dapartment A, tunis

Introduction
Polymedication is a major problem affecting an increasing number of patients, particularly the elderly which can be deleterious in terms of quality of life, morbidity and mortality.
Objective
The aim of the present study was to determine the prevalence of polymedication in elderly diabetic patients.
Methods
This was a descriptive cross-sectional study conducted at the Institut National de Nutrition in 2023 in diabetic patients aged over 70. Polymedication was defined as taking more than five tablets per day.
Results
We enrolled 70 diabetic patients. The mean age of the population was 73 ± 2.4 years, with females predominating (65.1%). Diabetes was poorly controlled in 73.77% of patients, with a mean glycated hemoglobin of $10.54\%\pm2.16$. Diabetes was complicated by retinopathy in 61% of cases. Comorbidities were dominated by hypertension and dyslipidemia in 84.1% and 85.7% of patients respectively. Polymedication concerned 64% of the study population. Statins were the most prescribed pharmaceutical class (78.2%), followed by antihypertensive drugs (69.7%), oral antidiabetics 51.2%)
Conclusion
Polymedication was common among elderly diabetic subjects. This may increase the risk of drug interactions and poor compliance.

Perception of the risk of developing type 2 diabetes among women with gestational diabetes

Mouna Elleuch, Younes Derbel, Hamdi Frikha, Dhoha Ben Salah, Kouloud Boujelben, Fatma Mnif, Mouna Mnif, Nadia Charfi, Faten Haj Kacem Akid, Mohamed Abid & Nabila Rekik Majdoub
Hedi Chaker University Hospital, Endocrinology

Introduction
Gestational diabetes poses a significant public health challenge in Tunisia and various regions globally, affecting approximately 1 in 6 pregnant women. While it typically resolves post-delivery, about 20% of individuals with gestational diabetes (GD) develop Type 2 Diabetes (T2D) within five to ten years thereafter. Recognizing this heightened risk is crucial for prompt adoption of preventive measures. This study aimed to evaluate the perception of the risk of developing T2D among women with GD.
Methods
A cross-sectional study conducted at the Obstetric Gynecology Department at Hedi Chaker Hospital in Sfax. We assessed socio-demographic characteristics, educational backgrounds, and familial history of diabetes among participants. Health risk perception was measured using the RPS-DD instrument.
Results
The study included 130 patients with GD. Results revealed that the majority of participants were aged over 30, possessed a high school education (36%), and half reported one or more family members with a history of diabetes. The majority of patients (59,7%) were at their third pregnancy. The findings indicated that the perception of future health risk was moderate (mean score 2,4/4). Specifically, the perception of developing Type 2 diabetes over the next ten years subsequent to gestational diabetes was relatively average; notably, 49% perceived virtually no

risk of developing diabetes in this timeframe. Additionally, patients showed an average perception of the impact of lifestyle measures on the subsequent risk of developing TD2 (5,5/11 on RPS-DD scale).
Conclusion
In this study, women with gestational diabetes exhibited an average perception and knowledge of the risk to their future health. Consequently, enhancing health risk perception is essential for promoting preventive measures among individuals with gestational diabetes.

Vitamin B12 and B9 deficiency in type 2 diabetes: Diabetic nephropathy risk assessment

Youssef Gharbi, Bchir Najla, Salma Salhi, Annam Benchhida, Dorra Dorraelguiche, Zouaoui Chadia & Haroun Ouertani
Military Hospital of Tunis, Endocrinology, Tunis, Tunisia

Introduction
Diabetic nephropathy (DN) is a major complication of diabetes and may be fatal at an end stage kidney disease. Several mechanisms lead to the basic lesion of DN (thickening of the glomerular basement membrane) including oxidative stress, inflammation and hyperhomocysteinemia. Being coenzymes of homocysteine metabolism, a deficiency in vitamin B12 and B9 will cause an accumulation of circulating homocysteine. Our objective was to evaluate the association between the deficiency of these vitamins and DN in type 2 diabetics.
Methods
It was a cross-sectional study that included 100 type 2 diabetic patients. Vitamin B12 deficiency was defined by a level $<$ 203 pg/ml. Vitamin B9 deficiency was certain for a level $<$ 3 ng/ml and possible for a level between 3 and 6 ng/ml. DN was considered in the presence of albuminuria $>$ 30 mg/24 h or a Glomerular Filtration Rate $<$60 ml/min
Results
In our population, 40% of patients had positive albuminuria and 11% had renal failure of all stages. In total, 43% of patients had DN. It was significantly associated to diabetic retinopathy ($P=0.015$) and diabetic neuropathy ($P=0.039$). The average vitamin B12 level was 220.62 pg/ml for patients with DN vs 209.43 pg/ml for those without DN. Vitamin B12 deficiency was not significantly associated to DN ($P=0.420$). The average vitamin B9 level was 8.83 ng/ml for patients with DN and slightly higher at 9.05 ng/ml for those without DN but with no significant association between possible vitamin B9 deficiency and DN ($P=0.796$).
Conclusion
Our study didn't show an association between vitamin B12 and B9 deficiency and DN. However, given the multitude of studies on the subject, more in-depth studies would be necessary to confirm the absence of this association.

Nutrients intake and gastrointestinal disorders in type 2 Diabetics

Hana Ben jemâa, Berriche Olfa, Rym Ben Othman, Amel Gamoudi, Emna Talbi & Jamoussi Henda
National Institute of Nutrition, A, Tunis, Tunisia

Introduction
Micronutrient deficiencies can contribute to the development or exacerbation of gastrointestinal disorders especially in type 2 diabetic patients. The aim of our study was to determine the effect micronutrient status on gastrointestinal symptoms in diabetic patients.
Methods
We conducted a retrospective descriptive study. We included 115 type 2 diabetics patients. A dietary survey was conducted for each patient to determine nutrient intake. We used the screening micronutrient deficiencies questionnaire (DDM) ''B'' related to digestive disorders and validated by the European Institute of Dietetics and Micronutrition (IEDM). The patients were classified into 3 groups depending on their score results: high, medium, low scores.
Results
The patients' median age was 57.93$\pm$7.48 years. The majority of the participants were women (67.8%), resulting in a sex ratio of 2.1. The majority of the patients are sedentary (73%). The majority of diabetic patients (58.3%) had high blood pressure. Sixty percent had dyslipidemia. The average duration of type 2 diabetes among patients was 10.94$\pm$7.33 years. Microvascular and macrovascular complications were found in 54,8% and 20% of the patients, respectively. High, medium, and low scores were noted in 23,5%; 40,8% and 35,7% of the patients, respectively, using the DDM B. We found negative associations between DDM B score and fiber intake ($P<0,001$). No significant associations were found between micronutrient intake and the DDM score.
Conclusion
Understanding the relation between gastrointestinal health and nutrition is essential for developing effective strategies for both preventing and managing these conditions.

What about breastfeeding in diabetic women?

Chaima Sdiri, Haifa Abdesselem, Emna Bornaz, Mariem Cheikhrouhou, Fatma Boukhayatia, Asma Ben Brahim, Rim Yahyaoui, Kamilia Ounaissa & Chiraz Amrouche
National Institute of Nutrition, Department of Nutritional Diseases (D), Tunis, Tunisia

Background
Breastfeeding offers short- and long-term health benefits to mothers and their infants. In the literature, many studies suggest that diabetic women breastfed their babies less than non-diabetic women. The aim of our study was to determine the breastfeeding rates in a group of diabetic women.
Methods
It was a prospective descriptive study conducted in pregnant women followed for pregestational diabetes at the Department of Nutritional Diseases « D » of the National Institute of Nutrition of Tunis. Women included in this study were contacted by telephone one week after delivery and they consulted at two and six months postpartum. Women who had an abortion or had been lost to follow-up were excluded from the study.
Results
We included 102 diabetic patients with a mean age of 35.12$\pm$4.8 years [ext:23-44]. Most patients had type 2 diabetes (82%). The mean duration of diabetes was 4.37$\pm$3.87 years. Twenty-four patients were excluded from the study. Most patients (73%) had given birth by caesarean section. Preterm delivery was noted in 14% of the cases. To one week after delivery, 40% of patients breastfed exclusively, 42% breastfed and bottle-fed, while 18% used formula milk only. After 2 months of childbirth, breast-feeding was noted in 77% of patients; it was exclusive in 44% of cases and partial in 33%. After six months of childbirth, only 10% of babies were exclusively breastfed, while the half were formula-fed. Hospitalization of the newborn in neonatology was the main obstacle to initiate breastfeeding, according to the patients included in the study (41%). Twenty-two patients considered the quantity of breast milk produced insufficient to cover the needs of the newborn. During hospitalization in the maternity ward, 30% of women were educated about breastfeeding techniques.
Conclusion
Our study highlighted the low rate of breastfeeding among diabetic women. Boosting education for diabetics on the importance of breastfeeding could improve this rate.

Prevalence of undernutrition among elderly diabetics in hospitals

Yesmine Jallouli, Rym Ben Othman, Syrine Trabelsi, Ramla Mizouri, Olfa Berriche, Faten Mahjoub & Henda Jamoussi
National Institue of Nutrition and Food Technology, Dapartment A, Tunis

Objective
To estimate the prevalence of undernutrition among elderly diabetic patients in hospital.
Patients and methods
Descriptive cross-sectional study enrolling 100 patients aged $\geq$ 70 years who were hospitalized in ward A of the National Institute of Nutrition in Tunis. The diagnosis of undernutrition was established according to the criteria proposed by HAS 2021.
Results
The mean age of included patients was 73 y$\pm$2.4 years with a female prevalence (65.1%). The mean HbA1c level was 10.54%$\pm$2.16%. The majority of patients were on insulin therapy (84.9%). Mean weight was 71.9$\pm$5.5 kg, corresponding to a mean BMI of 28.75$\pm$4.51 kg/m^2. Among elderly diabetics, 14% had a BMI

< 22. The overall prevalence of undernutrition was estimated at 49%. Sarcopenia was present in 42% of patients, of whom 31% had reduced muscle strength, 9% had reduced muscle mass and 2% had both reduced strength and muscle mass.
Conclusion
Nutritional screening is essential for all diabetic seniors, regardless of their calorie intake and BMI.

Cardiovascular risk in type 1 diabetes

Marwa El Arem, Bilel Ben Amor, Hanene Sayadi, Inès Khochteli, Ekram Hajji, Héla Marmouch, Sana Abid & Ines Bayar
Hospital Fatouma Bourguiba, Endocrinology

Objectives
The aim of our work is to evaluate the prevalence of cardiovascular risk factors in type 1 diabetics aged between 10 and 20 years.
Patients and methods
Retrospective study including 54 type 1 diabetic patients, followed at the endocrinology department of Fatouma Bourguiba hospital of Monastir during the year 2023.
Results
The mean age was 34.3 ±1.33 years with a female predominance (sex ratio=F/H) =2. they were all poorly balanced with a mean HbA1C=10.7±2.7%. the mean BMI was 22.8 ± 3.7 kg/m^2, with overweight observed in 12.9% and no patient was obese. the prevalence of smoking and hypertension were 16.4% and 7.3% respectively. The lipid profile showed LDL>1 g/l in 31% and hypoHDL-haemia in 31.4%. Diabetic nephropathy was found in 20% of patients, only one of whom had stage 4 renal failure. Diabetic retinopathy was found in 38.2%, half of whom had proliferative DR. Cardiovascular problems were mainly ischaemic heart disease (10.9%). Only one patient suffered a stroke.
Conclusion
These results suggest that after a decade of evolution, a diabetic accumulates several cardiovascular risk factors. This underlines the importance of comprehensive management of glycaemic control and other cardiovascular risk factors to improve cardiovascular morbidity.

Unveiling the diabetes dilemma: a comprehensive analysis of type 2 diabetes complications in tunisia

Souhir Maalej, Fatma Mnif, Siddiqa Soomauroo, Abdel Mouhaymen Missaoui, Dhouha Ben Salah, Khouloud Boujelben, Mouna Mnif, Nadia Charfi, Faten Hadjkacem, Mouna Elleuch, Mohamed Abid & Nabila Rekik
Hedi Chaker University Hospital, Endocrinology, Sfax

Background
Diabetes mellitus is a global chronic health challenge, and Tunisia is witnessing a concerning surge in the prevalence of type 2 diabetes (T2D). According to the IDF 2021, diabetes affects 10.8% of adults in Tunisia, equivalent to 869,400 cases among a total adult population of 8,046,400.
Materials and Methods
A retrospective descriptive study was conducted to gather data on diabetic patients with chronic complications. The study encompassed patients hospitalized in the Endocrinology Department of Hedi Chaker University Hospital in Sfax from January 1 to December 31, 2022. The research focused on the epidemioclinical and therapeutic profiles of complicated diabetic disease.
Results
The study comprised 114 patients, with 64 (56.1%) males and 50 (43.9%) females, resulting in a sex ratio of 1.28. The average age at hospitalization was 65.38±10.17 years, ranging from 41 to 87 years. The mean BMI was 28.8±6.2 kg/m^2;, with females exhibiting a higher average (32.2±6.5 kg/m^2;) compared to males (26.3±4.7 kg/m^2;). Dyslipidemia was the predominant risk factor (86.8%), followed by hypertension (74.6%), obesity (32.5%), and smoking (21.1%). The average diabetes duration was 12.87±8.38 years. Treatment modalities included exclusive use of oral antidiabetic drugs (OAD) for 61.4%, insulin for 17.5%, and a combination of OAD and insulin for 14.9%. Diabetic nephropathy was identified in 67.54% of patients, while diabetic retinopathy and neuropathy were present in 33.3% and 52.6%, respectively. Among the 90 patients with cardiovascular involvement, coronary insufficiency was the predominant macroangiopathy (59.7%), followed by heart failure, peripheral arterial disease, and stroke (10.5%).
Conclusion
Type 2 diabetes is linked to a wide array of complications, categorized as macrovascular and microvascular. This study illuminates the pervasive complications of type 2 diabetes, emphasizing the necessity for comprehensive management strategies addressing both macrovascular and microvascular aspects. A deep understanding of the epidemiology and treatment patterns of diabetic complications is vital for enhancing patient outcomes and preventing long-term complications.

Quality of life assessment in patients with diabetic foot

Malak Iggar, Haraj Nassim Essabah, El Aziz Siham & Chadli Asma
CHU Ibn Rochd, Endocrinology, Diabetology, Nutrition and Metabolic Diseases, Casablanca, Morocco

Introduction
Diabetic foot represents a daunting complication of diabetes, compromising the patient's functional prognosis and leading to a deterioration in the quality of life.
Objectives
To assess the quality of life of diabetic patients with diabetic foot and analyze the factors associated with a decline in quality of life.
Patients and methods
An observational, analytical, and prospective study involving 58 patients hospitalized in the Department of Endocrinology and Metabolic Diseases. The patient's quality of life was assessed using the SF36 score, and factors related to poor quality of life were analyzed using SPSS software.
Results
The average age of our patients was 52.5 years, with a male predominance in 59.5% of cases. The average duration of diabetes was 14.2 years, and that of foot ulcers was 3 months. Overall, the quality of life was low in all eight SF-36 subscales: physical functioning (mea n=45%); role limitations due to physical health (mea n=32%); role limitations due to emotional problems (mea n=33%); emotional well-being (mea n=52%); social functioning (mea n=37.45%); pain (mea n=55%); general health (mea n=35.6%), and vitality (mea n=35%). The presence of pain, ulcer recurrence, peripheral arterial disease (PAD), and a longer duration of ulcer evolution were associated with a poorer quality of life (p: 0.05).
Conclusion
Diabetic foot represents an economic and psychosocial burden, resulting in a significant deterioration in the quality of life for patients. Psychological support and better pain management are necessary to alleviate this burden.

Wolfram syndrom: a case report

Marwa El Arem[1], Hamza Elfekih[2], Fatma Ben Abdessalem[2], Koussay Ach[2], Yosra Hasni[2] & Molka Chadli Chaieb[2]
[1]Hospital Fatouma Bourguiba, endocrinology; [2]Farhat Hached University Hospital Sousse, Endocrinology

Wolfram syndrome is a rare, autosomal recessive entity characterized by several progressive neurodegenerative manifestations.
Observation
We report the case of a 27-year-old patient from a Consanguineous marriage, followed for hypogonadism with delayed puberty and insulin-requiring diabetes since the age of 13 with negative autoantibodies. His diabetes is complicated after 5 years of a mainly vegetative neuropathy with neurogenic bladder complicated by bilateral ureterohydronephrosis with intermittent catheterization, unfelt hypoglycemia and gastroparesis. The diagnosis of central diabetes insipidus was made after 13 years of progression of diabetes mellitus in the face of no improvement in the polyuropolydipsic syndrome despite glycemic control. This diagnosis was confirmed by a fluid restriction test and an hypothalamic pituitary MRI. Faced with this association, and the presence of a bilateral decline in visual acuity, Wolfram syndrome was suspected. An ophthalmological examination was completed which showed bilateral optical atrophy with minimal diabetic retinopathy. The ENT examination showed bilateral sensorineural hearing loss.

Conclusion
The clinical picture of Wolfram syndrome is quite rich and variable. This heterogenicity is a cause of diagnostic delay and the appearance of quite serious complications.

Assessment of vitamin d status and depression grade in patients with diabetes mellitus type 2 in chronic stress conditions

Maryna Bobryk[1], Viktoriia Yerokhovych[1], Dmytro Malyi[2] & Iuliia Komisarenko[1]
[1]Bogomoletz National Medical University, Endocrinology, Kyiv, Ukraine; [2]Bogomoletz National Medical University, Dentistry, Institute of Post-graduate Education, Kyiv, Ukraine

Introduction
Ukrainian population is facing many challenges of war including chronic stress, D deficit, often unavailability of medical care. In these conditions some diagnostic disadvantages of Diabetes Mellitus type 2 (DM 2) patients' status are also observed[1]. According to Ukrainian Consensus on Diagnosis and Management of Vitamin D Deficiency in Adults, approximately 20% of Ukrainian population has Vit D deficit (VDD) and 27% Vit D insufficiency (VDI)[2].
Aim of the study
To evaluate 25-hydroxyvitamin D level in DM 2 patients with different severity of depression.
Methods
121 DM 2 patients aged 19-75 years were examined. We studied the level of 25 hydroxycholecalciferol (25-OH D) using Chemiluminescent immunoassay. Diagnosis of VDD and VDI were made according to Clinical Practice in the Prevention, Diagnosis and Treatment of Vitamin D Deficiency: A Central and Eastern European Expert Consensus Statement[3]. Grade of depression was evaluated with Depression, Anxiety and Stress Scale, DASS 21. There were 5 grades of depression: Normal, Mild, Moderate, Severe, Extreme.
Results
Distribution of patients according to the severity of depression: 6 patients had no symptoms of depression, 24 patients had Mild, 43 Moderate, 42 Severe and 6 Extreme grade of depression. We observed inverse relationship between 25-OH D level and Depression grade in DM 2 patients, from 28.05 ± 2.6 ng/ml (correspond to VDI) in Mild depression to 9.5 ± 0.4 ng/ml (correspond to VDD) in Extreme depression ($P < 0{,}001$); inverse relationship between 25-OH D level and Body Mass index (BMI) (rSpearman = -0.304, $P = 0.001$).
Conclusion
In chronic stress patients with DM 2 need treatment with vitamin D and consultation of psychologist.
Keywords 25-OH D, Vit D deficit, Vit D insufficiency, Depression, Diabetes Mellitus, DASS21

Pubertal development in young type 1 diabetic patients: about 121 patients

Younes Boukaidi Laghzaoui, Nassim Essabah Haraj, Siham El Aziz & Asmaa Chadli
CHU Ibn Rochd, Endocrinology, Diabetology and Metabolic Diseases, Casablanca, Morocco

Introduction
Pubertal development is controlled by a series of hormones produced by the hypothalamus, pituitary and sex glands. In people with type 1 diabetes, blood glucose levels can affect the production of these hormones and, consequently, affect the pubertal development, inducing pubertal delay. The aim of this study is to describe the impact of diabetes and its various parameters on pubertal development in young type 1 diabetic patients.
Patients and Methods
This is a cross-sectional, descriptive, analytical study about 121 cases conducted in the Endocrinology Department of CHU Ibn Rochd in Casablanca, from January 1, 2019 to December 31, 2022. We included young type 1 diabetic patients aged between 14 and 20 years, whose diabetes diagnosis was more than 6 months old. The Tanner score was used to assess puberty in patients. Statistical analysis was performed using the SPSS 20 program.
Results
We recruited 121 patients with a mean age of 16.78, 58% female and 42% male. The duration of diabetes ranged from 1 to 14 years, with an average of 5.63 years. HbA1c ranged from 6.4% to 17.6%, with an average of 12.1%. Only 5% of patients were balanced, with HbA1c $<7.5\%$. In our study, the prevalence of delayed puberty was 21% (26 patients). We noted no significant relationship between toxic habits, duration of diabetes, regularity of follow-up, type of insulin therapy regimen, glycemic imbalance, total basal dose, frequency of hypoglycemic episodes, BMI and pubertal delay.
Conclusions
The prevalence of delayed puberty is high among diabetic patients in developing countries, and can be explained by various socio-economic factors: poor access to healthcare, poor diet and poor balance… Our results suggest that the occurrence of delayed puberty was not related to socio-demographic or diabetes-related factors.

EP854

Diabetic Mastopathy- a diagnostic dilemma

Hanaan Ashraf & Andrabi Basharat
University Hospital Sussex, Endocrinology, United Kingdom

Introduction
Diabetic mastopathy (DM) is a rare benign fibroinflammatory disease of the breast with the prevalence of 0.6–13%· seen in long standing Type 1 diabetes who may have other diabetes related complications. Its also been described in patients with type II diabetes, autoimmune diseases such as Hashimoto's thyroiditis. The term lymphocytic mastopathy in used interchanged due to the histopathology and for patients without diabetes. It presents in men and women presents as a solitary mass or bilateral disease. Both the clinical features and the imaging characteristics of DM can mimic those of invasive breast cancer. Lymphocytic mastitis with or without diabetes mellitus may represent a lymphoepithelial lesion of the MALT-type which is considered to bear a prelymphomatous potential. Diagnosis is complex, and biopsy of the lesion is often necessary to establish a proper lesion classification. Here, we report a case of Diabetic mastopathy.
Clinical Presentation
31 years old type 1 diabetic woman G1P1 presenting with right painless breast lump for 3 weeks duration. She has no other comorbidities other than long standing Type 1 DM and has been on Insulin Aspidra + Lantus. She is 11 months postpartum and stopped breastfeeding 4 months ago. On clinical examination she appeared normal built, normal general Physical examination; breast examination right subaeroelar hard mobile painless irregular nodule of 2 cm, no skin or nipple changes or lymphadenopaty. She was evaluated with bloods and usg breast. The Usg breast showed dense glandular tissue with 2 cm subaereolar lump appeared benign in nature. She was reviewed after 6 weeks for a repeat scan which showed 3 cm right ill defined mass with low echogenecity. She had a core biopsy which reported lymphocytic infiltration and fibrosis compatible with the diagnosis of diabetic mastopathy.
Discussion
Diabetic mastopathy is a rare benign breast lesion. It poses a clinical dilemma due to similarities of presentation with breast malignancy it can lead to additional investigations and surgery. Dm is seen with other diabetic complications such as neuropathy, retinopathy or nephropaty. Although our patient had long standing type 1 diabetes she did not have any other related diabetic complications. It can be diagnosed with the help of radiological imaging but as it may mimic invasive cancer. Core-needle biopsy remains to be a gold standard. In difficult cases complementary imaging methods such as ultrasound, mammography, and MRI should be used. This is important to confirm the diagnosis and to avoid any risk of missing early breast cancer. DM patient can be managed symptomatically and excision is not necessary in asymptomatic patients.

Nutrition for diabetic patients and oral health

Yesmine Jallouli, Zohra Hadj Ali, Sami Fitouri, Syrine Trabelsi, Olfa Lajili, Imen Hedfi, Chaima Jemai, Yosra Htira & Faika Ben Mami
National Institue Of Nutrition and food technology, dapartment C, tunis

Introduction
Diabetes is a chronic pathology with multivisceral repercussions, and the oral cavity is no exception. Oral disorders in diabetic patients are frequent and varied, negatively influencing their oral quality of life.
Objective
The aim of our work was to determine the link between the diet of the diabetic subject and oral health.
Methods
This was a descriptive cross-sectional study conducted at INNTA among 30 diabetic inpatients. Data were collected on the basis of a pre-established questionnaire, a biological check-up, a 24-hour dietary survey, a frequency survey and dietary habits.
Results
We enrolled 30 diabetic patients. The sex ratio F/H was 0.6. The mean age of our population was 45.94 ± 14.52 years. Type 2 diabetes predominated (67%) and was poorly controlled in 97% of patients, 50% of whom were treated with insulin. The average age of diabetes was 11.37 ± 9 years. According to the analytical study, there was a significant correlation between mucosal inflammation and diabetic nephropathy, as well as between periodontitis and diabetic retinopathy. Iron, calcium and chromium deficiency was significantly correlated with the number of decayed and decayed teeth. Gingival inflammation was significantly correlated with excess intake of simple sugar and thiamine.
Conclusion
Oral pathologies are an integral part of the complications of diabetes, which must be managed early to preserve patients' oral quality of life.

Prediction of glycemic imbalance during ramadan in non-fasting diabetic patients using artificial intelligence-based machine learning

Zaynab Hifdi[1], Imane Motaib[1], Saloua Elamari[1], Soukaina Laidi[1] & Marouan Fatima[1]
[1]Cheikh Khalifa Bin Zayed Al Nahyan Hospital, Casablanca, Morocco

Introduction
During Ramadan, the daily lifestyle undergoes changes that influence the glycemic balance of both fasting and non-fasting diabetic patients. The aim of this study is to predict glycemic imbalance during Ramadan in non-fasting diabetic patients using Machine learning models.
Methods
This is a prospective study which included all non-fasting diabetic patients during the month of Ramadan and followed at the endocrinology department of the Sheikh Khalifa University Hospital in Casablanca. We collected anthropometric and metabolic parameters during three consultations (before, during and after Ramadan). To predict imbalance, we trained artificial intelligence models based on Machine Learning using the collected data. Finally, we ran several simulations with the best-performing model, using the variables that proved to be the main predictors of poor glycemic control.
Results
We included 154 patients. The prevalence of poor glycemic control among patients was 52.6%. The Extra Tree Classifier was the best-performing model for predicting imbalance (accuracy $= 0.87$, AUC $= 0.87$). The most significant variables for predicting imbalance were: baseline caloric intake and its evolution, female sex, baseline weight, evolution of BMI and waist circumference, and total cholesterol level after Ramadan.
Conclusion
The clinical use of our results will enable us to target risk factors in order to improve glycemic control in non-fasting diabetics.

Screening for obliterating arteriopathy of the lower limbs in type 2 diabetics using the systolic pressure index

Ramla Mizouri, Berriche Olfa, Rym Ben Othman, Nadia Ben Amor & Jamoussi Henda
Institut De Nutrition, Tunis, Tunisia

Introduction
Lower limb arterial disease (PAAD) is a serious complication of diabetes and is particularly common in patients at high cardiovascular risk. Its management in diabetic patients is a major public health problem, with sometimes tragic consequences for the patient. The objective of our work was to detect PAD in type 2 diabetics.
Materials and Methods
This was a descriptive cross-sectional study involving 122 type 2 diabetics hospitalized at the National Institute of Nutrition. Systolic pressure index (SPI) was measured using a Spengler pocket Doppler. Obliterative arteriopathy of the lower limbs is defined by a systolic pressure index less than 0.9 or more or less significant arterial incompressibility (mediacalcosis) by an ABI greater than 1.3.
Results
The average age of our patients was 52.4 ± 7.3 years with a sex ratio of 0.96. The duration of diabetes was 11.07 ± 3.3 years. The majority of patients (78.7%) were on insulin therapy. The average HBA1c was 9.8%. The average BMI of our population was 28.18 kg/m^2. More than a third (35.2%) of our patients were smokers and 39.8% were sedentary. Hyper-LDLemia type dyslipidemia was found in 56.2% of patients. Arterial hypertension was present in 45.1% of patients. Macroangiopathic complications were dominated by ATCD of stroke (5.7%) and MI (4.9%). The ABI was less than 0.9 in 38.5% of cases and greater than 1.3 in 3.3% of cases, of which more than half of the cases (58%) were asymptomatic.
Conclusion
Obliterating arteriopathy of the lower limbs (PAAD) is a frequent and serious complication in diabetic patients. Which underlines the interest of an effective preventive approach and early detection.

Primary hyperparathyroidism: analysis of 132 cases

Mohamed Abderrahmane Ahmed Ebett, Chadli Asma, El Aziz Siham & Haraj N.EEE
University Hospital Center Ibn Rochd - Casablanca, Casablanca, Morocco

Introduction
Primary hyperparathyroidism, common in the general population with a prevalence of 1 to 6 per 1000, is caused by an overproduction of parathyroid hormone, often due to a benign adenoma of the parathyroid glands.
Objectives
The study aims to analyze the correlation between the clinical manifestations of hyperparathyroidism and abnormalities detected through ultrasound, scintigraphy, and computed tomography (CT).
Methods
A study of 132 patients at Ibn Rochd Hospital, Casablanca, from January 1988 to October 2023, focused on the epidemiological, clinical, paraclinical, and therapeutic aspects of primary hyperparathyroidism. The goal was to promote early diagnosis, relying on imaging data for detecting adenomas and parathyroid nodules.
Results
The study shows an average age of 53.4 years with a notable female predominance (85.93%). The analyses reveal a high average blood calcium level of 114.93 mg/l and an increased average phosphorus level of 22.20 mg/l. The average parathormone (PTH) level is high, at 830.56 pg/ml. Regarding symptoms and complications, 71.87% of patients suffer from bone pain, and 23.43% have renal lithiasis. Ultrasound revealed parathyroid adenomas in 64.06% of patients, while scintigraphy showed hyperfixation in 85.93% of them. CT results indicate that 64% of cases are due to parathyroid adenomas, with 6.25% representing hyperplasia and 1% parathyroid carcinomas. Additionally, 67% of patients have hypovitaminosis D.

Conclusion
These results indicate a significant prevalence of clinical manifestations and paraclinical findings typical of primary hyperparathyroidism. They highlight the importance of early screening and management to prevent complications, especially bone disease and nephrolithiasis. Focusing on correcting hypovitaminosis D could also be an important aspect of treatment for these patients. Surgery remains the standard treatment for removing the responsible adenomas.

Hypomagnesemia in type 2 diabetics and its impact on glycemiccontrol and diabetes chronic complications

Yosra Hasni[1], Jihen Ben Abdallah[2], Hamza Elfekih[1], Oumayma Zarrouk[1], Saoussen Mrad[2], Asma Maalal[2], Chaima Boughzala[2], Nassim Ben Hadj Slama[1] & Molka Chadli Chaieb[1]
[1]University Hospital of Farhat Hached, Endocrinology Departement, Sousse; [2]University Hospital of Farhat Hached, Biochemistry Laboratory, sousse

Introduction
Several studies have incriminated hypomagnesemia in the pathophysiology of diabetes, as the prevalence of this deficit in type 2 diabetics is high, and as it is correlated with glycemic control and chronic diabetic complications.
Aims
Studying the prevalence of hypomagnesemia in type 2 diabetics and assessing its impact on quality of life, glycemic control and chronic diabetic complications. Patients and methods: We conducted a descriptive cross-sectional study over a period from November 01, 2022 to January 31, 2023, including type 2 diabetic patients followed at the endocrinology department of CHU FARHAT HACHED. Data were collected from careful questioning, physical examination and medical records. Missing biological parameters were performed at the biochemistry laboratory of CHU FARHAT HACHED.
Results
We included 190 type 2 diabetics (sex ratio M/F 1.09), with a mean age of 60 $\pm$ 9.9 years and a mean diabetes duration of 11.9 $\pm$ 9.1 years. Diabetic retinopathy was present in 43.5% of our subjects. Diabetic nephropathy and diabetic peripheral neuropathy were present in 33% and 23.6% of patients respectively. 15.3% of our population had a coronary syndrome and 14.2% had a history of stroke or transient ischemic attack. Hypomagnesemia was present in 45.3% of our population, with a mean magnesemia of 0.74 $\pm$ 0.09 mmol/l. It was statistically correlated with fasting blood glucose ($P=0.004$, OR = 2.27) and HbA1c ($P=0.047$, OR = 1.53); for a FPG >8.95 mmol/l and for HbA1c values $>$ 8.25%, the prevalence of hypomagnesemia increases significantly. However, we found no correlation between magnesium and quality of life, nor with chronic diabetic complications.
Conclusion
Hypomagnesemia is a frequent biological abnormality in type 2 diabetics and is significantly correlated with glycemic control. Therefore, its screening in these patients is recommended for possible supplementation.

Impact of age on healthcare costs in type 2 diabetes patients with chronic complications: a retrospective study

Souhir Maalej, Fatma Mnif, Hamdi Frikha, Yesmine Elloumi, Khouloud Boujelben, Dhouha Ben Salah, Faten Hadj Kacem, Nadia Charfi, Mouna Mnif, Mouna Elleuch, Mohamed Abid & Nabila Rekik
Hedi Chaker University Hospital, Endocrinology, Sfax

Introduction
Type 2 diabetes (T2D) is a globally expanding disease with severe consequences. Cardiovascular and renal complications are concerning, leading to high costs for individuals and healthcare systems. Evaluating these costs is crucial to guide health policies and identify factors influencing these expenditures.
Materials and Methods
A retrospective descriptive study was conducted to collect data on diabetic patients with chronic complications. The study included patients hospitalized in the Endocrinology Department of Hedi Chaker University Hospital in Sfax from January 1 to December 31, 2022. The research focused on the impact of age on the expenses of managing complicated diabetes.
Results
The study involved 114 patients, with a sex ratio of 1.28. The average age of our population of T2D patients with chronic complications was 65 years, ranging from 41 to 87 years. In our study, 67.54% of patients were found to have diabetic nephropathy, while diabetic retinopathy and neuropathy were observed in 33.3% and 52.6% of cases, respectively. Among the 90 patients exhibiting cardiovascular involvement, the prevalent macroangiopathy was coronary insufficiency (59.7%), followed by heart failure, peripheral arterial disease, and stroke (10.5%). The average cost per patient was approximately 2,246.46 TND or 713.16 USD for an average hospitalization duration of 7 days. The difference in the average cost of care between patients under 65 and those 65 or older was statistically significant (2773.50 vs 1804.42 TND, $P=0.043$). This finding indicates that patients under 65 have higher care costs than those 65 or older. Table IV provides a detailed analysis of the variations in overall cost between the two age groups based on the different components of this cost. Specifically, advancing age correlated with a decrease in expenses related to cardiovascular, radiological, and medical treatment, with significant correlation coefficients of $r=-0.208$, $r=-0.245$, $r=-0.094$, respectively. Interestingly, age showed a positive correlation with expenses for biological explorations, with a correlation coefficient of $r=0.273$ and a P-value less than 0.001, potentially aiding in alleviating the financial burden and enhancing patient outcomes.
Conclusion
This emphasizes that aging itself, beyond managing classic risk factors, can significantly contribute to the onset of diabetes-related complications. The study's results highlight the importance of closely monitoring elderly diabetic patients, even if they have adequate control of their cardiovascular risk factors, to prevent and manage these complications.

Impact of the use of continuous subcutaneous insulin infusion versus multiple daily insulin injections in adults with type 1 diabetes mellitus

Irene Zayas Aguilar[1], Cristian Jesús Lucena Morales[1], Almudena Lara Barea[1], María de los Ángeles Cutilla Muñoz[1] & Isabel María Torres Barea[1]
[1]Hospital Universitario Puerta del Mar, Endocrinology and Nutrition Department, Cádiz, Spain

Objective
The aim of this study is to assess the impact of continuous subcutaneous insulin infusion (CSII) via a pump for patients with type 1 diabetes mellitus (DM1) on blood glucose and metabolic control.
Materials and methods
A descriptive study was performed in a cohort of patients with DM1, showing blood glucose measurements at one month, six months and one year after implantation of the CSII. In addition, we performed an intra-subject before-after study comparing the parameters with multiple daily insulin injections (MDI) and the use of CSII one month and six months after its implementation.
Results
The study included 34 patients with DM1 (70% women), the mean age was 34.38 años (28.22-40.54) years and the average time to progression of DM1 19.97 years (15.19-24.76). After one month of treatment the glucometric report a Time In Range (TIR) of 76.71% (73.02-80.41), Time Below Range (TBR) 1.93% (1.33-2.52) and Time Above Range (TAR) 21.00% (17.15-24.85); the Glucose Management Indicator (GMI) was 6.77% (6.64-6.91). At six months treatment we highlight: TIR 79.00% (76.29-81.71), TBR 2.10% (1.47-2.72), TAR 18.84% (16.23-21.45), GMI 6.74% (6.64-6.84); with a glycated hemoglobin (A1C) of 7.01% (6.72-7.30). At one year: TIR 80.65 % (78.14-83.15), GMI 6.69 %, (6.55-6.83). In the before-after study ($n=24$; 62.5% women) a significant improvement is observed one month after the use of the insulin pump with respect to MDI treatment: TIR (77.50 vs 55.62; $P<0.001$), TAR (20.55 vs 40.50; $P<0.001$), TBR (1.95 vs 3.87; $P=0.038$), GMI (6.78 vs 7.35; $P=0.003$) and coefficient of variation (CV) (29.93 vs 35.38; $P=0.01$). After six months of treatment, improvements were also observed in TIR (79.41%; $P<0.001$), TAR (18.68%; $P<0.001$), TBR (1.91%; $P=0.034$), CV (30.70%; $P=0.08$) and GMI (6.73%; $P=0.02$).
Conclusions
In the descriptive study, a TIR $>70\%$ was observed with the use of CSII at one month, six months and one year after treatment. In the before and after study, we observed an improvement in glucometric parameters (TIR, TBR, TAR, GMI, CV).

[1]National Institute of Nutrition and Technology, Deparment A, Tunis, Tunisia; [2]Zouhair Kallel Institute of Nutrition and Food Technology, Clinical Biology Laboratory, Tunis, Tunisia

Introduction
The World Health Organization recommends a daily salt intake of no more than 5 grams per day to prevent complications associated with excessive sodium intake. The aim of our study was to screen type 2 diabetic patients for excessive salt consumption using the Exsel Test.
Methods
This was a cross-sectional study including 106 type 2 diabetic patients which took place in department A of the National Institute of Nutrition and Food Technology in Tunis. The duration of the study was 6 months.
Results
The mean age was 55.46 ± 7.51 years. The sex ratio was 0.85. Hypertension was present in 49% of our patients. The mean BMI was 29.68 ± 5.92 kg/m^2. The majority of the population was obese. The mean waist circumference was 97.47 ± 14.18 cm. In our population, 28 patients (26.4%) had a positive Exsel Test. The majority of patients (68.8%) had a daily bread consumption of 240 g. Exsel Test was associated with waist circumference ($P=0.001$). We found a significant difference in BMI ($P=0.001$) between patients who had a positive exsel test and those who had a negative exsel test. In our study, the exsel test was associated with the frequency of consumption of salted cheese ($P=0.001$), preserves ($P=0.005$), oleaginous ($P=0.01$), variants ($P=0.005$) and sauces ($P=0.03$).
Conclusions
The ExSel test is easier to administer than other methods. Using this questionnaire offers a simple and practical way of identifying excessive salt consumers.

Diabetes self-management skills in patients considering Ramadan fasting: Sfax pre-Ramadan education workshops experience

Abdel Mouhaymen Missaoui, Fatma Mnif, Siddiqa Soomauroo, Khouloud Boujelben, Souhir Maalej, Mohamed Abid & Nabila Rekik
Hedi Chaker University Hospital, Department of Endocrinology, Sfax

Background and Aim
Ramadan-specific diabetes education (RDE) is fundamental to achieving safe fasting. During RDE sessions, healthcare providers should perform a risk assessment based on the patient's medical status and his glycemic self-managing competence. This study aims to appraise the educational skills of diabetic patients intending to fast.
Methods
We conducted a cross-sectional descriptive study including 35 diabetic patients who attended the RDE workshops organized by our Endocrinology and Diabetology Department in April 2021. We evaluated the patient educational background by applying self-administered questionnaires.
Results
The mean age was 58.5 ± 12 years, with a female predominance (73.9%). Most of the participants were receiving insulin therapy (56.5%). Some of them attended the workshops accompanied by a supportive family member (28.6%). Poor glycemic control was reported in 47.8%. The attendees had appropriate comprehension of the effects of their anti-diabetic agents in 60.9%. They featured solid dietary managing skills in 52.0%. Hypoglycemic events were more easily recognized and managed than hyperglycemic episodes (91.3% vs 56.5%). Barely 39.1% of patients could discern their specific glycemic targets. However, only 26.1% were performing regular self-monitoring of blood glucose (SMBG). Hypoglycemia, acute illness, and hyperglycemia were considered as indications to break the fast in 88.6%, 74.3%, and 28.6%, respectively.
Discussion
RDE programs should bring individualized knowledge on risk stratification, SMBG, diet, exercise, and physical activity for patients with diabetes. Healthcare providers are responsible for removing misconceptions and adjusting medications in patients considering fasting. Better recognition of circumstances requiring breaking the fast could avoid serious complications linked to food and water restriction during Ramadan. Several studies have demonstrated the clear benefits of these personalized programs on glycaemic control, weight loss, and the reduction of the risk of hypoglycemia, even in higher-risk individuals.

Factors affecting the level of therapeutic literacy in patients with type 2 diabetes

Mouna Elleuch, Insaf Nasri, Wissal Ghamgui, Khouloud Boujelbene, Mnif Mouna, Fatma Mnif, Dhouha Ben Salah, Charfi Nadia, Mohammed Abid, Feten Hadj Kacem & Nabila Rekike
Hedi Chaker Hospital, Endocrinology and Diabetology Department, Sfax, Tunisia

Background
Despite the significant rewards offered by diabetes education, programs are underused with a significant proportion of patients choosing not to attend.
Aim
The aim of this study is to identify the factors that determine the level of knowledge of diabetic patients about their disease.
Methods
Our study involved 61 type 2 diabetic patients followed at the endocrinology department of the university hospital or followed at the city basic health centre.
Results
Only 24.6% of our patients had knowledge of ETP programmes. Only one patient was a member of a diabetes association. Ignorance of the existence of such associations (31.1%) or lack of motivation to participate (26.2%) explained non-adherence in the remaining patients. In our series, socioeconomic status influenced the level of discipline and knowledge of the disease, and more than 45% of the population studied had a low socioeconomic status. Furthermore, it was shown that well-off patients recognized the origin of type 2 diabetes 8 times more than poor patients (OR = 8, $P=0.037$). Our study showed a significant association between a good level of therapeutic literacy and occupation, in particular being a female employee ($P=0.02$), the level of school education (university) and the socio-economic level ($P=0.037$). We confirmed the significant influence of patients' occupational status, educational level and socioeconomic level on their TPE level. There was a significant correlation between the objective assessment of patients' level of TVE and the use of new telecommunication technologies (0.316).
Conclusion
therapeutic education programs should be adapted to the needs of people in precarious socio-economic situations, taking into account their socio-demographic situation, level of education, etc.

Immunotherapy induced endocrinopathies: "pembrolizumab-induced pancreatitis presenting as diabetic ketoacidosis with concurrent hyperthyroidism-related atrial fibrillation"

Mohsin Mukhtar, Irbaz Nazir, Mirza Aftab & Colm McGurk
St. Luke's General Hospital, Kilkenny, Ireland

In this report, we discuss the case of a 77-year-old male with no previous history of diabetes or thyroid disease, undergoing pembrolizumab treatment for malignant melanoma. He presented to the emergency department in diabetic ketoacidosis (DKA) and shock after five days of vomiting, unable to eat or drink. Laboratory findings indicated severe metabolic disturbances, including high blood glucose and amylase levels, consistent with pembrolizumab-induced pancreatitis and subsequent pancreatic insufficiency leading to DKA. Additionally, the patient developed new-onset rapid atrial fibrillation and a thyroid profile indicative of hyperthyroidism, presumably secondary to the immunotherapy. He was successfully managed with a DKA protocol and intensive care, highlighting the complexity of treating immune checkpoint inhibitor-induced endocrine complications and the importance of a multidisciplinary approach in such cases

Physical exercise as a sustainability tool in men affected with metabolic syndrome-related late-onset central hypogonadism: role of endocrine-metabolic and neurovegetative outcomes

Luca Giovanelli[1], Biagio Cangiano[1,2], Silvia Federici[1,2], Daniela Lucini[1,3] & Marco Bonomi[1,2]
[1]University of Milan, Department of Medical Biotechnology and Translational Medicine, Milan, Italy; [2]Istituto Auxologico Italiano, IRCCS, Department of Endocrine and Metabolic Medicine, Milan, Italy; [3]Istituto Auxologico Italiano, IRCCS, Exercise Medicine Unit, Milan, Italy

Background
Late-onset central hypogonadism (LOH), whose prevalence is high among dysmetabolic males, impairs quality of life and increases cardiovascular risk. Although lifestyle modification is the first-line therapeutic strategy, it often fails in clinical practice, probably due to socio-cultural, economic and organisational barriers, as well as the lack of effective and sustainable intervention programs.
Aim
To delineate sustainable physical exercise programs and to assess the effects of such programs mainly on endocrine-metabolic and neurovegetative outcomes in a cohort of men with metabolic syndrome-related central LOH.
Methods
18-80-year-old men, consecutively referred to IRCCS Istituto Auxologico Italiano due to dysmetabolic central LOH, will be enrolled in this prospective study. Participants will undergo a structured and personalised exercise program (accompanied by an adequate nutrition program). After 6 months they will be subdivided into two groups, according to the weekly physical activity volume actually performed (above or below 600 MET·minutes/week). Changes in endocrine-metabolic and neurovegetative outcomes (e.g., gonadal axis function, glucose and lipid profile, body composition, cardiac autonomic regulation (CAR)) will be compared between the two groups. In particular, Autonomic Nervous System Index (ANSI), being extracted from the autoregressive spectral analysis of heart rate variability by combining the three most informative variables, will be used for non-invasive assessment of CAR[1]. Besides, genetic investigations will be performed to explore the potential role of genetic predisposition in the development of dysmetabolic LOH.
Preliminary results and discussion
Seven patients have been hitherto enrolled. As expected, they presented low percentages of fat free mass in the face of increased fat mass, and low SHBG levels. An impairment in both autonomic function (ANSI) was observed in comparison with reference populations from other studies. This is the first study assessing neurovegetative control by means of ANSI in hypogonadal men. Indeed, obesity/insulin resistance is associated with neurovegetative dysfunction, and lifestyle interventions have been shown to improve CAR in dysmetabolic patients. In this context, it will be interesting to explore the possible crosstalk between metabolic syndrome-related hypogonadism, autonomic dysfunction, and physical exercise. Notably, exercise prescription requires the clear definition of modality, intensity, frequency, duration and progression of exercise, tailored on patient's clinical conditions and goals. Intervention programs should be sustainable in economic and organisational terms, with a view to embedding behavioural changes in patient's everyday life.

Management of hypertriglyceridemia-induced pancreatitis - case series

Furhana Hussein[1], Gideon Mlawa[2], Ayan Mohammed[2], Syeda Anika Mahtab[2], Man-Yan Cheung[2], Ali Akram[3], Mariana Dram[2], Mahamud Bashir[2] & Agne Jovaisaite[2]
[1]Queen's Hospital, Endocrinology and Diabetes/Acute Medicine, London, United Kingdom; [2]Queen's Hospital, London, United Kingdom; [3]Queen's Hospital, Endocrine and Diabetes, Romford, United Kingdom

Background
Acute pancreatitis is both a medical and surgical emergency. Common causes of acute pancreatitis include gallstones and alcohol. Hypertriglyceridemia-induced pancreatitis is rare (1-4%); here we discuss management of 5 cases of hypertriglyceridemia-induced pancreatitis.
Case-1
37-year-old female presented to A&E with epigastric pain radiating to back and vomiting. Blood test showed raised amylase, triglyceride 81.6 and cholesterol 6.1. CT-Abdomen showed acute pancreatitis. She was treated conservatively with insulin sliding-scale and intravenous antibiotics. She was discharged on atorvastatin and fenofibrate.
Case-2
45-year-old male presented with abdominal pain radiating to back. Bloods showed raised triglycerides 43.1 and cholesterol 5.1. CT-Abdomen showed acute-on-chronic pancreatitis. Treated conservatively with insulin sliding-scale and kept nil-by-mouth initially.
Case-3
28-year-old female presented with acute generalised crampy abdominal pain and vomiting. Medical history included Type2 Diabetes Mellitus and high BMI. Blood test showed raised triglycerides 71.26. CT-Abdomen showed acute pancreatitis. Managed conservatively with an insulin sliding-scale and discharged on atorvastatin and fenofibrate.
Case-4
42-year-old male was admitted with abdominal pain, diarrhoea and vomiting. Blood showed raised triglycerides 40. CT-Abdomen showed acute pancreatitis. Treated with insulin sliding-scale and analgesia. He clinically improved and discharged with atorvastatin, fenofibrate and lifestyle advice.
Case-5
38-year-old male was admitted with left-upper-quadrant abdominal pain radiating to back and vomiting. Medical history included Type2 Diabetes Mellitus, hypercholesteremia and hypertriglyceridemia (non-compliant with medication). Blood showed raised amylase 378, triglycerides 28.77 and hyperglycaemia of 17. CT-Abdomen showed acute pancreatitis and treated conservatively with insulin sliding-scale and analgesia. Discharged on atorvastatin, fenofibrate and lifestyle advice.
Discussion
Hypertriglyceridemia is an increasing cause of acute pancreatitis and is associated with high morbidity and mortality risk. Hypertriglyceridemia-induced pancreatitis is caused by the hydrolysis of excessive triglyceride-rich lipoproteins releasing high concentrations of free-fatty-acids that cause inflammation of the pancreas. This case series describes initial management is conservative with insulin infusion, intravenous fluids and analgesia. Plasmapheresis is considered in severe pancreatitis where above measures have failed. Contrast-enhanced CT is important to look at severity, presence of gallstones and necrotizing pancreatitis.
Conclusion
Hypertriglyceridemia-induced acute pancreatitis is a rare but a well-established cause of acute pancreatitis. It is important to check lipid profile when a patient presents with acute pancreatitis as it is often associated with greater clinical severity and rate of complications. Early diagnosis with correct treatment will help prevent complications. It is important to advice on lifestyle changes and start on medications such as fenofibrate to help lower serum triglyceride levels.

Inflammatory and nutritional profile of elderly people hemodialyzed

Faten Mahjoub, Ramla Mizouri, Nadia Ben Amor, Rym Ben Othman & Jamoussi Henda
Institut De Nutrition, Tunis, Tunisia

Introduction
Protein-energy malnutrition appears frequently and early in course of chronic renal failure and represents a determining element of the morbidity and mortality. The objective of this study was to evaluate spontaneous food intake and to study the inflammatory profile of elderly people on hemodialysis.
Materials and methods
This cross-sectional and descriptive study involved 40 elderly hemodialysis subjects. All patients underwent a complete clinical examination and a biological assessment with a dosage of C-Reactive protein and a dietary survey by 3 day recording.
Results
The average age of the population was 71 ± 5.9 years. Evaluation of contributions energy consumption of patients showed an average daily intake of 25.3 ± 12.3 kcal/kg of ideal weight/d. The average total energy intake of patients on the day of dialysis and non-dialysis was respectively 29.7 ± 17.7 kcal/kg and 20.9 ± 6.9 kcal/kg with a statistically significant difference ($P = 0.001$). The ration Average protein content was 0.99 ± 0.57 g/kg on the non-dialysis day. It was decreasing statistically significantly ($P = 0.005$) on the non-dialysis day at 0.73 ± 0.28 g/kg. The mean CRP of the study population was 12.3 ± 4.2 mg/l. He exists a positive and statistically significant correlation between the rate of CRP and weight ($r = 0.41$; $P < 0.05$). The analytical study showed no positive association between CRP level and the following factors: age, gender, creatinine clearance and type of nephropathy.
Conclusion
Protein-energy malnutrition is a common pathological situation and serious in elderly hemodialysis patients who may be life-threatening. The development of a Tunisian nutritional guide intended for the elderly hemodialysis is imperative.

Mixed hypertriglyceridemia: a therapeutic challenge!

Ahmed Boukhalfa, Hanane Boualam, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Mohamed VI University Hospital Center, Marrakech, Morocco, Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakesh, Morocco

Introduction
Severe mixed hypertriglyceridemia (SMH) is a highly heterogeneous group of dyslipidemias, both phenotypically and mechanistically (1). The primary origin is dominated by familial combined hyperlipidemia; the most frequent genetic cause. The major concern is the development of acute pancreatitis. We report the case of a patient with mixed hypertriglyceridemia to illustrate the therapeutic difficulties encountered in managing.
Clinical case
Forty-eight years-old patient, type 2 diabetic, hypertensive, followed for mixed hypertriglyceridemia with hepatic steatosis. Initially put on a hypocaloric and hypolipidic diet with a combination of fenofibrates and statins, discontinued because of cholestatic hepatitis. Examination: bilateral corneal arc with xanthomas of the hands and left gluteal region. Lipid profile: total cholesterol: 5.53 g/l HDL-C: 0.4 g/l, TG: 14.2 g/l. Normal lipasemia. Cardiovascular workup showed concentric LVH. Indication for LDL apheresis was made, but the patient's lipid profile showed an incomplete response and fluctuated. Over the course of the last 3 sessions, the patient experienced malaise, hypotension and bradycardia, which led to suspension of LDL-apheresis. Given the improvement in liver function, treatment with fenofibrate 160 mg and pravastatin 40 mg, supplemented with omega-3 fatty acids, was reintroduced with good results.
Discussion and conclusion
Hypertriglyceridemia (HTG) is a common condition, most often caused by multiple, interrelated factors. Genetic hypertriglyceridemias are apparently uncommon. (2). Mixed HTG increases the risk of cardiovascular and cerebral events, and is frequently associated with metabolic syndrome. Acute pancreatitis is an extremely serious complication, and should be avoided in all cases of severe HTG. HTG accounts for 1-10% of all AP etiologies (3). Genetic diagnosis has precise indications. In our patient, after eliminating secondary causes, an essential mixed dyslipidemia was suggested. Fibrates and statins can trigger toxicity or worsen already impaired liver function, so they should be discontinued (4). LDL-apheresis is a better therapeutic alternative, especially in emergency situations (5), despite its limited cost and availability. Family screening is essential for children, and for women of childbearing age planning a pregnancy (1).

Keywords: Hypertriglyceridemia, pancreatitis, apheresis, statins, fibrates, genetics.

Plasmapheresis as treatment for hyperlipidemic severe pancreatitis

Zineb Ait Si Ali, Neima Hassan, Sana Rafi, Ghizlane El Mghari & Nawal El Ansari
Centre Hospitalo-Universitaire Mohammed VI Marrakech, Department of Endocrinology, Diabetology, Metabolic Diseases and Nutrition, Marrakech, Morocco

Introduction
Plasmapheresis is an extracorporeal blood purification method that removes potentially harmful macromolecules (molecular weight L15 - 50 kDa) from the blood. Pancreatitis is a potentially fatal complication of hypertriglyceridemia. The current mainstay of treatment for hypertriglyceridemia associated with pancreatitis includes heparin, insulin and lipid-lowering agents. Experience with plasmapheresis is limited. We report here our experience of using plasmapheresis in the treatment of a patient with severe acute pancreatitis induced by major hypertriglyceridemia.
Case report
A 40-year-old female patient with no specific pathological history, including no known dyslipidemia, diabetes, thyreopathy or nephropathy. Admitted to intensive care for grade E pancreatitis, revealed by a sharp pain in the epigastric region, radiating to the back associated with nausea and vomiting, evolving 3 days prior to her admission. Clinical examination revealed a conscious patient, hypotension to 84/60 mmhg, tachycardia to 105 bpm, polypneac to 30 cpm, distended abdomen with diffuse abdominal sensibility. No cutaneous xanthoma or eruptive xanthomatosis were found. On workup: WBC: 3100 hb: 10.7 plq: 362000 Triglycerides: 21.48 g/l Total cholesterol: 3.9 g/l PT: 87% Urea: 1.34 Creatinine: 55.13 mg/l GFR calculated at 9.11 ml/mn Natremia: 124mmol/l K: 5.12 mmol/l Calcemia: 49.88 mg/l Albumin 31g/l Calcemia corrected: 60 mg/l rechecked 48 h later at 84.89 mg/l CRP: 670 mg/l lipase 31.99ui/l. Abdominal CT: grade E pancreatitis with multiple fluid collections around the pancreas and important ascite. The patient underwent 2 sessions of plasmapheresis and 2 sessions of hemodialysis. The clinical and paraclinical outcome was favorable, with a control triglyceridemia of 4.55 g/l and improvement of renal function.
Discussion and conclusion
Betteridge *et al*, were the first to perform apheresis to lower triglyceride concentrations in 1978. Since then, plasmapheresis has become a therapeutic tool for major hypertriglyceridemia. Studies currently available have demonstrated that apheresis treatment is effective in rapidly and significantly lowering triglyceride concentrations. Most studies have shown that plasmapheresis generally reduces triglyceride levels by 60-70% in a single session. Relief of acute pancreatitis symptoms after one to three sessions of plasmapheresis has been reported. In addition, several studies have noted that a maximum reduction in morbidity and mortality can be achieved when plasmapheresis is used as early as possible.

Proteolytic cleavage of insulin receptor in the skeletal muscle of a wistar rat model of metabolic syndrome

Wendy Priscila Alcantar Villasana[1], Juan Pablo Pánico[2] & Marcia Hiriart[1]
[1]Instituto de Fisiología Celular, Neurociencia Cognitiva, Ciudad de México, Mexico; [2]Instituto de Investigaciones Biomédicas, Medicina Genómica y Toxicología Ambiental, Ciudad de México, Mexico

Extracellular proteolytic cleavage of insulin receptor (IR) and the generation of soluble insulin receptor (sIR) is a response of the liver and fat associated with physiological conditions and metabolic alterations mainly related to hyperinsulinemia. However, cleavage of this receptor has not been analyzed in skeletal muscle, a central tissue in insulin-mediated glucose homeostasis. This study aimed to analyze the insulin receptor subunits in the gastrocnemius and soleus muscles in a model of male young Wistar rats of metabolic syndrome induced by sucrose 20% in drinking water for 8 weeks. Using quantitative western blot analysis, we found the presence of at least 7 protein bands when using an antibody against the alpha subunit under reducing and non-reducing conditions. The band with the highest molecular weight in non-reducing conditions, which appears close to 315 kDa, possibly corresponds to the intact insulin receptor, whose abundance is not altered in our model. A greater abundance of the 157 kDa and 60 kDa fragments in non-reducing conditions and 25 kDa in reducing conditions was found in the treated animals compared to the control group. An additional 48 kDa fragment was found in the soleus muscle under non-reducing conditions, whose presence could be related to the metabolic differences between both muscles. A subsequent *in silico* analysis suggested that the fragments obtained through western blot may correspond to fragments resulting from proteolysis mediated by membrane proteases families (ADAM, MMP, calpains) that have been implicated in the past in the generation of IR soluble ectodomain. These findings suggest the shedding of IR from skeletal muscle in a hyperinsulinemic state characteristic of our metabolic syndrome model.

Characteristics of obese patients with a body mass index (BMI) of > 50 who opted for metabolic/bariatric surgery

Bunzo Matsuura, Hironobu Nakaguchi, Hidenori Senba, Ayumi Kanamoto, Masumi Miyazaki, Akihito Shiomi, Teruki Miyake, Shinya Furukawa & Yoichi Hiasa
Ehime University Graduate School of Medicine, Toon, Japan

Aim
The basis of treatment for obesity is diet and exercise therapy. Since 2006 at our hospital, lifestyle modification, such as diet and exercise, for obese patients has been provided through a team approach with a physician, dietician, nurse, physical therapist and psychologist. From 2016, a surgeon and anesthesiologist were added to the team for metabolic/bariatric surgery. The aim of this study is to clarify the characteristics of patients with a BMI of 50 or more who opted for metabolic/bariatric surgery (laparoscopic sleeve gastrectomy: LSG).
Patients & Methods
Of 40 patients who were received LSG between January 2017 and December 2021, 9 were in the super-obese (S) group with a BMI of 50 or more and 31 were in the obese (C) group with a BMI of 30 to less than 50. The preoperative weight loss rate, postoperative weight loss rate, postoperative body composition change rate, and postoperative rebound rate were compared.

Results
The male/female ratio in group S vs group C was 6/3 vs 13/18, mean age (years) was 42 vs 45, diabetes mellitus/other complication was 3/6 vs 21/10, mean preoperative weight (kg) was 160 vs 108, mean BMI was 57 vs 40. The preoperative weight loss rate (%) was 10.0 vs 5.6, 6-month postoperative weight loss rate (%) was 20.0 vs 16.4, and 1-year postoperative weight loss rate (%) was 21.6 vs 17.3. There was no difference in diabetes complete remission rate. There was a significant less postoperative weight rebound rate in group S than that in group C.
Conclusions
The surgical treatment was required in patients with very high obesity, with or without diabetes mellitus, and even if preoperative weight loss of 10% or more was achieved.

Screening and quantification of hepatic steatosis in obese patients using the controlled attenuation parameter (CAP)

Ahmed Mohamed Nefzi, Cherif Dhouha, Kahlaoui Fatma, Dabbebi Habiba, Yacoub Haythem, Hassine Hajer, Kchir Hela & Maamouri Nadia
RABTA Hospital, Hepato-gastroenterology "B", Tunis, Tunisia

Introduction
Liver steatosis currently represents a hepatic manifestation of metabolic syndrome. It occurs more frequently in patients with obesity, and liver biopsy remains the gold standard for the positive diagnosis of this condition. In recent decades, the positive diagnosis of hepatic steatosis has increasingly relied on non-invasive methods such as Controlled Attenuation Parameter (CAP). The objective of this study was to investigate the prevalence of hepatic steatosis diagnosed via CAP among obese patients and to determine the factors associated with the occurrence of moderate to severe steatosis in this group.
Methods
This is a retrospective, single-center, descriptive study including all obese patients undergoing screening for hepatic steatosis via CAP integrated into the Fibroscan Echosens 502 device. We collected age, various medical histories, anthropometric measurements, and CAP values. Obesity and its different classes were defined according to the World Health Organization recommendations. The different degrees of hepatic steatosis were defined as follows: Absence of steatosis (S0): CA$P < 294$ dB/m, Mild steatosis (S1): CA$P < 310$ dB/m, Moderate steatosis (S2): CA$P < 331$ dB/m, Severe steatosis (S3): CAP≥ 331 dB/m.
Results
Our population included 94 patients with an average age of 53.42 ± 11.4 years, ranging from 28 to 81 years, and a gender ratio of 0.3. Various medical histories were distributed as follows: Type 2 diabetes (29%), hypertension (23.7%), dyslipidemia (20.4%), hypothyroidism (7.5%), and obstructive sleep apnea syndrome (OSA) (1.1%). The mean BMI was 35.72 ± 4.8 kg/m^2, ranging from 30 to 54.5 kg/m^2. We observed hepatic steatosis in 50% of patients ($n=47$). The mean CAP value was 290.22 ± 60 dB/m, ranging from 109 to 400 dB/m. The different degrees of hepatic steatosis were distributed as follows: S1 (14.9%), S2 (29.8%), S3 (55.3%). In univariate analysis, factors associated with the occurrence of moderate to severe steatosis (S2-S3) were male gender ($P=0.028$), associated dyslipidemia ($P=0.047$), and BMI ≥ 35 kg/m^2 ($P=0.037$). In multivariate analysis, male gender and BMI ≥ 35 kg/m^2 were independently associated with the occurrence of moderate to severe steatosis in obese patients, with respective P-values of 0.02 and 0.03, and odds ratios of 3.47 and 2.68.
Conclusion
Our study suggests a notable prevalence of hepatic steatosis in obese patients, with greater severity in males with Class II and III obesity.

Study of patients referred for obesity to a nutrition consultation

Jose Antonio Ariza Jimenez[1], Maria del Carmen Vázquez Alférez[1] & Jorge Marín Martín[2]
[1]Hospital la Merced, Endocrinology and Nutrition, Osuna (Sevilla), Spain; [2]Hospital la Merced, Internal Medicine, Osuna (Sevilla), Spain

Introduction
Changes in dietary habits coupled with sedentary lifestyles have led to a true pandemic of obesity. This situation has also been observed in the new nutrition consultation at La Merced Hospital in Osuna (Seville), where, after 6 months of operation, 88.9% of the patients were referred due to obesity.
Objective
To analyze the profile of patients referred for obesity to the nutrition consultation at La Merced Hospital, as well as the sources of these referrals.
Materials and Methods
An observational descriptive study was conducted. Patients referred for obesity to the Nutrition Consultation at La Merced Hospital from August 1 to December 31, 2023, were recorded. The age, gender, and body mass index (BMI) of the patients were analyzed, along with the specialty making the referral. The official referral criteria were BMI >40 or 35 kg/m^2 with at least two comorbidities (diabetes, hypertension, dyslipidemia, or sleep apnea syndrome).
Results
A total of 137 patients referred for obesity were attended. 86 were females (62.77%), and 51 were males (37.23%). The mean age was 53 years (14-80), with the mean age for males being 52.33 years and for females 52.51 years. The mean BMI was 41.50 kg/m^2, with males at 41.92 kg/m^2 and females at 41.23 kg/m^2. Internal Medicine referred a total of 48 patients, followed by Traumatology with 32 patients, Pneumology with 24 patients, Surgery with 12 patients, Primary Care with 11 patients, Cardiology with 4 patients, Digestive with 2 patients, and Rheumatology, Anesthesia, Neurosurgery, and Rehabilitation with 1 patient each.
Conclusions
Obesity dominates most of the activity in the new nutrition consultation at La Merced Hospital. More women than men have been referred (62.77% vs 37.23%). The specialty that has referred more patients to the nutrition consultation for obesity is Internal Medicine, followed by Traumatology and Pneumology.

Metabolic syndrome: assessment of the role of biochemical indicators in diagnostics

Olga Moskalenko & Eduard Vilyamovich Kasparov
Federal Research Center «Krasnoyarsk Science Center» of the Siberian Branch of the Russian Academy of Sciences, Russian Federation

Metabolic syndrome (MS) is a pressing problem of modern medicine. The prevalence of MS has a worldwide tendency to increase and depends on many factors, which explains the difficulty in diagnosis, prevention programs and treatment of this pathology. It has been established that MS has a multifactorial etiology, in which psycho-social factors, genetic and environmental factors are important. At the subclinical stage, functional and biochemical changes associated with MS are reversible and with proper treatment, the severity of MS manifestations can be reduced. MS is defined as a combination of 3 of 5 conditions: central obesity, decreased cholesterol, high-density lipoprotein, increased triglycerides and blood glucose, arterial hypertension. Purpose of the study: to evaluate individual biochemical parameters in the development of metabolic syndrome.
Materials and methods
The main study group included 76 patients with MS and 41 people without MS, practically healthy volunteers (control group), comparable in age and gender to the main group. Blood plasma was studied: glucose levels were measured using the glucose oxidase method; The lipid profile was assessed (total cholesterol, total cholesterol, TG, NEFA, FL). Insulin was determined by enzyme immunoassay using the DRG test system. All study participants signed an informed consent approved by the ethics committee. Statistical data processing was carried out using application packages 'STATISTICA 10.0'.
Results
When analyzing the results obtained, an increase in the values of the insulin resistance index - HOMA-IR was revealed. This coefficient has the greatest diagnostic value and has received wide practical application. Calculation of HOMA-IR revealed an almost 2-fold increase in this indicator in patients with MS ($P<0.05$), which is a predictor of the risk of developing diabetes and cardiovascular diseases. The level of NEFA in patients with MS was increased in 95% of cases and was almost 2 times higher than normal values. Also, in patients with MS there was an increase in the levels of insulin and glucose in the blood compared to the control group ($P<0.05$). In patients with MS, the levels of total cholesterol and FL were normal, falling within the range of threshold values.
Conclusion
Thus, there is no doubt that early diagnosis of MS is important and currently the most effective strategy in preventing the progression of metabolic disorders is lifestyle correction (diet changes, weight loss, regular physical activity) in combination with pharmacotherapy or without drug treatment.

Enhancing nutritional assessment in tunisian children: development and validation of an arabic version of the quesca nutritional questionnaire

Ben Othman Rym, Amorri Amani, Salma Abadlia, Ben Zina Baya, Ben Mansour Nadia, Kasraoui Sabeh, Gamoudi Amel & Jamoussi Henda
National Institute of Nutrition and Food Technology, Tunis

Introduction
Unhealthy eating behaviors are common in children. Therefore, assessing children nutritional knowledge is crucial. The QuesCA, a validated French tool, serves this purpose. Our study aimed to develop and validate an Arabic version of QuesCA.
Methods
We conducted a multicenter cross-sectional study from December 2021 to June 2022. Our study was conducted at the National Center for School and University Medicine in Tunis and five randomly selected nurseries in Ariana governorate. Six hundred children aged from 9 to 15 years were included.
Results
Our study was conducted in two phases. The first phase focused on the development and validation of the Arabic version. Initially, two independent forward translations were conducted. One by a committee of Tunisian nutrition experts (focus group), and the second by a sworn translator. The focus group reviewed the obtained Arabic versions, identifying errors, detecting divergences, and adapting them to Tunisian specificities. Subsequently, a French national proficient in both French and literary Arabic performed a backward translation of the questionnaire. Using the Delphi procedure, the focus group compared the back-translation with the original version, producing thus a consensus translation deemed suitable for children in Tunisia. After the Delphi procedure, we sought opinions from primary and secondary school teachers regarding the obtained Arabic version. Then, a pre-test was conducted on 30 randomly selected students aged 9 to 15 in a primary school in Gabes governorate using the Arabic version. Ultimately, we obtained a final translated Arabic version through the development and revision process by the focus group. The second phase aimed to evaluate the reliability and validity of the finalized Arabic version. The 600 participants were debriefed for phrasing or comprehension issues, with noted comments and questions. Post-questionnaire, participants received correct answers and nutritional education sessions. For the reliability analysis, the global Cronbach's alpha was 0.3, below the threshold (0.7). Despite recalculations after removing items with low correlations, the alpha value remained below the threshold. Thus, we decided to keep the questionnaire unchanged with the same number of items. After reliability analysis, validity analysis was tested. Construct validity was not assessed given the single-item representation of each questionnaire theme, while content validity was thoroughly evaluated by the focus group.
Conclusion
Our study developed a validated Arabic version of the QuesCA questionnaire. Challenges, like a low reliability coefficient, emphasize the need for further research to refine the questionnaire

Sexuality in obese and pre-obese women: a descriptive cross-sectional study

Kouloud Boujelben[1], Mohamed Khairi Arous[1], Fatma Mnif[1], Dhouha Ben Salah[1], Mouna Elleuch[1], Rim Djebbi[2], Faten Haj Kacem[1], Nadia Charfi[1], Mouna Mnif[1], Mohamed Abid[1] & Nabila Rekik[1]
[1]Hedi Chaker Hospital, Endocrinology, Sfax, Tunisia; [2]Faculty of Medecine of Sfax, Sfax, Tunisia

Introduction
Obesity is a global pandemic with adverse health implications, notably impacting quality of life, including sexuality. There is growing evidence that obesity adversely affects sexuality, not only in males but also in females. The objective of our study was to ascertain the influence of obesity on various phases and aspects of sexual activity
Methods
We conducted a descriptive cross-sectional study involving women who engaged in sexual intercourse within the past four weeks and whose body mass index exceeds 25 kg/m^2;. For the assessment of sexual function, we utilized the Arabic version of the Female Sexual Function Index (arFSFI), where a score below 23 indicates female sexual dysfunction. All patients provided oral informed consent freely and voluntarily
Results
The study included 50 overweight and obese women, with a mean age of 38.5 $\pm$ 9.45. The average duration of marriage/cohabitation was 11.8 years. The majority of women were educated (88%). More than two-thirds of participants (78%) were obese, and 22% were overweight. Most women (80%) were in the reproductive age group, 6% had primary or secondary amenorrhea, and 14% were menopausal. The mean BMI was 37 $\pm$ 8.7 kg/m^2;. The average Female Sexual Function Index (FSFI) score was 27.4 $\pm$ 6.2. We observed that 12% had sexual dysfunction, 42% had a lack of desire, and 24% experienced pain during sexual intercourse.
Discussion and conclusion
The rate of women experiencing sexual dysfunction is lower than that reported in the literature. This could be explained by the difficulty women in our context face in discussing their sexuality in general and their discomfort in particular. The lack of desire may be associated with a negative perception of body image. Our study emphasizes the need to raise awareness and educate healthcare professionals working with obese women on sexual health, in order to detect dysfunctions and improve the quality of life for patients.

Epidemiological profile of chronic renal disease in obese people: prospective study in avicenna military hospital - marrakech

El Jadi Hamza[1] & Hicham Baizri[2]
[1]Avicenna Military Hospital, Endocrinology and metabolic diseases, marrakech, Morocco; [2]Avicenna Military Hospital, Endocrinology and metabolic diseases, Marrakech, Morocco

Obesity is accompanied by chronic diseases including cardiometabolic diseases. Obesity is also an independent factor of renal risk that deserves to be taken into account. The aims of our work were to determine the prevalence of chronic kidney disease related to obesity independently of all other usual risk factors and to describe its epidemiological characteristics in our population. We conducted a prospective descriptive and analytic study over a period of 12 months in 38 patients over 18 years of age, with a BMI $>$ 30 Kg/m^2 and without diabetes, hypertension, or other apparent cause chronic kidney disease, collected at the consulting service of the Military Hospital Avicenna of Marrakech. The average age of our patients was 38 years with a female predominance (sex ratio (m/w) of 0.80). The average BMI was 35.35 kg/m^2;, the average TT was 98.61 cm with android obesity in 88.2% of men and 85.7% of women. Dyslipidemia was found in 68.42% of patients, hyperuricemia in 18.42%, microalbuminuria in 13.15%, macroalbuminuria in 7.89% and hematuria in 2.6%. Glomerular hyperfiltration was present in 13.15% of cases and no patient had a GFR $<$ 60 ml/min/1.73m^2. The prevalence of chronic kidney disease among obese people in our population was 10.5%. Older obese patients with high BMI, hypertriglyceridemia, hypercholesterolemia, and hyperLDLemia were the most affected, with statistically significant differences between the 2 groups of patients with and without chronic kidney disease ($P < 0.05$). The results of our study warn of the need for cost-effective and well-adapted prevention measures to reverse the growing epidemic of obesity in the world.

The controlled attenuation parameter (CAP) and metabolic syndrome: is there a link?

Meriam Dalhoum[1], Olfa Berriche[1], Rim Ben Othmen[1], Emna Talbi[2], Raja Tlili[3], Sahar Hamza[3], Amel Gammoudi[1], Awatef Kacem[2], Lamia Kallel[3] & Henda Jamoussi[1]
[1]National Institute of Nutrition in Tunis, Human Obesity Research Unit, Tunis, Tunisia; [2]National Institute of Nutrition in Tunis, Biochemistry Laboratory, Tunis, Tunisia; [3]Mahmoud El Matri Hospital, Ariana, Tunis, Gastroenterology Department, Tunis, Tunisia

Introduction
The prevalence of non-alcoholic fatty liver disease (NAFLD) is increasing worldwide. Since its earliest descriptions, NAFLD has been associated with the metabolic syndrome and its components.
Objective
To assess the relationship between Controlled Attenuation Parameter (CAP) values and the various components of metabolic syndrome.
Materials and methods
We carried out a longitudinal study including 161 patients with non-alcoholic fatty liver detected by a fibroscan using the CAP function (threshold $>$ 248 dB/m

for M and XL probes) and followed up for obesity at the Human Obesity Research Unit of the National Institute of Nutrition in Tunis. They were interviewed, anthropometrically measured (weight, height, body mass index (BMI), waist circumference (WC)) and biologically assessed.
Results
The mean age of our population was 49.23 ± 11.15 years. Patients were divided into 143 women (88.8%) and 18 men (11.2%). Mean BMI was 41.14 ± 6.37 kg/m^2; and mean WC was 119.21 ± 14.82 cm. Among our patients, 59 (36.6%) had diabetes, 66 (41%) were hypertensive, 63 (39.1%) had hypertriglyceridemia and 90 (55.9%) had hypo-HDL cholesterol. The prevalence of metabolic syndrome in our patients was 57.9% and the severity of hepatic steatosis increased significantly with the prevalence of metabolic syndrome ($P < 0.001$). In univariate analysis, there was a statistically significant positive linear relationship between CAP and the majority of metabolic syndrome parameters except hypoHDL cholesterol, CAP values were significantly higher in patients with diabetes, hypertension and hypertriglyceridemia respectively (respectively $P = 0.004$; $P = 0.02$ and $P = 0.016$ respectively).
Conclusion
Our study shows that there is a significant correlation between CAP values and the various parameters of the metabolic syndrome, which thus favors the onset of hepatic steatosis in obese patients, justifying comprehensive management targeting all risk factors.

Changes in sex hormone levels after bariatric surgery and its association with weight loss in morbidly obese patients

Vindya Wellala[1], Udai Wijethunga[2], Dr. Udith Bulugahapitiya[3], Anuradha Jayasuriya[2] & Hasani Karunarathna[4]
[1]University Hospital Coventry & Warwickshire, United Kingdom; [2]Colombo South Teaching Hospital - Kalubowila, Dehiwala-Mount Lavinia, Sri Lanka; [3]National Hospital of Sri Lanka, Colombo, Sri Lanka; [4]University of Colombo, Colombo, Sri Lanka

Introduction
Bariatric surgery has become an essential option for long-term weight loss in morbidly obese population.
Objective
This study was aimed at investigating the effects of bariatric surgery on sex hormone levels and potential hormonal changes associated with significant weight loss in a cohort of 49 patients with obesity.
Methodology
Forty-nine patients with obesity, scheduled for bariatric surgery in Colombo South Teaching Hospital, Sri Lanka were enrolled in this prospective study. Preoperative assessments included demographic information and anthropometric measurements. The baseline sex hormones, including follicular stimulating hormone (FSH), luteinizing hormone (LH, testosterone), Sex Hormone Binding Globulin (SHBG), and symptomatology related to hypogonadism, were collected. Postoperative follow-ups were conducted at regular intervals to evaluate weight changes and hormonal profiles.
Results
Thirty-one females and 19 males were analysed. The mean weight before surgery among females were 124 kg (SD = 16.7), and males were 129.1 kg (SD = 19.6). The prevalence of Polycystic Ovary Syndrome (PCOS) in females was 64.5% ($n = 20$). The prevalence of obesityrelated hypogonadism was 64% ($n = 11$) among males. The average weight loss by 12 months after surgery was 40.2 kg (95% CI 36.7–43.63, $P < 0.05$) in females, and males had an average weight reduction of 39.2 kg (95% CI 33.00–45.54, $P < 0.05$). The Sex hormone binding globulin (SHBG) level was significantly increased in males 63.9% from baseline (95CI; 40.9-86.5: $P < 0.05$) and females in 50.5% from the baseline (95%; 61.75-121.3; $P < 0.05$) at the end of 12 months after surgery. It was positively correlated with weight loss, percentage of total fat loss and waist circumference reduction in both males and females. Total testosterone increased significantly in men at the end of 12 months 6.4 nmol/l (95%C; I4.2-7.6: $P < 0.05$. Total testosterone levels showed a significant positive correlation with weight loss parameters in males. There was no significant correlation found in gonadotrophin levels or oestrogen levels in males or females. The free androgen index improved in females at the end of 12 months, but no significant change was seen in males. These changes led to the resolution of PCOS in 72.4% of the female population. And obesityrelated male hypogonadism led to a resolution of 84.3%.
Conclusions
There was significant improvement in SHBG following bariatric surgery in males and females. The remarkable rate of resolution of PCOS and male obesity-related hypogonadism after bariatric surgery provides strong evidence supporting a causal role of obesity and adipose tissue dysfunction in the development of gonadal dysfunction in severely obese subjects.

Factors associated with the risk of developing eating disorders in young doctors

Faten Haj Kacem Akid, Hana Charfi, mouna elleuch, Dhoha Ben Salah, Fatma Mnif, Nadia Charfi, Mouna Mnif, Mohamed Abid & Nabila Rekik Majdoub
Hedi Chaker Hospital, Sfax, Tunisia

Introduction
Young doctors in training are considered a population at risk for developing eating disorders. These disorders have multifactorial origins and require early and rapid screening, often utilizing the SCOFF questionnaire. Our aim is to screen and identify factors associated with the development of eating disorders among medical residents.
Materials and Methods
This is a cross-sectional, descriptive, and analytical study involving 70 medical residents working at Hedi Chaker University Hospital in Sfax over a 2-month period: November and December 2023. A self-administered questionnaire was distributed to our population using the Google Forms application.
Results
The average age of our population was 28 years, with a clear female predominance and a sex ratio of 0.55. Eating disorders were present in 27% of our population. Within our sample, 10% of medical residents had a history of psychiatric disorders, especially depression, and 79% used psychoactive substances, particularly coffee. Among participants, 56% engaged in weight control methods, especially through dietary habits and exercise. Psycho-affective consequences were observed, with 20% of the studied population showing symptoms of anxiety, and 10% exhibiting depressive symptoms. Among the factors studied, the use of weight control methods, the use of psychoactive substances, and anxiety were significantly associated with the risk of developing an eating disorder (P-value less than 0.05). Other factors were investigated, but they were not significantly related to the risk of eating disorders, such as gender, marital status, socioeconomic status, and depression.
Conclusion
The results of our study underscore the importance of screening for eating disorders in young doctors undergoing training. Additionally, socio-cultural, clinical, and psychological factors were associated with the risk of developing eating disorders in our population.

Prediction of body fat percentage: development and validation of new anthropometric equations

Hadda Meroua Hani[1], Bennouar Salam[2], Kerrouche Asma[1] & Abdi Samia[2]
[1]Departement of Pharmacy, Faculty of Medecine, University SAAD DAHLEB, Blida; [2]Central Laboratory of Clinical Biology, University Hospital Center of Blida, Blida

Introduction
Obesity is a public health concern, several evidence have linked excess body fat to various metabolic disorders such as type 2 diabetes. In clinical practice, body mass index (BMI) is the most commonly used anthropometric index to define overweight and obesity given its simplicity and affordability. However, it has many limitations that are now widely recognized. Indeed, BMI is unable to compartmentalize body weight. Moreover, its cut-off values for the diagnosis of overweight and obesity set by the World Health Organization (WHO) are also advised, regardless of age, gender or physical activity level.
Aim
The aim of this study was to test the validity of existing equations, retrieved from the literature, in the Algerian adult population. To develop, and validate, new predictive equations for body fat percentage (%BF) using simple and easy-to-measure anthropometric parameters.
Methods
This is a cross-sectional study including 877 Algerian adults who underwent a body composition assessment by the direct segmental multi-frequency bioelectrical impedance technique (Inbody770). Participants were randomly divided into two groups: the development group ($n = 577$) and the validation

group ($n=300$). To develop the equations, multiple linear regression models were analyzed. The predictive performance of the developed equations was compared with the direct technique. The following validation tests were used: Student's t-test for paired samples, correlation, and BlandeAltman diagram. Diagnostic accuracy has also been assessed.

Results

Four existing equations were tested, and all showed statically significant bias. Four new equations were developed; all had satisfactory predictive performance, with a correlation coefficient ranging from 0.72 to 0.94 in men and 0.87 to 0.93 in women. The best-fitting equation was based on body mass index, waist-to-hip ratio, and chest circumference. The diagnostic accuracy of this equation was 96.7% in men and 95.3% in women.

Conclusion

The newly developed equations based on anthropometric parameters can serve as a simple tool for the accurate prediction of BF% in adult subjects, at both individual and epidemiological levels.

Hypogonadism in men with type 2 diabetes: a close look at anthropometric insights

Anis Grassa, Manel Jemel, Salma Salhi, Brahim Khalfa, Marwa Chiboub, Emna Talbi, Hager Kandara & Ines Kammoun
National Institute of Nutrition and Food Technologies, Zouheir Kallel

Introduction

Obesity and hypogonadism (HG) are two conditions frequently observed in people with type 2 diabetes (T2D). The complex relationship between obesity and hormonal imbalances, particularly hypogonadism, remains a key area of interest in understanding the overall health profile of men with T2D.

Methods

In this cross-sectional study involving 250 men with T2D undergoing diabetes consultations, comprehensive clinical examinations were carried out, including measurements of weight, height, and waist circumference(Wc). Testosterone levels, specifically Free Testosterone (FT) and Bioavailable Testosterone (BT), were determined using the Vermeulen formula[1]. Hypogonadism was defined by meeting one of the following criteria: Total Testosterone (TT) below 231 ng/dl, FT below 6.5 ng/dl, or BT below 150 ng/dl. We defined two groups: (HG) hypogonadic patient and (non-HG) for non hypogonadic patients. Antropometric indices were compared in the two groups.

Results

The median age (IQR) of men with HG was 59 years [56-64], with a prevalence of 27.2% ($n=68$). In comparison to the non-HG group, patients with HG had a higher average weight (84.9 ± 14.3 vs 82.7 ± 11.7 kg; $P=0.192$), as well as a higher BMI (28.3 ± 4.5 vs 27.9 ± 3.8; P 0.492). The mean WC was also higher in the HG group (98.3 ± 10.3 cm vs 97.3 ± 8.9; P 0.481), as well as android fat distribution (65.7% vs 67.0%; P 0.471). Although obesity was higher in the HG patients (35.8% vs 26.7%), this difference was not significant ($P=0.162$). A significant inverse correlation was found between weight and the levels of TT (r: -0.313, $P<10^{-3}$), FT (r: -0.141, $P=0.030$, and BT (r: -0.134, $P=0.036$). In a multivariate analysis, considering age, glycemic control, and inflammatory status, weight emerged as an independent risk factor for HG in men with T2D. Indeed, each kilogram of weight was associated with a 1.05 times increased risk of HG (adjusted Odds Ratio = 1.05; 95% confidence interval = [1.01-1.08]; $P=0.006$).

Conclusion

These findings underscore the significant role of weight as an independent risk factor for HG in men with T2D, even after adjusting for other relevant variables. Further research and interventions targeting weight control may contribute to improved hormonal health outcomes in this patient population.

Managing childhood obesity: teleconsultation as good as routine care

Bharat Saboo[1], Aniket Inamdar[2], Shweta Saboo[3], Dhruvi Hasnani[4] & Vipul Chavda[5]
[1]Prayas Diabetes Center, Metabolic health, Indore, India; [2]Samarpan clinic, Omerga, India; [3]Prayas Diabetes Center, Indore, India; [4]Rudraksha Institute of Medical Sciences, Ahmedabad, India; [5]Rudraksha institute of medical sciences, Ahmedabad, India

We all know that care delivery can become too much exhaustive and regular follow-up by patients in not maintained in India due to various reasons. This study aimed to compare the long-term effects of tele consultation (TC) and routine care (RC) on the weight status of children with obesity. Patients aged 5-14 years from the OPD, India were assigned to either TC or RC for 6 months after completing a standard obesity treatment programme during the period of march 2022 to July 2022. They were followed up for an average of 1 year. The study included 32 children (TC, $n=16$ and RC, $n=16$) with a mean (SD) age of 12.8 (3.5) years and a BMI SDS of 3.8 (0.4). There was no significant difference in BMI SDS change between the groups during the study ($P=0.7$) or at 1.5 years after the first clinic visit, TC = - 0.54 and RC = 0.57 BMI SDS units ($P=0.7$). Gender did not affect the results. The groups also did not differ in the average time spent by caregiver per patient during the study ($P=0.6$). All patients completed the follow-up. The study concluded that TC was as effective and efficient as RC in treating paediatric obesity and could provide more flexibility for patients and healthcare providers. Also in a resource crunched country like India it can be of a great help to provide optimum healthcare. More work in this area is needed.

Effect of Macronutrient Intake on Tolerance to Chemotherapy in Breast Cancer Patients

Selma Mohsen[1], Berriche Olfa[1], Ben Mansour Hajer[2], Rym Ben Othman[1], Mehrez Achwak[1], Mezlini Amel[2] & Jamoussi Henda[1]
[1]National Institute of Nutrition, Service A, Tunis, Tunisia; [2]National Institute Salah Azaiez, Oncology, Tunis, Tunisia

Introduction

Macronutrient intake in cancer therapy is a controversial subject. Low protein intake could lead to malnutrition and cachexia. This can affect the response to chemotherapy. To date, there are no clinical studies to answer this question. The aim is to assess the influence of different macronutrient intakes in breast cancer patients on the digestive tolerance of chemotherapy.

Methods

This was a cross-sectional, descriptive study conducted over a 6-month period in patients with breast cancer undergoing chemotherapy. Macronutrient intakes were collected using a dietary survey and assessed according to ESPEN recommendations. A protein daily intake of less than 1.2 g/kg corresponds to an inadequate intake. Carbohydrate and fat intakes of over 55% and 30% respectively corresponded to excessive intakes. The digestive effects studied were vomiting, diarrhoea and constipation. The tolerance was assessed according to WHO grades ranging from 0 to 5. High grades 3 and 4 signified toxic grades.

Results

During this study 107 patients were enrolled. The mean age was 52.56 ± 9.75 years. The average of total energy intake was 2187 kcal/day. The intake was hypocaloric in almost 60% of cases. Insufficient protein intake was found in 35.5% of cases. Excessive fat intake was found in 84% of patients. And excessive intake of polyunsaturated fatty acids and cholesterol was noted in around 10% of cases. The digestive effects studied were: nausea/vomiting noted in 70% of cases, diarrhoea in 73% and constipation in 80% of cases. In multi-variate analysis, inadequate protein intake was associated with the severity of nausea/vomiting and diarrhoea, with respective P-values of 0.01 and 0.02. Carbohydrate intake was also associated with the severity of nausea/vomiting and diarrhoea, with respective ORs of 1.05 and 1.6 ($P=0.05$). Excessive cholesterol intake was identified as a risk factor for grade 3 and 4 of vomiting ($P=10$-3) and of constipation ($P=0.028$).

Conclusion

Tolerance of chemotherapy differs from one patient to another depending on nutritional status. A balanced diet is therefore essential in the treatment of breast cancer in order to improve efficacy and quality of life for patients.

The obesity paradox in murine models of sepsis

Weronika Wasyluk[1], Marcin Czop[2] & Agnieszka Zwolak[1]
[1]Medical University of Lublin, Department of Internal Medicine and Internal Medicine in Nursing, Lublin, Poland; [2]Medical University of Lublin, Department of Clinical Genetics, Lublin, Poland

Introduction
Sepsis is defined as a life-threatening organ dysfunction caused by a dysregulated host response to infection. In sepsis, a phenomenon called obesity paradox has been described, which involves a reduction in mortality in patients with a body mass index allowing for the diagnosis of overweight and obesity. In the clinical context, the phenomenon is confirmed by current meta-analyses. The aim of the study is a systematic review and meta-analysis of studies on obesity paradox conducted on an animal model of sepsis.
Methods
A search was performed on PubMed for articles published up to December 31, 2023. Studies examining obesity-related mortality in a murine model of sepsis were selected.
Results
We identified 19 studies that reported sepsis mortality data from 36 experiments. Obesity was obtained in the diet-induced obesity model or in the leptin deficiency model. Sepsis was induced in the cecal ligation and puncture, cecal slurry injection, lipopolysaccharide injection or Staphylococcus aureus inoculation models. In the studies, obesity in the experimental groups (obesity model) was, depending on the study, higher or lower than in the control groups. Nine studies using the same obesity model (diet-induced obesity) and sepsis model (cecal ligation and puncture) were selected for meta-analysis. There was no statistically significant difference between animals receiving a high-fat diet and animals from the control group receiving a standard diet ($P=0.5716$). The statistical regression analysis showed that a higher age at the time of introduction of a high-fat diet ($P<0.001$) and a longer duration of feeding with a high-fat diet ($P<0.001$) reduce mortality, while a higher age ($P<0.001$) at the time of sepsis induction increases mortality. In the above model, the regression coefficient R^2 is 0.86 ($P<0.001$).
Conclusions
The results indicate the role of study protocol in the obtained results. The age of the animals at particular stages of the study and the duration of use of the high-fat diet may be important for the obtained results. Further research is necessary to confirm and better understand this phenomenon.

Comparative study of body mass index and percentage of body fat in the definition of obesity

Hadda Meroua Hani[1], Bennouar Salam[2], Kerrouche Asma[1] & Abdi Samia[2]
[1]Departement of Pharmacy, Faculty of Medecine, University SAAD DAHLEB, Blida; [2]Central Laboratory of Clinical Biology, University Hospital Center of Blida, Blida

Introduction
Body Mass Index (BMI) is recommended by the World Health Organization (WHO) for assessing weight due to its simplicity, reliability, and accessibility. However, as highlighted in several studies, it does not accurately reflect body fat and does not account for physiological changes in body composition that occur during different periods of life, or across sexes.Aim: Our study aimed to determine the prevalence of underweight, overweight, and obesity according to both definitions – BMI and Percentage of Body Fat (PBF) measured by bioelectrical impedance analysis.
Methods
This is a retrospective cross-sectional study on a population of 877 Algerian volunteers who underwent a body composition assessment using multifrequency segmental direct bioelectrical impedance analysis (MSD-BIA). WHO cutoffs were used for the definition of underweight, overweight, and obesity. The comparison was made using the Pearson chi-squared test.
Results
Statistical analysis revealed numerous discrepancies between the two definitions. Indeed, 38.9% of women had a high PBF while being classified as underweight according to BMI (<18.5 kg/m^2;). 48.4% and 80.6% of men and women, respectively, had a high PBF while being considered normal weight according to BMI (18.5-25 kg/m^2). 12% of men and 0.7% of women classified as overweight according to BMI (25-30 kg/m^2) had a normal PBF. Additionally, 1.7% of men classified as obese according to BMI (>30 kg/m^2) had a low PBF.
Conclusion
Obesity has become a major health problem. The use of BMI alone appears ineffective in our population; therefore, a direct measurement of body composition is desirable to establish a correct diagnosis and act quickly to prevent potential impacts and complications, especially metabolic and cardiovascular.

Effects of depression, anxiety and quality of life on mid-term weight loss after sleeve gastrectomy

Faten Mahjoub, Abir El Amri, Ramla Mizouri, Nadia Ben Amor, Saida Boumefteh & Jamoussi Henda
Institut De Nutrition, Tunis, Tunisia

Introduction
Obesity is a leading cause of morbidity and mortality globally, with significant physical and psychological repercussions. The aim of our study was to assess anxiety-depressive symptoms and health-related quality of life at the mid-term following bariatric surgery and to determinate their effect on mid-term weight loss.
Methods
We conducted a descriptive longitudinal study at the obesity research unit of the National Institute of Nutrition and Food Technology in Tunis on 30 obese patients who had undergone sleeve-gastrectomy with a medical follow-up of at least 5 years. Anxiety and depressive disorders were screened using the Hospital Anxiety and Depression scale (HAD), which includes 14 items. Seven questions related to anxiety and seven others to depression. The outcome of sleeve gastrectomy and changes in quality of life over the mid-term were assessed using the BAROS (Bariatric analysis and reporting outcome system) evaluation scale.
Results
The mean age of our patients was 43 ± 9.5 years. In the mid-term post-sleeve gastrectomy period, the prevalence of anxiety was 87% (6 patients had mild anxiety, 16 patients had moderate anxiety and 4 patients had severe anxiety) and the prevalence of depression was 60% (6 patients had mild depression, 8 patients had moderate depression and 4 patients had severe depression). The association between depression and weight loss at 2 and 5 years after sleeve gastrectomy was statistically significant, the more severe the depression the less weight loss ($r=-0.45$, $P=0.01$), ($r=0.48$, $P=0.007$) respectively. No statistically significant association was found between anxiety and loss of excess weight in the mediumterm post sleeve gastrectomy. Calculation of the overall BAROS score showed that 20 patients had a score >3, so surgery resulted in a good or very good outcome in 66% of patients. Analysis of the relationship between the global score and the percentage of excess weight lost at 5 years showed an excellent correlation between these two data ($P=0.01$).
Conclusion
The presence of depressive disorders after sleeve gastrectomy significantly predicted attenuated post-surgical weight loss. It is important to consider and treat these disorders, as they are important factors in a patient's quality of life.

Ketogenic diet (KD) as a nutritional therapeutical option for women suffering from polycystic ovary syndrome

Tamta Sharadze[1,2], Teona Nutsubidze[3] & Tekle Bakhtadze[3]
[1]National Institute of Endocrinology Georgia, Tbilisi, Georgia; [2]National Institute of Endocrinology Georgia, Endocrinoly, Tbilisi, Georgia; [3]National Institute of Endocrinology Georgia, T, Georgia

The ketogenic diet (KD) has been extensively studied as a potential therapeutic approach for various conditions, including Polycystic Ovary Syndrome (PCOS) in women. We describe a 29-year-old overweight woman with PCOS. Clinically, she presented with hirsutism, acne, and pink stretch marks in the hip and abdomen areas, no significant menstrual cycle disturbances were reported. Patient underwent a 12-week KD regimen. Initially, her body mass index (BMI) was 33.5, with a weight of 87.9 kg. After the diet, she experienced a significant weight loss of 12.2 kg, reducing her weight to 75.7 kg and her BMI to 28.8. Remarkably, patient's hormonal profile showed considerable improvement. Patient at the beginning of the study had a HOMA-IR 3.7 confirming insulin resistance. At the end of the study, a significant decrease was observed in glucose (pre 98 mg/dl vs post 92 mg/dl) and insulin (pre 15.2 uIU/ml vs post 10,78 uIU/ml) and consequently in the HOMA-IR (pre 3,7 vs post 2.4). Luteinizing Hormone (LH) to Follicle-Stimulating Hormone (FSH) ratio, which was reversed at the study's outset (2.42), normalized post-diet (1.44). There was a decrease in free testosterone levels (from 4.6 pg/ml to 3.71 pg/ml) and Dehydroepiandrosterone Sulfate (DHEA-S) levels (from 5.02 µg/ml to 4.07 µg/ml). Additionally, there was an increase in estradiol (from 73.4 pg/ml to 82.6 pg/ml) and progesterone levels (from 0.21 ng/ml to 0.32 ng/ml). The patient's Ferriman Gallwey Score showed a minor decrease (from 11.3 to 10.5), indicating a slight improvement in symptoms. KD is an effective option for women with PCOS to manage weight and hormonal imbalances. Further research is needed on its long-term sustainability and potential side effects, as this short-term study reported no adverse effects.

Immune checkpoint inhibitor-associated diabetes mellitus

Joana Vinhais, Beatriz R. Pereira, David Veríssimo, Catarina Ivo, Ana Cláudia Martins, João Nunes e Silva, Dolores Passos, Luís Lopes, João Jácome de Castro & Mafalda Marcelino
Hospital das Forças Armadas, Serviço de Endocrinologia, Lisbon, Portugal

Introduction
The immune checkpoint inhibitors (ICI) are increasingly being used in the treatment of several malignancies. ICI are monoclonal antibodies that inhibit immune checkpoints, thus stimulating the action of the immune cells to attack the tumour cells. The overstimulation of the immune system can lead to several endocrinopathies, such as autoimmune diabetes, known as ICI-associated diabetes mellitus (ICIDM).
Case Report
In September 2023, a 62-year-old male presented to the emergency department with diabetic ketoacidosis (DKA). He had no prior diagnosis of diabetes mellitus. The patient was diagnosed with clear cell renal cell carcinoma in November 2022 and underwent right nephrectomy in January 2023. In May 2023 there were detected pulmonary metastases, initiating immunotherapy with nivolumab and ipilimumab one month after, which led us to suspect of autoimmune diabetes secondary to ICI. In admission, the patient presented with polyuria, polydipsia, and loss of 3 kg in the past week, and a biochemical evaluation that revealed DKA with a glycemia of 590 mg/dl, a ketonemia of 6.2mmol/l, and arterial pH of 7.303. The autoimmunity study with anti-GAD, anti-ICA, anti-insulin and anti-IA2 was negative, the C-peptide was low (0.26 ng/ml) and the HbA1C was 6.5%. Abdominopelvic CT was performed and did not show neoplastic lesions or sins of pancreatitis. Furthermore, the study of other endocrinopathies potentially associated with ICI was negative. Glycaemic control was achieved with insulin perfusion followed by intensive insulin therapy. The patient was then discharged, monitored with a continuous glucose monitoring device and under intensive insulin therapy, which he currently maintains, with good control of glycaemic profile.
Discussion
ICIDM presents as an acute symptomatic and severe hyperglycaemia with a high prevalence of DKA (in approximately 70% of the cases), a near-normal HbA1C and an undetectable C-peptide, suggesting a rapid progression of beta-cell destruction. In this case report, approximately 3 months after starting an ICI, the patient presented with DKA, a HbA1C of 6.5%, and a low C-peptide which indicated rapid progression to insulin insufficiency. Roughly 60% of the cases of ICIDM described in the literature doŕt have diabetes autoantibodies, as occurred in this case report. In accordance with other endocrinopathies associated with ICI, ICIDM requires lifelong treatment with the deficient hormone, in this case insulin.
Conclusion
This case report is in line with other case studies available in literature and not only alert us to this unusual diagnosis, but also for the need to screen these patients for endocrinopathies associated with ICI.

Identification of etiology in non-diabetic hypoglycemia in resource poor settings: experience from a tertiary care center in sri lanka

Shahini Winson Gnanathayalan[1], Isuru Jayawardana[2], Nethrani Pathirana[3], Sharmika Sivageethan[4], Beminahennadige Fernando[4], Vinitharann Varunanantharajah[4], t g Athukorala[4], Uditha Bulugahapitiya[4], manilka Sumanatilleke[4] & Prasad Katulanda[4]
[1]National Hospital Sri Lanka, Diabetes and Endocrinology, Colombo, Sri Lanka; [2]National Hospital Sri Lanka, Diabetes and Endocrinology, COLOMBO, Sri Lanka; [3]National Hospital Sri Lanka, Colombo, Sri Lanka; [4]National Hospital Sri Lanka, COLOMBO, Sri Lanka

Background
Non-Diabetic Hypoglycemia is a rare entity in Endocrinology. After the confirmation of hypoglycemia with Whipple's triad and excluding drug induced hypoglycemia, identification of underlying etiology using appropriate and targeted investigations is fundamental to institute specific management. It is challenging in resource poor settings due to unavailability and high cost of some investigations such as insulin autoantibodies and insulin-like growth factr-2 (IGF-2) level.
Methods
We retrospectively analyzed 11 patients who were diagnosed with non-diabetic hypoglycemia in 2023, in a tertiary care center in Sri Lanka
Results
Among the 11 patients, six patients, three and one were diagnosed with insulinoma, Insulin autoimmune syndrome (IAS) and nesidioblastosis respectively. Another one patient with neurofibromatosis type 1(NF-1) was diagnosed with non-islet cell tumor hypoglycemia (NICTH) due to metastatic gastrointestinal stromal tumor (GIST). Among patients with insulinoma, 2 had multifocal insulinoma in the background of MEN-1 syndrome and NF-1 respectively. Among cases of IAS, two were idiopathic and the other one was carbimazole induced. The patient with nesidioblastosis didn't have a history of gastric surgeries. Most patients had recurrent level-3 hypoglycemia. Timing of the symptoms, whether fasting or postprandial was not reliably helpful in differentiating between the etiologies because one patient with insulinoma had predominantly post-prandial hypoglycemia and two patients with IAS had almost fasting symptoms. All cases of insulinoma and nesidioblastosis had insulin/c-peptide ratio of less than one with insulin recovery after PEG precipitation of more than 70%, while all three patients with IAS had very high insulin levels with the ratio of much more than one and insulin recovery after PEG precipitation of less than 10%. The diagnosis of IAS was confirmed by the presence of insulin autoantibodies in all cases. The case of NICTH had hypo-insulinemic hypoglycemia with suppressed beta-hydroxy butyrate level, low IGF-1 and positive response to glucagon challenge test. IGF-2 level could not be performed.
Conclusion
This series highlights the challenges in identifying the cause of non-diabetic hypoglycemia especially in resource poor settings. The timing of hypoglycemia is not a good indicator to differentiate the etiologies. In the resource-limited settings where insulin autoantibodies cannot be done freely, insulin/c-peptide ratio with insulin recovery after PEG precipitation might be a good alternative to diagnose IAS. The diagnosis of NICTH can be made in a patient with malignancy having hypo-insulinemic hypoglycemia with suppressed ketogenesis, low IGF-1 and positive glucagon challenge test as IGF-2 assay is very expensive and not available in many settings.

DOI: 10.1530/endoabs.99.EP965

Immunotherapy-induced endocrinopathies: unraveling a clinical case of immune-mediated diabetes firstly and thyroid pathology secondly

Anastasiia Kriuchkova & Vladislav Evseev
Saint Petersburg, Saint Petersburg, Russian Federation

Immunotherapy, a cancer treatment leveraging the individual's immune system, has demonstrated its efficacy by eliciting responses from immune cells in and around tumors, notably tumor-infiltrating lymphocytes (TILs). The presence of TILs often correlates with more favorable outcomes in cancer cases. Immune-mediated adverse events (imAEs) accompany immunotherapy in 13.7-54% of patients, with the involvement of the endocrine system detected in nearly 10% of cases, representing a common form of imAEs. Despite the potential involvement of any secreting endocrine glands, immune-mediated thyroid dysfunction stands out as the most prevalent variant. A distinctive aspect of endocrine imAEs lies in the ability to safely continue immune therapy concurrently with replacement hormonal treatment. On the other hand, if these issues are discovered later, they may worsen and necessitate resuscitation or urgent care. Immune-mediated diabetes is a rare complication, with an incidence rate reported at only 0.1%. This report aims to describe a clinical case involving the primary development of diabetes during ongoing immunotherapy with pembrolizumab, coupled with the secondary development of thyroid gland pathology. The case involves a 51-year-old female diagnosed with Central cancer of the right intermediate bronchus (squamous cell carcinoma), stage IIB (pT2bN1(1/30) cM0). Since June 13, 2023, the patient has been undergoing adjuvant immunotherapy with pembrolizumab. Her medical history includes prior observation by an endocrinologist due to nodal formations in the thyroid gland without thyroid disfunction. After completing 4 th cycles of immunotherapy, she noticed a sudden and significant change in her health condition, characterized by a strong thirst and a dry mouth. Immediate medical check revealed elevated blood glucose levels up to 17 mmol/l, glucosuria, acetone in urine (+++), glycated hemoglobin at 8.3%, C-peptide (fasting) at 1.16 μIU/ml, Insulin (fasting) at 1.16 μIU/ml, and TSH at 3.2 μIU/ml. The presence of absolute insulin deficiency did not raise any doubts, and the diagnosis of type 1 immune-mediated diabetes was established. Insulin therapy in a basal-bolus regimen was immediately initiated, complemented by continuous glucose monitoring. Subsequent blood monitoring indicated a decrease in TSH levels and an increase in free T3, signaling the initiation of thyroid tissue destruction amidst ongoing treatment. This case underscores the importance of timely identification and management of immune-related complications on such

therapy, shedding light on the unique challenges presented by the interplay between immunotherapy, endocrine function, and resultant adverse events.

Alopecia universalis and epilepsy in a patient with type 1 diabetes

Jelena Andric, Anamarija Zrilic Vrkljan & Vlatka Pandzic Jaksic
Dubrava University Hospital, Department of Endocrinology, Diabetes and Metabolic diseases, Zagreb, Croatia

Background
Alopecia areata is a common non-endocrine manifestation in autoimmune polyendocrine syndromes (APS). Alopecia universalis is its most severe form with total loss of scalp and body hair. Several attempts at classifications for multiple combinations of autoimmune disorders in APS were proposed. Type 1 diabetes is associated with epilepsy due to glycemic extremes and microvascular damage, but a shared etiology mediated by anti-glutamic acid decarboxylase antibodies (anti-GAD) was also recognized.
Case presentation
A 38-year-old patient was admitted to our clinic with severe diabetic ketoacidosis. A few days before he had generalized seizure attack. Besides being shaved and mostly white beard, he had no scalp, no eyebrows, eyelashes, and any other body hair. He was diagnosed with alopecia universalis at the age of 3, epilepsy at the age of 9, and type 1 diabetes at the age of 18 years. Laboratory studies showed undetectable C-peptide, very high HbA1c, elevated anti-GAD, normal thyroid peroxidase antibodies, thyroid hormones, calcium, and basal cortisol. Low compliance with insulin, diet and anti-seizure therapy was presumed. The mental impairment after recurrent seizures together with probable permanent psychological changes made the control of his diabetes extremely difficult.
Conclusion
The typical successive occurrence from the very early age suggests a probable common autoimmune etiology of his disorders. Thyroid and adrenal autoimmunity are still absent which is not typical for known APS. Immunotherapy in such longstanding diseases would probably lack effectiveness, but early recognition and intervention - potentially even preventive - might provide an opportunity for avoiding the development of such a severe clinical presentation.

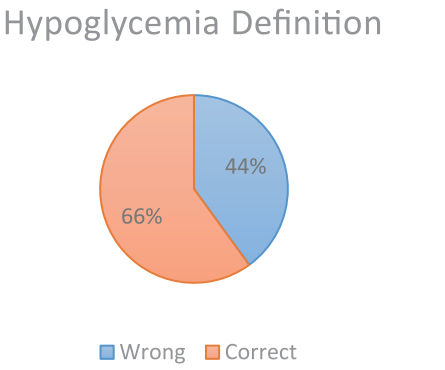
EP981

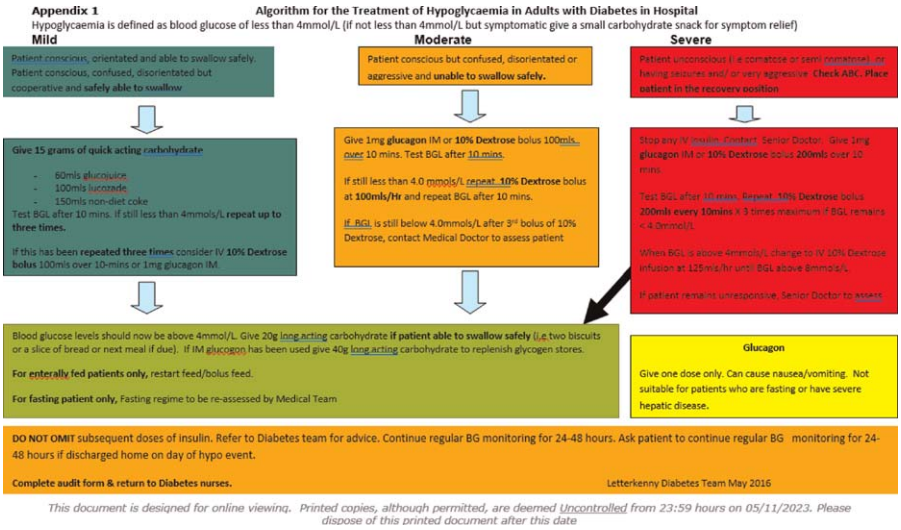
Healthcare staff awareness of hypoglycemia among in patients in a model 3 hospital university hospital

Azhar Al-Shaibany[1], Marketa Vyskocilova[2] & Rowa Abdulla[2]
[1]Letterkenny University Hospital, Endocrinology, Letterkenny, Ireland; [2]Letterkenny University Hospital, Letterkenny, Ireland

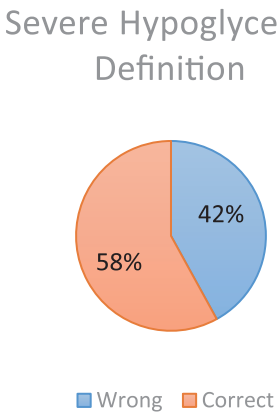
Background
Hypoglycemia is defined as a blood sugar less than 4mmol/l. It is defined clinically in the presence of Whipple's triad, characterized by signs and symptoms of hypoglycemia, low plasma glucose and reversal of symptoms on correction of hypoglycemia. Inpatients prevalence of hypoglycemia ranges from 3.5% to 10.5% with the majority of patients affected having diabetes and receiving insulin therapy[1]. Hypoglycemia is one of the side effects of intensive glycemic control and between 20-25% of in patients with diabetes will experience hypoglycemia during hospital stay[2]. Hypoglycemia's is also associated with poorer outcomes and reduced quality of life in patients living with diabetes[2]. Patients are at increased risk of hypoglycemia, especially those prescribed glucose lowering drugs like insulin and sulfonylurea. Around 25% of patients who are admitted to hospitals take glycemic lowering medications. Inpatient hypoglycemia increases morbidity, mortality, prolonged hospital stay, and increases hospital 30 day readmission rates and also increases the cost of treatment[3]. Mortally among inpatients with hypoglycemia are high as 6.5%, compared to 3.8% in those who do not experience hypoglycemia4. Therefore, it is important that healthcare workers are knowledgeable in the recognition and treatment of hypoglycemia[4].
Aims and Objectives
This audit aimed to assess the knowledge of healthcare staff (nonconsultant) hospital doctors and nurses of the local hypoglycemia management protocol among inpatients in our hospital.
Guidelines
Our local protocol for the treatment of hypoglycemia present in every ward.
Methods
Over a two week period between the dates off 10/10/2023 and 25/10/2023 a best of five questionnaires was administered at random to 60 non consultant hospital doctors and nurses. These questionnaires were collected in common areas such ED, Wards, ICU, CCU in relation to definitions, treatment and prevention of hypoglycemia were gathered under observation and analyzed against the hospital policy to determine awareness of the local policy.
Results

Q1

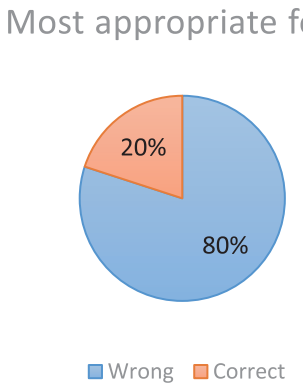




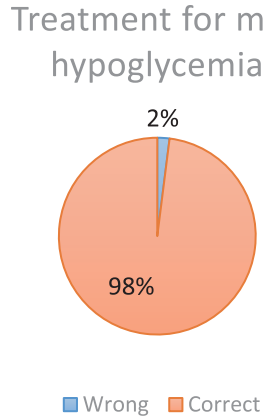
Q2



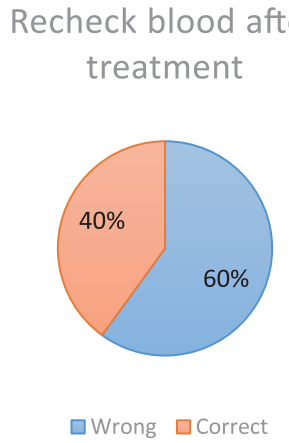
Q3:



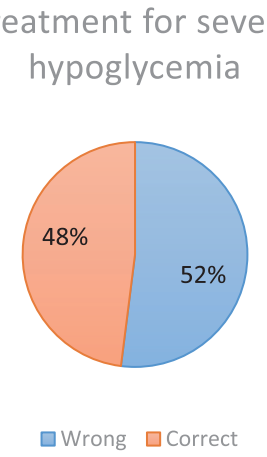
Q4:



Q5:



Q6:



Conclusion

To sum up, our audit findings highlight a concerning lack of awareness regarding hypoglycemia management. This knowledge gap significantly affect patient safety, as timely and appropriate intervention is critical in preventing severe consequences. The results suggests the need for increased education and training of healthcare providers, to improve their understanding of hypoglycemia and how to manage it effectively. This can significantly lead to better outcomes and an enhanced quality of patient's life.

Recommendations

- Regular training programs.
- Use visual aids and handouts.
- Regular audits.

Pathways to diagnosis and missed opportunities in newly diagnosed T2DM with NAFLD

Supriyo Mukherjee[1], Bishnupriya Mukherjee[1], Anjali Goswami[1], Chun Shing Kwok[2] & Anne Phillips[3]
[1]Research Centre for Diabetes Hypertension and Obesity, Medicine, Samastipur, India; [2]Cardiology Registrar, University Hospitals of North Midlands NHS Trust, Newcastle, United Kingdom; [3]Faculty of Health Education and Life Sciences, Department of Post-Qualifying Healthcare Practice, Birmingham City University, Birmingham, United Kingdom

Introduction & Objective
This poster shows various pathways for patients who were recently diagnosed with T2DM and NAFLD in North Bihar, India. It also analyses trajectories as well as missed opportunities and earlier intervention possibilities.
Methods
The study was conducted at RCDHO in Samastipur, Bihar. A total of 148 participants were enrolled and data was obtained from questionnaires and analysis of healthcare records.
Results
In the healthcare sector, the journey towards well-being often diverges into three distinct pathways, each steering individuals towards different outcomes. On the favourable pathways, those who seek consultations from highly skilled and MBBS qualified doctors experience a streamlined process of diagnosis and optimal management of their health concerns. The expertise of these healthcare professionals ensures early and effective identification of issues, paving the way for timely and targeted interventions. Contrastingly, the unfavourable pathways are fraught with impediments that hinder the trajectory towards health improvement. Delays often ensue when individuals opt for non-specialist consultations, leading to a protraction in the diagnostic and management phases. Financial difficulties become an additional roadblock, impeding access to necessary healthcare services. Late referrals to health professionals exacerbate the situation, further complicating the path to recovery. Within this intricate web of healthcare dynamics, missed opportunities emerge as a critical concern. The lack of awareness about health issues and the absence of awareness-based screening contribute to a failure in early detection. Limited availability of specialized care and diagnostic tools further impedes progress, while inadequate knowledge among healthcare providers adds a layer of complexity to the situation. The domino effect continues with low timely referrals and economic constraints, collectively creating missed opportunities for individuals to attain optimal health outcomes. Addressing these multifaceted challenges is paramount to fostering a healthcare system that ensures equitable access, early intervention, and improved overall well-being for all.
Conclusion
Critical improvements in healthcare necessitate a multifaceted approach. Strengthening systems of referral is essential for seamless patient transitions between care levels. Concurrently, enhancing health literacy empowers individuals to make informed decisions, fostering a proactive approach to well-being. Investing in healthcare infrastructure ensures sufficient resources for diagnosis and treatment, while comprehensive training for healthcare providers equips them to navigate evolving healthcare demands effectively. A poignant priority lies in raising awareness and broadening access for the early diagnosis and treatment of Type 2 Diabetes Mellitus

(T2DM) with Non-Alcoholic Fatty Liver Disease (NAFLD), addressing a pressing need for proactive management and improved health outcomes.

Management of the diabetic foot: experience of the diabetology department of the army central hospital. about 282 cases

Imane el ghebir, Hani Meriem, Rehaimia Amina & Ait Abderrahmane Samir
Army Central Hospital, Diabetology, Algiers, Algeria

Introduction
The diabetic foot is a public health problem. It can cause serious complications leading to amputation.
Aim
To determine the clinical, biological, therapeutic and evolutionary characteristics of the diabetic foot.
Patients and Methods
Prospective descriptive study conducted at the HCA Diabetology Department, over a period of 36 months. Inclusion of all hospitalized or followed up patients in consultation for a diabetic foot. The total number of patients was 281.
Results
The average age of patients was 61.82 years. The majority of them (74%) were males of which, 94% had T2DM. The median age of diabetes was 15 years. A diabetic foot ulcer was the reason for the initial discovery of diabetes in 4.7% of the patients. Over 65% of the patients were on insulin. One or more degenerative complications were noted in 94.8% of them. 25.4% of the patients had at least one history of amputation. The right foot was affected in 52.3% of the cases. The median consultation time at the diabetology department was 30 days. Infected diabetic feet accounted for 54.9% of the cases. The most frequent entry portal for foot infections was inter-toe intertrigos in 31% of cases, followed by trauma in 25.51% and the plantar neuropathic ulcer in 24.13%. Dermo-hypodermatitis was the most frequent type of infection, representing 86.2% of the cases. The average duration of antibiotic therapy for infected feet was 14.73 days. Osteitis was present in 87.6% of patients with infected feet; they were treated medically in 69.2% of cases. 16% of patients underwent minor amputation. Median hospital stay was 22 days, with extremes ranging from 7 to 101 days. Median time to definitive healing was 30 days.
Conclusion
The diabetic foot is a public health problem because of the risk of wounds progressing to amputation. Proper education of diabetic patients and early multidisciplinary medical care can improve prognosis and prevent recurrence.

DOI: 10.1530/endoabs.99.EP985

Characteristics of type 2 diabetes evolving for more than 10 years in a tunisian population

Nesrine Dhieb, Chaima Jemai, Mariem Cheikhrouhou, Chaima Sdiri, Sami Fitouri, Yosra Htira, Zohra Hadj Ali, Imen Hedfi, Olfa Lajili & Faika Ben Mami
National institute of nutrition of Tunis, C

Introduction
Diabetes mellitus is a chronic disease. Long-standing diabetes increases the prevalence of degenerative complications. The aim of our study was to determine the clinical and biological characteristics of a population of type 2 diabetic patients whose diabetes had been evolving for more than 10 years.
Methods
This was a descriptive cross-sectional study about 100 type 2 diabetic patients hospitalized in the national institute of nutrition of Tunis. For each patient, we carried out an interview and physical examination, we assessed anthropometric parameters and we examinated the feet. Then we graded the podiatric risk for each patient. Creatinine clearance was calculated using the CKD-EPI formula.
Results
The mean age was 57.20 ± 8.48 years. Sex ratio was 0.35. 29% of patients were smokers. Median weight was 91 kg with extremes of 65 and 110 kg. The median BMI was 30.46 kg/m^2; with extremes of 22.50 and 38.28 kg/m^2. The mean duration of diabetes was 14.79 ± 4.55 years. All patients were on insulintherapy. The majority of patients (70%) were on NPH insulin. The mean HbA1C was 10.33%. Mean creatinine clearance was 93.16 ± 19.19 ml/l/1.73 m^2. The respective frequencies of diabetic neuropathy, diabetic retinopathy and diabetic nephropathy were 30%, 55% and 46%. Macroangiopathy was present in 35% of cases (coronary artery disease (10%), stroke (3%), obliterative arteriopathy of the lower limbs (18%). Podiatric risk was null for the majority of the population (55%). Frequencies of podiatric risks of 1, 2 and 3 were 55%, 25%, 18% and 2% respectively. Factors significantly associated to poditric risk was smoking ($P=0.026$), BMI ($P<0.001$), Hypertension ($P=0.038$) and diabetic nephropathy ($P<0.001$).
Conclusion
The duration of diabetes exceeding 10 years was characterised by a high prevalence of degenerative complications. Rigorous early management of diabetes and comorbidities is essential to prevent complications.

DOI: 10.1530/endoabs.99.EP986

EP987

Glucometric comparison in DM1 patients after implantation of continuous glucose monitoring

Elena Martínez Silla, Enrique Redondo Torres, Javier García Sánchez, Raúl Rodríguez Juárez, Miguel Quesada Charneco & Pablo-José López-Ibarra Lozano
San Cecilio Clinical University Hospital, Endocrinology and Nutrition, Granada, Spain

Introduction and Objectives
Continuous glucose monitoring (CGM) has demonstrated benefits in the prevention of hypoglycemia in patients with type 1 diabetes mellitus (DM1) vs flash monitoring (CGM). Our aim was to analyze the clinical characteristics, indication and glucometric changes in patients using MFG after CGM implantation.
Material and methods
Retrospective observational study of 13 patients under follow-up for DM1 in Endocrinology consultations at the Hospital Universitario Clínico San Cecilio with suboptimal glycemic control using MFG who underwent implantation of MG (Dexcom G6). Demographic variables related to the disease and its complications and glucose monitoring parameters before and after implantation of the Dexcom G6 system were studied.
Results
7 women and 6 men were evaluated. Mean age 40 ± 14.1 years, mean time of diabetes evolution 16.9 ± 11.1 years. Mean BMI 24.7 ± 3.27. 2 kg/m^2. Only 2 patients had microangiopathic complications. The mean time of use of MFG was 2.5 years and of MG 7.8 months. In 12 patients, the indication for CGM was frequent hypoglycemia, the remaining case being due to skin reaction. After the indication for CGM, HbA1c (6.9 vs 6.4%, $P=0.039$), time below range (7.4 vs 2.5, $P=0.001$) and coefficient of variation (37.5 vs 32.8, $P=0.004$) decreased significantly. There were no significant changes in time in range or time in hyperglycemia.
Conclusions
In our study, the use of GCM compared to previous MFG use is related to better glycemic control in patients with DM1 in terms of HbA1c, with reduced time in hypoglycemia and coefficient of variation. GCM systems may be useful in the management of the DM1 patient with a tendency to hypoglycemia and wide glycemic variability.

Unraveling syndromic diabetes in the context of h syndrome - a rare genetic entity with multisystemic manifestations - case report

Souhir Maalej, Fatma Mnif, Siddiqa Soomauroo, Abdel Mouhaymen Missaoui, Mouna Mnif, Dhouha Ben Salah, Mohamed Abid & Nabila Rekik
Hedi Chaker University Hospital, Endocrinology, Sfax

Introduction
The H syndrome, an autosomal recessive genodermatosis, is characterized by cutaneous and systemic manifestations resulting from mutations in the SLC29A3 gene (10q22.2), leading to histiocytic infiltration of multiple organs. This study presents a new observation of H syndrome.
Observation
We report the case of a 33-year-old patient, born of consanguineous parents, with a history of diabetes diagnosed at the age of 28 and treated with oral antidiabetic drugs (OAD). Hospitalized for an acidocetotic decompensation associated with acute pyelonephritis and an abscess of the anal margin, she exhibited poorly controlled diabetes (HbA1c = 11.7%) under OAD. Clinical examination revealed a pronounced dysmorphic syndrome, characterized by bilateral, symmetrical, hyperpigmented, and thickened plaques present for five years, with hypertrichosis. These lesions were observed not only on the inner thighs but also in the pubic and lumbar regions. The patient also presented buttock lipodystrophy, swelling with hyperpigmentation of the labia majora, camptodactyly, hallux valgus, and dental deformity. Erythematous, annular, and figurate lesions, slightly keratotic without atrophy, were present on the cheeks and nose. Dermoscopy revealed multiple telangiectasias forming a reticulated network. A 4mm punch biopsy showed a lymphocytic and histiocytic infiltrate, with positive immunohistochemistry for CD68. The patient had a short stature (1.53m) of familial origin, hepatomegaly associated with bicytopenia (leukoneutropenia and

hypochromic microcytic anemia at 5.8 g/dl), elevated ferritin levels (273.3 ng/ml), and low serum iron (2.1 umol/l) persisting even after sepsis resolution. An osteomedullary biopsy revealed grade 2 medullary fibrosis, excluding neoplastic infiltration. The diagnosis of H syndrome was confirmed through histological and immunohistochemical examinations. Echocardiography was normal, and the patient was referred to an Ear, Nose, and Throat (ENT) specialist for hearing loss screening. Follow-up since insulin initiation demonstrated good glycemic control.
Conclusion
This case highlights the importance of considering H syndrome in diabetic patients with atypical cutaneous, hematological, and skeletal manifestations. The management of this complex condition requires a multidisciplinary approach involving specialists in dermatology, endocrinology, hematology, and genetics. This observation contributes to enhancing the understanding of the links between H syndrome and diabetes, emphasizing the need for a comprehensive evaluation for optimal management of this rare pathology.

Frailty in elderly diabetics: frequency and associated factors

Maryam Cheikhrouhou, Kamilia Ounaissa, Nesrine Dhieb, Hana Ben jemaa, Mariem Naifar, Emna Bornaz, Haifa Abdesslem & Chiraz Amrouche
national nutrition institute, Department of Nutritional Diseases D, Tunisia

Introduction
The care of elderly people with diabetes depends on their clinical and functional state. The prognosis and therapeutic goals are impacted by the degree of fragility The aim of this study was to assess the level of frailty in a group of elderly diabetic subjects.
Methods
This was a cross-sectional study including twohundr edelderly type 2 diabetic patients. All of them were screened for the five Frieds'frailty criteria. A patient was considered frail if he presented three or more criteria out of five and pre-frail if he presented less than three criteria.
Results
The median age was 70 years (IIQ [72-76.75]). The mean diabetes duration of 16.5 ± 9.26 years. The frequencies of each of fields'criteria in descending order are physical inactivity (86.5%), decreased walking speed (62%), decreased muscles'strength (40.5%), asthenia (40.5%) and decreased muscle mass (11.6%). Frailty was diagnosed in 54% of patients. While 43.5% of subjects were pre-frail and only 2.5% were not frail. Factors associated with frailty were advancedage ($P=0.003$), female gender ($P=0.002$), poorly controled diabetes ($P=0.002$) and depression ($P<0.001$).
Conclusion
Prevention, early detection and management of frailty in elderly diabetics are of crucial importance to optimize diabetes management and mitigate its impact on the quality of life of these patients.

MODY in pregnancy: a report of two clinical cases

Maria Salomé Serranito, Bruno Bouça, Inês Manique, Olga Gutu, Paula Bogalho, Nelson Cunha & José Silva-Nunes
Hospital Curry Cabral, Lisboa, Portugal

Introduction
Distinguishing between gestational diabetes and MODY (Maturity Onset Diabetes of the Young) during pregnancy is relevant for therapeutic approaches and potential maternal-fetal complications. However, performing genetic study for MODY in pregnant women is uncommon.
